Being large, polar, hydrophilic molecules, the NMBAs do not cross cell membranes readily, but evidence exists that most of these drugs do gain limited entrance into the cerebrospinal fluid and may be associated with CNS effects. Pancuronium administration reportedly reduced the minimum alveolar concentration of halothane in humans.⁶⁷ However, a subsequent study in humans found that pancuronium, atracurium, or vecuronium administration had no effect on the minimum alveolar concentration (MAC) of halothane.⁶⁸ Accidental administration of NMBAs into the cerebrospinal fluid has caused myotonia, autonomic effects, and seizures.^{69,70} Laudanosine, a metabolite of atracurium, easily crosses the blood-brain barrier in dogs, and high concentrations may stimulate the CNS.⁷¹ Clinically useful dosages of atracurium, however, are unlikely to result in the formation of a sufficient quantity of laudanosine to alter the CNS.

Protein Binding

All nondepolarizing NMBAs are protein bound, but the clinical significance of such binding is unclear. Presumably, only the unbound fraction of drug is available to interact at ACh receptors and induce paralysis. In studies of people who had hepatic cirrhosis with decreased plasma protein concentrations, the proportion of d-tubocurarine, pancuronium, and vecuronium bound to plasma protein was not different compared with healthy patients who had normal plasma protein concentrations.^{72,73} Thus, despite the theoretical concerns of low plasma protein increasing the proportion of free, active drug, the amount of NMBA that is protein bound in hypoproteinemic patients appears to remain unchanged.

Nonneuromuscular Effects of Succinylcholine

Several, often undesirable, nonneuromuscular side effects are associated with the administration of succinylcholine. These sequelae include hyperkalemia; increased intraocular, intracranial, and intragastric pressure; and muscle soreness.

Hyperkalemia

Succinylcholine administration is associated with a transient increase in serum potassium levels. Succinylcholine activates the nicotinic motor end-plate receptors but, unlike ACh, is not immediately degraded by acetylcholinesterase. This produces depolarization characterized by open ion channels that enable potassium

ions to egress from the muscle fiber into the extracellular space. As a result, serum potassium concentrations can rise transiently after drug administration. In healthy patients, this increase is usually without adverse effects, provided that cardiovascular disease is not present and preadministration serum potassium levels are normal. In patients with burns, severe muscle trauma, muscular denervation, nerve damage, or neuromuscular disease, extrajunctional ACh receptors proliferate over the surface of the muscle fiber. This increase in receptor density is accompanied by an increase in sensitivity to the depolarizing muscle relaxants and an increase in the amount of intracellular potassium released in response to succinylcholine administration. The increase in extrajunctional ACh receptor density begins to occur within 2 days after the injury and can persist for 2 to 3 months.⁷⁴

Intraocular Pressure

Succinylcholine administration increases intraocular pressure. In humans, intraocular pressure usually peaks within 2 to 4 min and remains increased for at least 6 min after administration.⁷⁵ The mechanism responsible for the increase in intraocular pressure is presently unknown but likely involves altered circulation to the eye. The administration of the calcium-channel blocker nifedipine attenuates this increase.⁷⁶ Administration of succinylcholine to patients who have penetrating eye injuries should be avoided because it can cause ocular evisceration. Controversy exists as to whether administration of a nondepolarizing NMBA prior to succinylcholine prevents increases in intraocular pressure. It is important to realize that the use of any induction technique that might cause gagging or forceful coughing will raise intraocular and intracranial pressure and thus must be avoided in patients who have an open globe. Induction with a rapid-acting injectable anesthetic and being certain that adequate anesthetic depth has been achieved prior to attempting tracheal intubation are critical in preventing intraocular pressure increases.

Intragastric Pressure

Because succinylcholine administration causes muscle contraction that manifests clinically as fasciculations of the skeletal muscles, abdominal constriction and increases in intra-abdominal and intragastric pressure can occur, increasing the potential for regurgitation.

Intracranial Pressure

Muscle fasciculations induced by succinylcholine may also increase intracranial pressure. In humans, prior administration of a nondepolarizing NMBA prevents the increase in intracranial pressure. Since most domestic animals can be easily intubated without use of an NMBA, it is recommended that succinylcholine be avoided in patients with intracranial hypertension. As with penetrating eye injuries, a rapid, smooth induction of anesthesia is a more desirable strategy in preventing unnecessary increases in intracranial pressure.

Muscle Responses

Succinylcholine administration is often associated with muscle soreness. Myalgia results from muscle fasciculations that occur

during the initial depolarization of the motor end plate.⁷⁷ The intensity of the fasciculations and the intensity of muscle pain are correlated.⁷⁸ Although skeletal muscle enzymes such as creatine kinase increase after succinylcholine administration, whether animals experience muscle pain similar to that of humans is unknown, but likely.^{79–81}

Muscle Relaxants in Anesthetized Animals

The use of muscle relaxants in veterinary practice is not as frequent as in human medicine. Human patients are frequently given muscle relaxants to facilitate endotracheal intubation and surgical access. Most animals can be intubated relatively easily without paralysis, and muscle relaxation caused by inhalant anesthetic agents is adequate for most procedures. Because of the need for familiarity with NMBA pharmacology and mechanical ventilation, the use of muscle relaxants in animals has been limited mostly to teaching hospitals and adequately equipped specialty practices and research institutions.

Indications

Muscle relaxants may be administered for numerous reasons. To facilitate intubation, muscle relaxants are typically given with hypnotic drugs to eliminate laryngeal spasm and provide rapid control of the airway. The need for a motionless, centrally positioned eye during intraocular or corneal surgery often requires the use of a muscle relaxant. Other indications include prevention of unconscious spontaneous movement, reduced resistance to controlled ventilation, and facilitation of surgical access during surgery.

Precautions

Because the muscles of respiration are paralyzed, ventilation must be controlled, either by a mechanical ventilator or by a staff member who can manually ventilate the patient until muscle strength is restored. Muscle relaxants have no sedative, anesthetic, or analgesic properties, so it is critical that the animal be adequately anesthetized to render it completely unconscious. Assessing the level of anesthesia in a paralyzed patient is more difficult than in a nonparalyzed patient because the usual indicators of depth (e.g., purposeful movement in response to a noxious stimulus, palpebral response, and jaw tone) are abolished. When including an NMBA in an anesthetic protocol, anesthetists must be certain they can reliably maintain an adequate plane of surgical anesthesia and level of ventilation.

Historically, muscle relaxants have been given alone to animals for capture or restraint, including use as the sole agent for brief surgical procedures (e.g., equine castration). At this time, the use of such inhumane practices is not justified because of the widespread availability of safe and effective anesthetics. The administration of an NMBA alone to an awake patient for immobilization purposes is also considered inhumane.

Selection

When choosing a muscle relaxant, one must consider many factors, including the species to be paralyzed, the reason for paraly-

sis, the duration of action required, the health status of the patient, and concurrent drug administration. Relaxants will differ in the onset of action, duration of action, recovery time, cardiovascular effects, and route of elimination. If a rapid onset and brief action are needed, the choice might be rocuronium or mivacurium, whereas doxacurium may be selected for longer action without significant cardiovascular effects. Atracurium is metabolized via Hofmann elimination and may be a good choice when hepatic or renal disease is present.^{35,36}

Because many factors will affect the intensity and duration of muscle paralysis, monitoring of neuromuscular blockade is useful for titrating the dose needed for the desired effect. It is important to remember that individual muscle groups respond differently to muscle relaxants. The diaphragm is less sensitive to the effects of muscle relaxants compared with the muscles of the limbs.⁸² Therefore, a higher dose may be required to abolish spontaneous ventilation compared with the dose for facilitation of fracture reduction. In horses, when a dose of muscle relaxant required to abolish the hoof twitch is administered, the facial twitch will often remain, though at reduced strength.^{83,84} When not monitoring hoof-twitch tension, it should be appreciated that the facial twitch may be present even when adequate relaxation has been achieved in the limb for performing the surgical procedure.

Factors Affecting Neuromuscular Blockade

A number of factors can influence the duration of action, intensity, and recovery from neuromuscular blockade. Whenever a muscle relaxant is administered, neuromuscular function must be monitored during the anesthetic and recovery periods to avoid overdosing and residual paralysis.

Impaired Metabolism and Excretion

Hepatic failure may alter the initial effect of nondepolarizing muscle relaxants because of an increase in the volume of distribution. However, their effect may be increased from decreased metabolism, especially when drugs dependent on hepatic biotransformation (e.g., vecuronium) are administered.^{85–87} Impaired liver function may also prolong or cause residual neuromuscular blockade.⁸⁸ In general, muscle relaxants are not highly protein bound to albumin, typically less than 50% bound.^{89–92} Thus, the net effect of low albumin may not be clinically significant. Decreased esterase activity may slow the biotransformation of mivacurium and atracurium. Patients with biliary obstruction may have reduced hepatic clearance of muscle relaxants.⁹³ The clinical impact of hepatic failure depends on the specific NMBA and dose administered.

In patients with renal insufficiency, paralysis may be prolonged when muscle relaxants that rely predominantly on renal elimination (gallamine, pancuronium, or doxacurium) are given.^{94–97} Recovery from mivacurium administration may also be prolonged, possibly because of decreased pseudocholinesterase activity.⁹⁸ Atracurium pharmacokinetics are generally unaffected, but if a constant-rate infusion is given to a patient with renal failure, laudanosine may accumulate.⁹⁹ It is best to avoid

the use of high doses, repeated doses, or continuous infusions of muscle relaxants that primarily depend on renal elimination in patients with significant renal disease.

Anesthetic Drugs

Inhalant anesthetic agents cause a time and dose-dependent enhancement of the intensity and duration of block produced by muscle relaxants.¹⁰⁰ The explanation for this interaction is complex, with inhalational agents suppressing motor evoked potentials in response to spinal cord and transcranial stimulation. Muscle contractility is altered, and variation in regional muscle blood flow causes a greater fraction of the relaxant to reach the site of action.¹⁰¹ The effects are greatest after administration of a long-acting relaxant or during a continuous infusion. The order of potency of some of the inhalational anesthetics in enhancing muscle relaxant effects is as follows: diethyl ether > enflurane > isoflurane > desflurane > halothane.¹⁰¹ Also, antagonism of the block may be delayed, especially if inhalant anesthesia is continued after administration of the reversal agent. Monitoring of neuromuscular function helps to facilitate the appropriate dosing of muscle relaxants during inhalational anesthesia.

Most injectable anesthetic agents have only minor effects on the neuromuscular blocking properties of muscle relaxants. Induction agents, such as thiopental, ketamine and propofol, may minimally enhance neuromuscular blockade.¹⁰¹

Acid-Base Disturbances

Generally, respiratory acidosis increases the intensity of muscle blockade, whereas respiratory alkalosis decreases the effect.^{102–105} Both metabolic acidosis and alkalosis may potentiate the effects of muscle relaxants and make it more difficult to antagonize relaxant-induced muscle paralysis.^{102,103,105,106}

Electrolyte Disturbances

Alterations in serum concentration of potassium, magnesium, and calcium influence neuromuscular blockade. Decreases in extracellular potassium result in hyperpolarization of the end plate and resistance to ACh-induced depolarization.¹⁰⁷ A relative increase in extracellular potassium lowers the resting membrane potential, opposing the effect of the muscle relaxant.¹⁰⁷ Increased serum magnesium concentrations compete with ionized calcium, decreasing ACh release. Accordingly, in patients given magnesium sulfate, the duration of action of muscle relaxants may increase.¹⁰⁸ Hypocalcemia decreases ACh release, muscle action potential, and muscle contraction strength, thus increasing the effect of the neuromuscular block.^{107,109} Typically, hypercalcemia decreases the effect of d-tubocurarine, pancuronium, and possibly other NMBAs, resulting in a higher dose requirement to achieve paralysis.¹⁰⁷

Hypothermia

This generally slows drug elimination and decreases nerve conduction and muscle contraction. The overall clinical effect will vary with the degree of hypothermia. Care is required when administering muscle relaxants in cold environments. Doses may need to be reduced to prevent prolonged paralysis.

Age

Youth is associated with altered dose requirements of muscle relaxants. Receptor immaturity and decreased clearance appears to increase the potency of muscle relaxants in the young.^{110–112} On the other hand, very young animals may require higher doses of muscle relaxants because of increased extracellular fluid and a larger volume of distribution when compared with adults. In addition, in younger animals, muscle relaxants usually have a faster onset of action while neuromuscular function recovers more quickly, so a lower dose of antagonist is usually required at the termination of the procedure.¹¹³

Although the data from published studies are not always clear-cut, old age may be associated with an increase in the effect of muscle relaxants, perhaps because of a lower volume of distribution and decreased rate of clearance. In elderly human patients, a delay in reversal and the need for higher doses of reversal agents are common, and likely attributable to slower spontaneous recovery.^{114,115}

Neuromuscular Disorders

Animals with neuromuscular disorders may exhibit unpredictable responses to both depolarizing and nondepolarizing muscle relaxants. Care should be taken when administering muscle relaxants to patients with neuromuscular disorders or a history of muscle weakness or wasting.

Peripheral neuropathies may be classified as idiopathic, familial, metabolic, or immune mediated. In human patients, peripheral neuropathy may increase the effect of nondepolarizing muscle relaxants because of neural damage and the possibility of denervation-induced upregulation.¹¹⁶ These patients may also be predisposed to succinylcholine-induced hyperkalemia.¹¹⁷

Diseases such as tick paralysis and botulism impair presynaptic release of ACh. Patients with presynaptic neuromuscular disorders show an increased sensitivity to nondepolarizing muscle relaxants. Myasthenia gravis is an autoimmune disease that causes generalized muscle weakness from a decrease in the number of ACh receptors on the motor end-plate muscle membrane. ACh is released normally, but its effect on the postsynaptic membrane is reduced. Patients with myasthenia gravis may be resistant to succinylcholine-induced paralysis, but are extremely sensitive to nondepolarizing relaxants and have an increased sensitivity toward succinylcholine-induced phase II block.^{118,119} Patients with myasthenia gravis do not appear to be more sensitive to succinylcholine-induced hyperkalemia or malignant hyperthermia.¹²⁰ From published reports of dogs with myasthenia gravis, the initial dose recommendations of atracurium and vecuronium are 0.1 mg/kg and 0.02 mg/kg, respectively.^{121,122}

Antimicrobial and Other Drug Interactions

The most notable effects on neuromuscular blockade occur with the administration of polymyxin and aminoglycoside antimicrobials, but can also occur with tetracycline, lincomycin, and clindamycin. Polymyxins may depress postsynaptic sensitivity to ACh and enhance channel block.^{123,124} Antagonism with either neostigmine or calcium may be difficult and unreliable.¹²⁴ Ami-

noglycosides, such as gentamicin, kanamycin, neomycin, streptomycin, and tobramycin, have a presynaptic site of action, as evidenced by depressed ACh release. The ability to antagonize blockade with calcium supports this mechanism and site of action.¹²⁴ Studies in anesthetized cats and horses given atracurium have shown a significant decrease in twitch tension after administration of gentamicin (2 mg/kg intravenously [IV]), but recovery times were not significantly changed.^{125,126} Cats given gentamicin (10 mg/kg IV) during neuromuscular blockade have shown a significant decrease in tibialis cranialis twitch response.¹²⁷ Furthermore, dogs given a single daily dose of gentamicin (6 mg/kg IV as a bolus) had significantly decreased twitch tension, while recovery time did not differ from that for controls.¹²⁸

Tetracycline administration presumably depresses ACh release through calcium chelation. The enhanced blockade is usually reversible with calcium, but not neostigmine, administration.¹²⁴ The primary site of the inhibitory action of lincomycin may be directly on the muscle. It may also have slight presynaptic and postsynaptic activity. This effect is poorly reversed with neostigmine or calcium but partially reversed with 4-aminopyridine.¹²⁴ Clindamycin has a greater neuromuscular blocking effect than lincomycin: The mechanism is direct inhibition of the muscle, and reversal is difficult with either calcium or neostigmine administration.¹²⁴ Penicillins and cephalosporins appear to have a negligible effect on overall neuromuscular function.¹²⁴ Nevertheless, whenever an antibiotic is administered to a patient also given a muscle relaxant, the possibility of an enhanced block and/or residual paralysis should be considered. Close patient monitoring is recommended well into the recovery period.

Lithium administration may also increase or prolong neuromuscular blockade by competing with sodium and decreasing ACh release. The effects of muscle relaxants have been potentiated by numerous classes of drugs, including beta blockers, doxapram, anticonvulsants, steroids, and H₂-receptor antagonists.¹⁰¹

Monitoring Neuromuscular Blockade

Neuromuscular function should be monitored whenever a muscle relaxant is administered. Appropriate monitoring will facilitate proper dosing of both the muscle relaxant and its antagonist. To prevent residual paralysis and muscle weakness in the recovery period, it is critical that monitoring be continued until the function is fully restored. Evoked motor responses to peripheral nerve stimulation are used to evaluate the degree of neuromuscular blockade. Many handheld peripheral nerve stimulators are available (Fig. 15.3).

Sites of Stimulation

Sites for stimulation of peripheral motor nerves in dogs and cats include the peroneal and ulnar nerves (Figs. 15.4 and 15.5). In horses, the facial nerve and superficial peroneal nerve are most commonly used (Figs. 15.6 and 15.7). Contact electrodes are placed over the nerve to be stimulated, and the resultant motor response is compared with the prerelaxant response.

Fig. 15.3. Peripheral nerve stimulator.

Fig. 15.4. Superficial peroneal nerve stimulation in a dog.

Electrical Stimulation Characteristics

When monitoring neuromuscular function in veterinary patients, there are standard methods for stimulating peripheral nerves. The output from the peripheral nerve stimulator should be a square-wave stimulus lasting 0.2 to 0.3 ms. Ideally, the output current of the nerve stimulator should be adjustable, enabling a *supramaximal impulse* (i.e., a current slightly greater than that required to elicit the maximum motor response) to be applied to the nerve. A supramaximal stimulus ensures that all fibers in the nerve bundle are depolarized. Since muscle fibers contract in an all-or-none fashion, any subsequent changes in the evoked motor response during supramaximal stimulation of the peripheral nerve are caused by changes at the neuromuscular junction or muscle level, not by loss of nerve fiber input.

Fig. 15.5. Ulnar nerve stimulation in a dog.

Fig. 15.7. Peroneal nerve stimulation in a horse.

Fig. 15.6. Facial nerve stimulation in a horse.

Pattern of Stimulation

Ideally, the peripheral nerve stimulator should have a variable output and be capable of providing single-twitch, train-of-four, tetanic, and double-burst patterns of stimulation. Examples of the evoked muscle response to supramaximal stimulation before and after administration of a muscle relaxant are presented in Fig. 15.8. Partial neuromuscular block with depolarizing and nondepolarizing relaxants modifies the recorded responses to these stimulation patterns. These modified responses are summarized in Table 15.2.

Single Twitch

When using the single twitch, the simplest form of nerve stimulation, the degree of relaxation is assessed by dividing the elicited response by the prerelaxant response. The *prerelaxant response* is the twitch response measured immediately prior to the administration of the muscle relaxant. Since ACh release is decreased by the prejunctional effects of the relaxant, the frequency of single-twitch stimulation should be no greater than approximately one twitch every 7 to 10 s.¹²⁹ If the stimulus is applied too frequently, the resultant twitch response will be artificially low,

causing inaccuracy in determination of the degree of relaxation. Twitch response is not depressed until 75% to 80% of receptors are blocked and will be abolished when approximately 90% to 95% of receptors are blocked.¹³⁰

Train of Four

The *train-of-four (TOF) pattern* of stimulation is the delivery of four supramaximal impulses over 2 s (2 Hz). The TOF can be repeated every 10 to 20 s without significant temporal effects. The relaxation level is determined by comparing the ratio of the intensity of the fourth twitch to the first twitch (T_4/T_1 ratio). Since the TOF serves as its own control, it is not necessary to determine baseline values prior to relaxant administration, although proper stimulator function should be verified before paralysis. In the absence of neuromuscular blockade, the T_4/T_1 ratio will be 1.0. After a nondepolarizing muscle relaxant is administered, when approximately 70% of receptors are occupied the twitches will fade, beginning with the fourth, followed by the third, second, and first twitches.¹³¹ The dose of relaxant given will determine the degree of fade, the strength of any remaining twitches, and how long the twitches are absent. During recovery, the twitches will reappear in reverse order. A T_4/T_1 ratio of 0.7 or greater is associated with adequate clinical signs of recovery from the muscle relaxant.¹³²

During the phase I block from a depolarizing relaxant, the TOF fade will be absent. However, repeat administration or continuous infusion of the depolarizing drug can cause a phase II block. When this occurs, fade will be seen following a TOF stimulus (Table 15.2).¹³³

Tetanic Stimulation

Sustained muscle contraction is achieved by continuously delivering a high-frequency (50 Hz) supramaximal stimulus for 5 s.¹³³ Partial neuromuscular blockade from nondepolarizing relaxant administration will reduce tetanic height and cause fade.¹³⁴ Although this pattern of stimulation is helpful for detecting residual neuromuscular blockade during the anesthetic recovery period, it is important to remember that tetanic stimulation can be painful for lightly anesthetized or conscious patients.¹³⁵

Table 15.2. Responses during partial neuromuscular block^a

Criteria	Depolarizing Block	Nondepolarizing Block	Phase II Block
Fasciculation before onset of block	Yes	No	—
Time for onset	Short	Longer	—
Single twitch	Depressed	Depressed	Depressed
Tetanic height	Depressed	Depressed	Depressed
Tetanic fade	Minimal or absent	Present and marked	Present and marked
Train-of-four fade	Minimal or absent	Present and marked	Present and marked
Posttetanic facilitation	Minimal or absent	Present	Present
Response to anticholinesterases	Block is prolonged	Block is antagonized	Block is antagonized

^aDistinguishing features of depolarizing, nondepolarizing, and succinylcholine-induced phase II block. The left column lists the different patterns of nerve stimulation or other characteristic, and the second, third, and fourth columns list the respective responses in the presence of partial neuromuscular block.

Posttetanic Facilitation

Posttetanic facilitation is an increase in an evoked response from a stimulus delivered shortly after tetanic stimulation. This is thought to be caused by increased ACh release from the nerve terminal, but other theories exist.¹³⁰ It is characterized by either an increase in twitch tension or a decrease in the degree of fade in response to either a single-twitch, TOF, or double-burst pattern of stimulation. Posttetanic facilitation is often the first clinical indicator of recovery from neuromuscular blockade.^{136,137}

Double-Burst Stimulation

Double-burst stimulation (DBS) is the delivery of two minitetic bursts, two to four impulses each, delivered at a rate of 50 Hz and 750 ms apart. When DBS is used, a ratio of the response to the second burst compared with the response to the first burst (D_2/D_1) is calculated. DBS may be superior to TOF because not only does DBS correlate highly to TOF when assessed via mechanomyography, but fade is more readily seen with DBS using both visual and tactile means.¹³⁰ An additional advantage

Fig. 15.8. Diagram showing different peripheral nerve stimulation patterns for monitoring neuromuscular function (**top panel**). Under each pattern is shown the characteristics of the evoked muscle responses measured mechanically before (**center panel**) and during (**bottom panel**) partial block.

of DBS is that D_1 is detectable at a deeper level of neuromuscular blockade than is T_1 .¹³⁸

Quantifying Evoked Responses

Whenever a muscle relaxant is administered, neuromuscular function must be monitored until normal neuromuscular function is restored. Residual blockade during the recovery period can cause serious complications. Proper monitoring provides information about the degree and duration of neuromuscular blockade, and assures the observer that no residual blockade is present prior to recovery from anesthesia. In veterinary patients, the most common method used for assessing the degree of neuromuscular blockade is visual observation of the evoked response from peripheral nerve stimulation. With experienced observers, visual observation is adequate in most clinical situations. However, more accurate evaluation of the depth and duration of block is best achieved when the muscle response is recorded and measured. The two methods for accurately quantifying the evoked response are mechanically recorded, where the twitch tension by the muscle is measured using a force displacement transducer, and electromyographically recorded, where the muscle action potential is measured.

Mechanomyography

Mechanomyography (MMG) measures the evoked response of the stimulated muscle by force translation. The use of this method has been described in cats, dogs, horses, ponies, cows, and llamas.^{45,125,126,139–141} With the limb immobilized, stimulating electrodes are placed over a peripheral nerve (peroneal or ulnar). The force transducer is attached to a paw or hoof at a right angle to the direction of muscle contraction. For maximum evoked muscle-twitch tension, a resting tension of 100 to 300 g should be applied. A supramaximal stimulus is applied to the nerve by using a single-twitch, TOF, or double-burst stimulation pattern. The resultant twitch tension can then be quantified. By using MMG, the depth and duration of neuromuscular blockade can be determined accurately. However, limitations make its use in many clinical situations impractical. To prevent changes in resting tension and twitch angle, the limb must be immobilized and no movement should occur during the recording period.¹⁴²

Electromyography

Electromyography (EMG) measures the compound action potential of muscle fibers contracting during a supramaximal stimulus of a peripheral motor nerve. With the stimulating electrodes placed over a peripheral nerve, the recording electrode is placed over the innervation zone of the muscle, midway between its origin and insertion. Also required are a reference electrode, placed over the insertion site, and a ground electrode, placed between the other two electrodes. EMG has the advantage of requiring less or no limb immobilization and no resting tension, and there are more choices as to which muscles may be used.¹⁴² In a study in dogs given atracurium, there was no statistical difference between MMG and EMG during TOF stimulation for either T_1 or T_4/T_1 .¹⁴³ The disadvantage of EMG is that it may be difficult to obtain proper electrode placement for accurate results, particu-

larly in smaller patients. Until a standard method is developed and validated for various species and sites of monitoring, MMG will remain the gold standard for quantifying evoked responses.

Reversal of Neuromuscular Blockade

Nondepolarizing Blockade

As previously reviewed, acetylcholinesterase is present in high concentrations at the neuromuscular junction. It hydrolyzes ACh into choline and acetic acid, terminating the effects of ACh. The effects of nondepolarizing muscle relaxants are antagonized by administering an anticholinesterase (also known as an acetylcholinesterase inhibitor). This class of drugs inhibits the enzyme acetylcholinesterase, increasing the concentration of ACh molecules at the neuromuscular junction. Since nondepolarizing muscle relaxants and ACh compete for the same postsynaptic binding sites, the ACh increase can tip the balance of competition in favor of ACh, and neuromuscular transmission is restored.

The anticholinesterase drugs used to antagonize neuromuscular blockade include edrophonium, neostigmine, and pyridostigmine. They differ in how they inhibit acetylcholinesterase activity. Edrophonium produces a reversible inhibition by electrostatic attachment to the anionic site and by hydrogen bonding at the esteratic site on acetylcholinesterase. The action of edrophonium is relatively brief because a covalent bond is not formed and ACh can easily compete with edrophonium for access to the enzyme. Neostigmine and pyridostigmine inhibit acetylcholinesterase by forming a carbamyl-ester complex at the esteratic site of acetylcholinesterase. This bond lasts longer when compared with the bond of the enzyme with ACh, thereby preventing acetylcholinesterase from accessing ACh.

The reversal agents vary in their onset of action. In order from the shortest to the longest onset is edrophonium < neostigmine < pyridostigmine. In human patients, neostigmine is 4.4 times more potent than pyridostigmine and 5.7 times more potent than edrophonium for reversal of nondepolarizing neuromuscular blockade.¹⁴⁴ The duration of action is similar for both neostigmine and edrophonium, whereas that of pyridostigmine is approximately 40% longer.^{144,145} In cats, neostigmine is 12 times more potent than edrophonium.¹⁴⁶

Antiacetylcholinesterase agents are primarily metabolized by the liver, with hepatic biotransformation eliminating 50% of a neostigmine dose, 30% of an edrophonium dose, and 25% of a pyridostigmine dose. Renal excretion eliminates the remainder of the drug. Patients with renal failure will have prolonged elimination of an anticholinesterase drug.

The ACh accumulation following the administration of an anticholinesterase drug is not specific to the neuromuscular junction. While nicotinic effects occur at the neuromuscular junction and autonomic ganglia, muscarinic cholinergic effects occur because of inhibition of acetylcholinesterase at the sinus node, smooth muscle, and glands. Clinical effects of increased ACh concentrations at these sites include bradycardia, sinus arrest, bronchospasm, miosis, intestinal hyperperistalsis, and salivation. For this reason, it is advised that an anticholinergic drug, either atropine or glycopyrrolate, be administered immediately prior to re-

versal of neuromuscular blockade with an anticholinesterase. When choosing between atropine and glycopyrrolate, one must consider that atropine has a faster onset of action, which is more likely to cause an initial tachycardia, and will cross the blood-brain and blood-placental barriers. Compared with neostigmine and pyridostigmine, the muscarinic effects of edrophonium are mild, so it may be chosen for reversal when one wants to avoid the use of an anticholinergic. For example, edrophonium is frequently chosen in equine patients because anticholinergic drug administration has been associated with the development of ileus and colic.

Depolarizing Blockade

Recovery from succinylcholine (phase I block) is rapid and spontaneous because of succinylcholine hydrolysis by plasma cholinesterases. Recovery may be delayed in patients with decreases in plasma cholinesterase levels or activity. The administration of an anticholinesterase would actually prolong the depolarizing block.¹⁴⁷ On the other hand, a phase II block from succinylcholine can be antagonized similarly to the nondepolarizing muscle relaxants, emphasizing the need for determining the type (phase I or phase II) of block present when using succinylcholine (Table 15.2).^{148,149}

Centrally Acting Muscle Relaxants

Guaifenesin is used routinely as a muscle relaxant in large animal species. Its mechanism of action is to disrupt nerve impulse transmission at the level of the internuncial neurons of the spinal cord, brain stem, and subcortical areas of the brain. At therapeutic doses, skeletal muscle relaxes, but there is little effect on the respiratory muscles or diaphragm. Guaifenesin does not provide analgesia or produce unconsciousness. Therefore, it should not be used alone for any painful surgical or diagnostic procedure. No antagonist is available to reverse the muscle relaxant effects of guaifenesin.

Guaifenesin is commercially available as either a powder, which is reconstituted to the desired concentration with sterile water, or as a ready-made solution. Concentrations of 5%, 10%, and 15% have been used, with a 5% solution in 5% dextrose being the most common. Guaifenesin administered intravenously in high concentrations (>10%) can cause hemolysis, hemoglobinuria, and venous thrombosis.¹⁵⁰ Tissue can be damaged if guaifenesin is inadvertently administered perivascularly.¹⁵⁰

The cardiopulmonary effects of guaifenesin, alone or in combination with xylazine, ketamine, or thiobarbiturates, have been studied in horses. When guaifenesin is given alone, heart rate, respiratory rate, right atrial pressure, pulmonary arterial pressure, and cardiac output are unchanged. Systolic, diastolic, and mean arterial pressures are decreased. Xylazine (1.1 mg/kg IV), given prior to guaifenesin administration, reduced the dose necessary to achieve lateral recumbency (88 ± 10 mg/kg) compared with guaifenesin alone (134 ± 34 mg/kg). The addition of xylazine typically decreases heart rate, respiratory rate, cardiac output, and arterial oxygen partial pressure (PaO₂). Central venous pressure increases, whereas systolic, diastolic, and mean arterial blood pressures commonly decrease.^{151,152}

Guaifenesin can be combined with thiopental for both induction and maintenance of anesthesia in horses. Following premedication with either xylazine or acepromazine, a combination of guaifenesin and thiopental (2 to 3 g of thiopental in 1 L of 5% guaifenesin) is given for induction or, alternatively, guaifenesin is given until the horse is wobbly and buckling at the knees, and then a bolus of thiopental (4 mg/kg) is administered. Short periods of anesthesia (<1 h) can be maintained by a continuous infusion of the guaifenesin-thiopental combination.

A significant amount of guaifenesin crosses the placental barrier in pregnant mares.¹⁵² Stallions may have up to 1.5 times longer action compared with mares. The longer recovery time in male horses is attributed to slower drug elimination from the plasma.¹⁵³

Guaifenesin has also been combined with thiobarbiturates or ketamine for use in cattle, small ruminants, and swine.^{154,155} Although guaifenesin has been used in dogs, the large volume requirement makes it impractical for routine use in this species.¹⁵⁶ However, when combined with a thiobarbiturate or ketamine-xylazine, guaifenesin has proven an effective component when immobilizing dogs.¹⁵⁷

Peripherally Acting Muscle Relaxants

Dantrolene is a hydantoin derivative that interferes with excitation-contraction coupling, thus relaxing skeletal muscle through a decrease in the amount of calcium released from the sarcoplasmic reticulum. Therapeutic doses do not adversely affect cardiac or smooth muscle and do not depress respiration.¹⁵⁸ Dantrolene is the drug of choice for the treatment of malignant hyperthermia. In swine, the recommended dose is 1 to 3 mg/kg IV when treating a malignant hyperthermia crisis and 5 mg/kg orally for prophylaxis.¹⁵⁹ Dantrolene is supplied in 20-mg vials in powder form with 3 g of mannitol to improve solubility. It is reconstituted using 60 mL of sterile water to achieve a concentration of 0.33 mg/mL. The oral preparation comes in 50-mg capsules.

The prophylactic use of dantrolene in animal patients prone to malignant hyperthermia is no longer routinely recommended. Pretreatment with dantrolene prior to anesthesia does not guarantee effective blood levels and, in equine patients, may produce unwanted skeletal muscle weakness during the recovery period. In susceptible patients, an anesthetic regimen using nontriggering anesthetics should be used, and dantrolene should be immediately available. However, the intravenous preparation of dantrolene may be cost prohibitive and not economically justifiable for many veterinary clinics to keep in stock. Most human hospital pharmacies have the intravenous formulation and may sell the needed amount to the veterinary clinic when required. Compounding the oral preparation for intravenous use has been described. The process is complex and time consuming, but dantrolene powder can be stored for rapid reconstitution during a malignant hyperthermia crisis.^{160,161}

Metabolism of dantrolene is via the liver through oxidative and reductive pathways. Metabolites and the unchanged drug are excreted in the urine. Dantrolene can cause muscle weakness, nausea, and diarrhea. Fatal hepatitis has occurred in human patients

after chronic treatment with dantrolene.¹⁶² Severe myocardial depression has been reported when dantrolene is administered concurrently with verapamil or other calcium channel blockers.^{163,164} Synergism, resulting in a delayed recovery of neuromuscular function, has been observed with dantrolene and vecuronium coadministration.¹⁶⁵

Introduction

When providing anesthesia and analgesia to animals, veterinarians often administer combinations of drugs without fully appreciating the possible interactions that may and do occur. Many interactions, both beneficial and harmful, are possible, considering the number of drugs that are coadministered. Although most veterinarians view drug interactions as undesirable, modern anesthesia and analgesic practice emphasizes the use of drug interactions for the benefit of the patient (multimodal anesthesia or analgesia).

A distinction should be made between drug interactions that occur *in vitro* (such as in a syringe or vial) from those that occur *in vivo* (in patients). Interactions and incompatibilities may occur as a consequence of mixing drugs in the same vial or syringe prior to administration, or when drugs interact in patients. Veterinarians frequently mix drugs together (compound) in syringes, vials, or fluids before administration to animals. *In vitro* reactions, also called *pharmaceutical interactions*, may form a drug precipitate or a toxic product or inactivate one of the drugs in the mixture. *In vivo* interactions are also possible, affecting the pharmacokinetics (absorption, distribution, or elimination) or the pharmacodynamics (mechanism of action) of the drugs and can result in enhanced or reduced pharmacological actions or increased incidence of adverse events.

Drug interactions usually result from administration of (a) two drugs in one formulation, as a fixed-dose mixture; (b) two drugs in separate formulations simultaneously; (c) a second drug during prolonged use of the first drug; and (d) two drugs at specific

time intervals. Drug interactions can be classified as either pharmacokinetic or pharmacodynamic. *Pharmacokinetics* refers to what the body does to drugs, and *pharmacodynamics* refers to what drugs do to the body. Pharmacokinetic interactions produce changes in drug concentration at the receptor site by altering absorption, elimination, or distribution. Pharmacodynamic interactions occur when one drug alters the response to another.

In vitro Drug Interactions

Acid-Base Interactions

Mixing drugs or solutions that vary in pH or acid-base characteristics may result in an incompatible mixture because of opposition of charge (anion-cation) or interference with the stability of a solution because of acid-base interactions. For example, drugs formulated as hydrochloride salt (HCl) are done so to maintain a pH balance that will ensure that the drug is soluble in an aqueous solution. The HCl may also be critical for the solubility and stability of the compound. If the solution is alkalized by adding bicarbonate or other bases, the compound may become unstable or precipitate.

The pH of common intravenous fluids is lower than many clinicians appreciate. For example, 0.9% sodium chloride and 5% dextrose solutions can have a pH as low as 3 (Table 16.1).¹ A drug added to a bag containing an acidic solution may lose activity or precipitate if alkalinity is needed for drug stability or solubility. The pH values of common intravenous solutions are listed in Table 16.1.

Chemical Incompatibilities

These reactions occur as a result of chemical interactions among active ingredients, inactive ingredients, vehicles, and preservatives. Veterinarians should not admix drug solutions without first consulting a pharmaceutical reference^{2,3} or the drug manufacturer. The drugs listed in Table 16.2 have often been cited as being incompatible with other drugs or solutions. Interactions with injectable drugs can be found in Trissel's book of interactions or the *USP Drug Information*, volume 1.^{2,3} Signs of interactions and incompatibilities can include haziness of the solutions, precipitation, bubble formation, or a color change. Some interactions cause drug hydrolysis and oxidation, for example, sympathomimetic catecholamines, such as dobutamine, dopamine, or epinephrine may oxidize to a slight pink without significant loss of potency. However, if the color changes to brownish, it should not be used because this is a sign of significant oxidation.

Solutions

These may be incompatible with other solutions because of ionic interactions. For example, sodium bicarbonate (NaHCO_3) reacts with calcium-containing solutions, forming calcium carbonate. Admixing tetracyclines with calcium-containing solutions results in precipitation. In general, hydrochloride salts (e.g., dobutamine HCl, dopamine HCl, and epinephrine HCl) should not be mixed with alkaline solutions. Vitamin B₁ (thiamine hydrochloride) is unstable in alkaline solutions and should not be mixed with alkalizing solutions, carbonates, or citrates.

Table 16.1. Common fluid solutions and components.

Fluid	Na ⁺	K ⁺	Ca ²⁺	Cl ⁻	pH
0.9% Saline	154	0	0	154	4.5–5.7
0.45% Saline	77	0	0	77	4–7
Ringer's solution	147	4	4.5	156	5.0–7.5
Lactated Ringer's	130	4	3	109	6.0–7.5
5% Dextrose (D ₅ W)	0	0	0	0	3.2–6.5

D₅W, 5% dextrose solution.

Table 16.2. Anesthetic drug in vitro incompatibilities with other drugs and solutions.

Drug	Compatibility with Other Drugs	Compatibility with Fluid Solutions	Important Considerations
Bupivacaine HCl	pH 4.0–6.5. Avoid strongly acid or alkaline solutions. Sodium bicarbonate has been added to local anesthetics just prior to administration to decrease pain from injection. Raising the pH will accelerate the onset of anesthetic action.	Compatible with fluid solutions.	Do not use if solution becomes cloudy, yellow, or pink. If pH is adjusted (e.g., pH 6–7) with alkalizing solutions, the drug is stable if used soon after mixing.
Buprenorphine Butorphanol	Do not mix with sodium barbiturates.	Infuse with sodium chloride.	Protect from light.
Calcium chloride	Will precipitate with sodium bicarbonate.		Do not mix with compounds known to chelate with calcium.
Dexamethasone sodium phosphate	pH 7.0–8.5. Do not mix with acidifying solutions.	Compatible with most IV solutions.	
Diazepam	pH 6.2–6.9. Hydrolysis will occur if combined with low pH solutions. Precipitation will occur with aqueous solutions.	Precipitation occurs when mixed with water-based (aqueous) solutions. Ringer's based solutions and dextrose will cause precipitation.	Protect from light. There is no loss if stored in hard plastic syringe. However, if stored in soft plastic (PVC) infusion bags or tubing, significant sorption will occur (e.g., 80%–90% in 24 h).
Dobutamine HCl	pH 2.5–5.5. Do not mix with alkalizing drugs.	Do not mix with alkaline solutions. Compatible with most fluid solutions.	Slight pink tinge to solution can occur without loss of potency, but do not use if solution turns brown.
Dopamine HCl	pH 2.5–5.0. Do not mix with alkalizing solutions.	Do not mix with alkaline fluids. Compatible with most fluid solutions.	Do not use if solution turns color.
Epinephrine HCl	pH of solution is acidic. It is destroyed by mixing with alkaline drugs.	Incompatible with alkaline solutions and oxidizing solutions.	Do not mix with bicarbonates, nitrates, citrates, and other salts. It is compatible with plastic in syringes. When solution becomes oxidized, it turns brown. Do not use if this color change is observed.

Table 16.2. Anesthetic drug in vitro incompatibilities with other drugs and solutions (*continued*).

Drug	Compatibility with Other Drugs	Compatibility with Fluid Solutions	Important Considerations
Fentanyl citrate		Compatible with most fluid solutions.	No loss measured when stored in plastic infusion sets.
Furosemide	pH of solution, 8.0–9.8. Stable with alkaline drugs, but do not mix with acidifying drug solutions with pH < 5.5	Do not mix with acidic solutions.	Compatible in plastic syringes and infusion sets.
Glycopyrrolate	Acidic pH (2–3). Do not mix with drugs that will alkalize the solution.	Do not mix with alkaline solutions (pH > 6.0). Compatible with most other fluids.	
Heparin sodium	Heparin is acidic and will react with some basic compounds.	Infuse with dextrose solutions.	No loss occurs in various solutions. No sorption to plastic has been reported.
Hydromorphone HCl	Do not mix with diazepam or bicarbonate.	Stable in most fluid solutions.	
Isoproterenol HCl		Compatible with dextrose and saline solutions.	Degradation occurs at pH > 6.0.
Ketamine HCl	Acidic solution. Do not mix with alkaline solutions such as barbiturates. Avoid mixing ketamine and diazepam.	Compatible with saline and dextrose solutions.	Solution may turn slightly dark, which does not affect potency.
Lidocaine	pH of solution, 5–7. Compatible with most drugs. It can be alkalized to pH 7.2 without loss of stability.	Stable in fluids, including dextrose solution.	Aqueous solution is stable in mildly acid and alkaline conditions. If pH is adjusted (e.g., pH 6–7) with alkalizing solutions, the drug is stable if used soon after mixing. No sorption to plastic syringes has been reported.
Lorazepam		Compatible with fluid solutions such as dextrose and saline.	Dilute solution for IV use. There is significant sorption to PVC containers.
Meperidine HCl	Compatible with most drugs.	Compatible with most fluid solutions.	Compatible with plastic syringes.
Midazolam HCl	pH of solution, ca. 3.0. Increasing the pH to >7 will result in drug loss.	Compatible with fluid solutions.	No sorption with plastic or fluid containers is reported.
Morphine sulfate	pH of solution, 3.5–7.0. Stable at low pH, but degradation will occur at pH > 7.	Stable in most fluids (dextrose and saline solutions).	No sorption to plastic has been reported.
Nitroglycerin	pH of solution, 3.0–6.5. Do not mix with other drugs.	Compatible with most fluid solutions.	Sorption to containers, especially PVC plastic, is extensive and will result in significant loss.
Oxymorphone HCl	pH of solution, 2.7–4.5. Compatible with most drugs.	Compatible with most fluid solutions.	
Pentobarbital sodium	pH of solution is 9.0–10.5. It will precipitate if combined with most hydrochloride-based drugs or anything with low pH. Alkaline solution will affect other coadministered drugs.		Aqueous solutions are not stable. Will precipitate readily in solutions with low pH.

(*continued*)

Table 16.2. Anesthetic drug in vitro incompatibilities with other drugs and solutions (*continued*).

Drug	Compatibility with Other Drugs	Compatibility with Fluid Solutions	Important Considerations
Phenobarbital sodium	pH of solution, 9.2–10.2. It will precipitate if combined with most hydrochloride-based drugs or anything with low pH. Alkaline solution will affect other coadministered drugs.		Will precipitate readily in solutions with low pH.
Phenytoin sodium	pH of solution, 10.0–12.3. Do not mix with acidifying drugs.		Will precipitate readily in solutions with low pH.
Propofol	pH of solution, 7.0–8.5 and lower (depends on manufacturer).	Compatible with fluid solutions such as dextrose and saline.	Oil and water emulsion formulation that will encourage microbe growth. Do not freeze. More stable in glass than in plastic.
Sodium bicarbonate	Alkaline solution; pH 7.0–8.5. Do not mix with acid solutions.	Do not mix with solutions that contain calcium (e.g., Ringer's) or precipitation may occur.	
Sodium nitroprusside	pH of solution, 3.5–6.0.	Dextrose solution is recommended for infusion.	Very sensitive to light. Cover with foil during infusion.
Thiopental sodium	pH of solution, 10–11. If not kept at alkaline pH, precipitation will occur.		Reconstituted solution is stable for only 3 days at room temperature or 7 days refrigerated.

HCl, hydrochloride; IV, intravenous; and PVC, polyvinyl chloride.

Diazepam

Diazepam is notorious for its instability in solutions and its ability to adsorb to plastic containers. Diazepam is formulated in organic solvents (e.g., propylene glycol, ethanol, and benzyl alcohol) and is not soluble in aqueous solutions. If the diazepam solution is added to an aqueous solution, it will become hazy or precipitate unless the solution is very dilute (e.g., 1:50 to 1:100). In addition, diazepam is known to adsorb to soft plastic containers, such as those composed of polyvinyl chloride (e.g., PVC infusion bags and plastic tubing). Heparin, when used in flush solutions, is physically incompatible with diazepam.

Changes in pH That Affect Drug Stability or Solubility

According to the *USP-NF*,³ improper pH ranks with exposure to elevated temperature as a factor most likely to cause a clinically significant loss of drug efficacy. A drug solution or suspension may be stable for days, weeks, or even years in its original formulation, but when mixed with another liquid that changes the pH, it can degrade in minutes, hours, or days. A pH change of 1 unit might decrease drug stability by a factor of 10 or greater. These types of interactions are more likely at the extremes of pH, for example outside the range of 4 to 8 (see Table 16.2 for pH values of commonly used anesthetic and adjunctive drugs). Some drugs undergo epimerization (steric rearrangement) when ex-

posed to a pH range higher than the optimum for the drug. Other drugs are oxidized, which is catalyzed by high pH, rendering the drug inactive. Oxidation is often visible through a color change.

Some drugs are alkaline when in solution and will raise the pH of other admixed drugs, resulting in instability or precipitation. Examples of drugs that will increase the pH of solution above 6 are sodium bicarbonate, barbiturates, alkaline-buffered antibiotics, and aminophylline. Barbiturates are notable because the alkalinity of their solutions. Sodium salts of barbiturates in solution (e.g., pentobarbital sodium, phenobarbital sodium, or sodium thiopental) have a pH of approximately 10. If mixed with any solution that lowers the pH, for example, a hydrochloride-based solution, precipitation will occur instantly.

In vivo Drug Interactions

These are reactions that occur in patients when more than one drug is administered. Studies in people have demonstrated that, as the number of drugs coadministered to a patient increases, the incidence of drug interactions also increases. The consequences of drug interactions are most severe for drugs that have a narrow therapeutic index (i.e., when the ratio of toxic dose to effective dose is small). In vivo drug interactions may change drug absorption, drug disposition, biotransformation, and excretion (pharmacokinetic interactions).

Pharmacokinetic Drug Interactions

These interactions include (a) alteration in absorption, (b) alteration in drug-biotransformation enzymes, (c) alteration in protein binding, (d) changes in renal or hepatic clearance, and (e) changes in drug distribution.

Absorption (Systemic Availability)

Most patients undergoing anesthesia are fasted; however, oral medications are occasionally administered in the immediate perioperative period (e.g., orally administered nonsteroidal anti-inflammatory drugs [NSAIDs]). Most anesthetic and anesthetic adjunctive drugs (e.g., opioids) slow gastrointestinal motility and can delay passage of drugs to the small intestine, where most oral drugs are absorbed. Some drugs require an acidic environment to dissolve before gastrointestinal absorption. Antacid compounds, proton-pump inhibitors (omeprazole), or H₂-receptor blockers (famotidine, ranitidine, and cimetidine) can suppress stomach acid production, which may decrease the absorption of other drugs. There are few documented examples where this type of interaction has affected analgesic or anesthetic drug efficacy, however. It is well documented that orally administered antifungal and antibiotic drugs are affected by stomach acidity. It should be noted that fasted animals have a higher stomach pH than normal and often in the same range as animals administered an H₂ blocker or proton-pump inhibitor.⁴

Divalent cations (Mg²⁺ and Ca²⁺) in antacid drugs will bind to tetracyclines and prevent absorption from the gastrointestinal tract. Divalent and trivalent cations, especially Fe³⁺, Ca²⁺, Mg²⁺, and Al³⁺, can bind to and prevent absorption of fluoroquinolone antibiotics. Gastrointestinal protectants, such as sucralfate (which contains aluminum) and antacids (containing Mg²⁺ and/or Al³⁺), will decrease absorption of fluoroquinolone antibiotics (e.g., enrofloxacin and ciprofloxacin) and tetracyclines.

Alteration in absorption as a desirable drug interaction is best demonstrated by the practice of adding epinephrine to local anesthetic solutions. Epinephrine prolongs the duration of local anesthetic action by reducing blood flow (secondary to epinephrine-induced vasoconstriction) and thus delaying systemic absorption of the local anesthetic. The second gas effect represents enhanced absorption from the alveoli of volatile anesthetics administered with nitrous oxide. Rapid absorption of nitrous oxide concentrates the other anesthetic in the alveoli, thereby enhancing absorption of the volatile agent.

EMLA cream (lidocaine 2.5% and prilocaine 2.5%) is an interesting example of a physical change that occurs when two drugs are mixed with a resulting favorable impact on absorption. The cream contains equal parts of the local anesthetics lidocaine and prilocaine that combine to produce a eutectic mixture. Neither local anesthetic is effective when applied to unbroken skin, but the eutectic mixture can penetrate skin.

Interactions Involving the Multidrug Resistance Efflux Pump

The multidrug resistance (MDR) efflux pump, also known as P glycoprotein (P-gp), is coded for by the MDR gene(s) and can be

Table 16.3. Substrates and inhibitors of P glycoprotein that may affect anesthetic drug actions.

P-glycoprotein substrates	
	Opiates (loperamide, morphine)
	Digoxin
	Quinidine
	Ivermectin
	Verapamil
	Antihistamines
	Cyclosporine
	Doxorubicin
	Diltiazem
P-glycoprotein inhibitors	
	Ketoconazole
	Erythromycin
	Cyclosporine
	Grapefruit juice
	Fluoxetine
	St. John's wort
	Paroxetine
	Verapamil
	Quinidine

involved in several important drug interactions.^{5,6} The P-gp is located in membranes and is responsible for pumping drug compounds across a membrane and out of the cell. P-gp can be protective (e.g., removing ivermectin from the central nervous system [CNS]) or lead to decreased drug effectiveness (e.g., chemotherapeutic drug resistance in cancer cells).

P-gp is responsible for pharmacokinetic changes because it is located in the intestine, biliary tract, liver, placenta, and blood-brain barrier (BBB). The best-known pharmacokinetic effects are (a) the pumping of drugs into the intestinal lumen, thereby decreasing systemic absorption and increasing drug clearance from the body; and (b) the P-gp, located in the BBB, that affects the CNS uptake and elimination of certain compounds. P-gp is an integral part of the BBB and participates in neuroprotection of the brain by regulating drug entry.⁷ Because P-gp is located also in the gastrointestinal tract, placenta, and kidneys, among other organs, inhibition of P-gp by ketoconazole, cyclosporine, calcium-channel blockers (diltiazem), and antiarrhythmics (lidocaine and quinidine) may have a variety of consequences.⁸ In some cases, drugs such as cyclosporine can be both a substrate and an inhibitor of P-gp (see Table 16.3). Rifampin and corticosteroids can act as inducers (they increase the activity) of P-gp.

Ketoconazole can inhibit P-gp in the intestine and increase oral absorption of other drugs, including cyclosporine. Concurrent administration of ketoconazole has been known to decrease dose requirements for cyclosporine by one-third. Cyclosporine may inhibit P-gp in the BBB and increase the CNS concentration of some drugs, such as those within the avermectin group. There are anecdotal reports of dogs developing clinical signs consistent with avermectin toxicosis after having received both cyclosporine and avermectin-like drugs.

There have been no reports of anesthetic drugs affecting P-gp

interactions. However, because inhibition of P-gp influences the BBB, clinicians should be aware of the potential for exaggerated CNS anesthetic effects when an animal has received a P-gp inhibitor. Some opiates are substrates for P-gp in the BBB, although this is less established in the veterinary species of interest. However, an exaggerated CNS response (e.g. sedation or respiratory depression) might result from administration of an opiate and an inhibitor of P-gp.

Interactions That Affect Hepatic Drug Clearance

Changes in hepatic clearance are usually a consequence of changes in hepatic blood flow, although other actions (e.g., effects on microsomal enzyme activity) can result from one drug influencing the metabolism of another. Blood-flow changes are most noted when the liver extracts a high fraction of drug from the blood presented to it. Drugs most affected are those known as *high clearance drugs*. Lidocaine, meperidine, and opiates (e.g., morphine, oxymorphone, and hydromorphone) are examples of analgesic drugs that have high hepatic extractions. Inhalational anesthetics, such as halothane, can reduce liver blood flow.

Many drugs must be biotransformed by microsomal enzymes in the liver to make them more water soluble for excretion into the bile or urine. Drugs metabolized by the liver can undergo phase I or phase II reactions. Phase I reactions metabolize the drug to a more water-soluble compound. These reactions often are oxidative, but other reactions, such as reduction, also occur. Phase II reactions occur via conjugation. The best-known example is that of conjugation with glucuronic acid, but other conjugation reactions with amino acids, acetyl groups, and sulfates are possible. Drugs that affect the liver's biotransformation enzymes can cause clinically significant drug interactions.

Cytochrome P-450 Family of Enzymes

The cytochrome P-450 (CYP) enzymes have been studied in great detail in humans, and a family of these enzymes have been identified that participate in the metabolism of drugs. The CYP-3A4 enzymes are probably the most important of this group because they have the largest number of substrates (about half the drugs currently prescribed clinically). However, CYP-2D6, CYP-1A2, CYP-2C9, and CYP-2C19 also can be important for drug metabolism. The presence and significance of these enzymes in domestic animals have not been documented nearly as well. Animals also have these families of enzymes, although the activity of each group is not the same.⁹ Of the species compared (dogs, cats, and horses), none of them resemble the same pattern as humans.

Microsomal Enzyme Induction

Drugs and compounds can increase hepatic microsomal (cytochrome P-450) enzyme activity. Since some of these enzymes are found in intestine as well as the liver, enzyme induction can cause faster biotransformation, resulting in lower oral bioavailability and/or faster plasma clearance. The enzymes most commonly affected by induction are the mixed-function oxidases (phase I oxidation reactions). Enzyme induction causes an in-

crease in activity as well as an increase in enzyme content within the endoplasmic reticulum.

Some drugs are specific in their inducing ability. For example, a drug may induce one group of enzymes without affecting another. The drugs that are most affected by enzyme inhibition are those that undergo metabolism by hepatic enzymes and are lipid soluble. Affected drugs usually have a low hepatic extraction ratio. The time for induction to occur is usually 2 to 3 weeks after initial exposure, and it may take weeks to months for enzyme activity to return to normal after the inducing drug is withdrawn. Potential enzyme inducers are listed in Table 16.4.

Microsomal Enzyme Inhibition

Hepatic microsomal enzymes responsible for drug biotransformation may be inhibited by certain drugs and compounds. Inhibition usually occurs via competitive binding to form an inactive drug-enzyme complex. Inhibition almost immediately follows drug exposure. In many cases, a metabolite of the drug is responsible for enzyme inhibition. Noncompetitive inhibition is also possible when a drug is not a substrate for the enzyme, but alters its function in some manner.

Examples of drugs that inhibit microsomal enzymes are listed in Table 16.5. Some of the microsomal enzyme inhibition-mediated drug interactions that have been described in veterinary patients include cimetidine inhibition of theophylline metabolism, chloramphenicol inhibition of barbiturate metabolism, ketoconazole inhibition (by as much as 85%) of cyclosporine metabolism, ketoconazole inhibition of prednisolone metabolism, and ethanol or 4-methyl-pyrazole inhibition of alcohol dehydrogenase, which converts ethylene glycol to toxic metabolites (this effect is used to treat toxicosis). One well-known example of enzyme inhibition that has clinical consequences in people is the inhibition of acetaminophen metabolism following alcohol consumption. This inhibition can lead to accumulation of hepatotoxic metabolites that form via other pathways.

During the anesthetic period, the nature of enzyme inhibition is important to patients that receive drugs requiring hepatic biotransformation to terminate their effect. For example, if there is concurrent enzyme inhibition, the risks of anesthesia may be altered. Veterinarians should be cognizant of the potential prob-

lems that may occur if they administer or prescribe a drug that has enzyme-inhibiting effects when also administering anesthetics. Fortunately, clearance of inhalant anesthetics and drugs cleared via renal excretion are usually not directly affected.

Interactions That Involve Drug Protein Binding

Alterations in protein binding occur but are rarely of clinical significance. Drugs exist in unbound (free) and bound forms in the blood. The free form is generally immediately available to exert pharmacological effects, but the bound form is not. Drug displaced from protein distributes rapidly into tissue and is available for biotransformation and excretion. The net effect of a displacement interaction is usually small, transient, and frequently unrecognized.

Some drugs are known to compete for binding sites on albumin and other proteins, altering the unbound fraction of a second drug. For most drugs, the amount of protein (and protein-binding sites) in the plasma greatly exceeds the number of drug molecules in the plasma, and binding is rarely saturated. Interactions that involve displacement of protein-bound drugs are therefore rare unless there is severe hypoproteinemia or the drug is so highly protein bound that it occupies most of the binding sites. Only drugs that are highly protein bound (usually defined as approximately 80% to 85% or greater bound), exhibit high clearance rates, and have a low therapeutic index are likely to be involved in protein-binding interactions of clinical significance. Two recent reviews illustrate that drug protein-binding interactions have minimal consequences in most situations of multiple-drug administration.^{10,11} Although changes in plasma protein binding may have an important influence on individual pharmacokinetic parameters, changes in plasma protein binding will usually not greatly influence the clinical exposure of a patient to a drug.¹¹

Pharmacodynamic Drug Interactions

These interactions include drug interactions at the same receptor sites or at different sites. In anesthesiology, pharmacodynamic interactions are frequently used clinically, and pharmacokinetic interactions much less often. Pharmacodynamic interactions of marked clinical significance can affect the cardiovascular, respi-

ratory, and central nervous systems, as well as the neuromuscular junction and metabolism.

It is also common to give drugs that interact to produce complementary effects, to reduce side effects, or to terminate an effect of a drug. Some examples of these types of desirable interaction are (a) the systemic administration of an opioid to reduce the concentration of inhalation agent required to prevent patient response to a noxious stimulus, (b) atropine administration to reduce or prevent the muscarinic effects (e.g., salivation or bradycardia) of anticholinesterases (e.g., neostigmine) when used to counter the action of nondepolarizing neuromuscular blocking agents, (c) administration of an opiate partial agonist or agonist/antagonist (e.g., buprenorphine or butorphanol) to blunt the effects of a pure opiate agonist, and (d) the use of anticholinesterase compounds to antagonize the action of nondepolarizing neuromuscular blocking agents by blocking the hydrolysis of endogenous acetylcholine.

Interactions are possible with the concomitant use of stimulants and sedatives and/or anesthetics. Among the commonly encountered stimulants are the sympathetic amines (phenylpropanolamine, ephedrine, and pseudoephedrine) and other drugs that exert their effects through dopaminergic mechanisms. Selegiline is a monoamine oxidase B (MAO-B) inhibitor at low doses (MAO-A and B inhibitor at high doses) that has been administered to animals for treatment of canine hyperadrenocorticism and cognitive disorder. In addition to its indirect dopaminergic effects, it is metabolized to *l*-amphetamine and *l*-methamphetamine in animals.¹² The amphetamine *l*-isomer is not as pharmacologically active as the *d*-isomer (e.g., dextroamphetamine), but high doses of selegiline (3 mg/kg) have caused excitement and restlessness in dogs, presumably via amphetamine effects.¹³ MAO-B inhibitors are generally less likely than MAO-A inhibitors to cause severe anesthetic drug interactions, but they still may exacerbate CNS toxicity of other excitatory drugs. Of the interactions reported in humans, coadministration of selegiline with selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine and paroxetine has caused CNS reactions and the potential for the *serotonin syndrome* characterized by muscle rigidity, tremors, restlessness, and altered mental status.¹⁴ Other signs of serotonin syndrome may not involve the CNS and include dysfunction of the respiratory and cardiovascular system and hyperthermia. Such reactions associated with selegiline have not yet been documented in veterinary medicine. There does not appear to be a larger potential for severe interactions between selegiline and sympathomimetic amines (e.g., phenylpropanolamine and ephedrine) because selegiline does not inhibit MAO-A at clinically relevant doses. Nevertheless, when prescribing selegiline with sympathetic amines or MAO inhibitors such as amitraz (Mitaban), one should advise owners of the potential interaction and clinical manifestations. There have been reported serotonin-mediated reactions in humans when selegiline has been administered with the opiate meperidine, but documentation of the clinical occurrence of these reactions in veterinary patients is lacking. Because this reaction is caused by a metabolite of meperidine, other opiates are considered less likely to cause this reaction.

Nonsteroidal Anti-inflammatory Drug Interactions

NSAIDs such as carprofen, meloxicam, etodolac, tepoxalin, firocoxib, and deracoxib are used to treat pain and inflammation. In large animals, flunixin meglumine, ketoprofen, and phenylbutazone are often used. The mechanism of action of an NSAID is primarily via inhibition of cyclooxygenase (prostaglandin endoperoxide synthase) isoenzymes. Prostaglandin synthase 1 (cyclooxygenase 1 [COX-1]) is primarily a constitutive enzyme expressed in tissues. Prostaglandins, prostacyclin, and thromboxane synthesized by this enzyme are in part responsible for normal physiological functions. Prostaglandin synthase 2 (COX-2) is synthesized by macrophages and inflammatory cells and is inducible after stimulation by cytokines and other mediators of inflammation. Contrary to initial beliefs, though, COX-2 may be constitutive in some tissues. This has recently raised concerns about the ability of COX-2–selective drugs to spare physiological prostaglandin production in some tissues and their safety in certain situations. NSAID development in the 1990s and early 2000s focused on selective inhibition of COX-2, with the goal of producing analgesia and suppressing inflammation without inhibiting physiologically important prostanoids. However, more profound inhibition of COX-2 may not always be beneficial, because COX-2 products appear to be beneficial in some tissues and disease states. For example, COX-2 products have biological importance in angiogenesis, renal function, regulation of bone resorption, reproductive function, and healing of gastroduodenal ulcers.¹⁵ Prolonged COX-2 inhibition has also been associated with a higher risk of cardiovascular complications (stroke and myocardial ischemia) in humans, because it unbalances the production of endogenous prostanoids by preserving COX-1 function, which may promote platelet aggregation and vasoconstriction.¹⁶ Consequently, COX-2–selective drugs (valdecoxib, celecoxib, and rofecoxib) used in humans have received increased scrutiny by the medical community in recent years, and two have been voluntarily withdrawn from the U.S. market. Unbalanced COX-2 enzyme inhibition appears to increase risk of adverse events in some patient populations, and, because of this concern, future directions of NSAID development may need to be reexamined.¹⁷

The action of NSAIDs in animals raises questions about the potential for adverse interactions. Some theoretical interactions are worthy of consideration. NSAIDs might interfere with prostaglandin-mediated vasodilation that may be necessary for tissue perfusion during anesthesia. Prostaglandins may be important for the action of cardiovascular drugs such as angiotensin-converting enzyme (ACE) inhibitors (e.g., captopril, enalapril, benazepril, and lisinopril). Prostaglandins may also mediate some of the pharmacological effects of diuretics such as furosemide. Furosemide and ACE inhibitors stimulate prostaglandin synthesis to increase renal blood flow and produce vasodilation and natriuresis. Consequently, NSAID inhibition of prostaglandin synthesis may decrease the action of ACE inhibitors and furosemide.¹⁸ NSAIDs may decrease the antihypertensive effect of ACE inhibitors. For aspirin, this action appears to be dose related.^{19,20} This warning is listed in the United States

Pharmacopeia-Drug Information (*USP-DI* 2004) and has been reported in people, but its clinical significance has been debated.^{19,20} The administration of an ACE inhibitor with the NSAID tepoxalin is not associated with adverse renal effects.

Because NSAIDs are generally highly protein bound, interactions with other highly protein-bound drugs are possible, but as discussed previously, unlikely.²¹ Manufacturers' labels on veterinary NSAIDs have warned veterinarians that coadministration of NSAIDs (many of which are over 90% protein bound) could increase free fractions of coadministered drugs such as phenobarbital and produce adverse effects. However, despite the frequently cited potential protein-binding interactions between NSAIDs and other drugs, there are very few documented cases where this has resulted in an adverse outcome, and the clinical significance of protein-binding interactions has likely been exaggerated.

One last possible NSAID interaction worthy of consideration is the combination of an NSAID with a fluoroquinolone antibiotic, causing CNS toxicity in people.²² This type of interaction with currently available fluoroquinolones used in animals (enrofloxacin, marbofloxacin, orbifloxacin, and difloxacin) has not been reported, however.

Renal Interactions with NSAIDs and Anesthetics

In the kidney, prostaglandins play an important role in modulating the tone of blood vessels and regulating salt and water balance, especially during periods of renal stress. Renal injury caused by NSAID use has been described in people and horses. Reported cases of toxicity occur when high doses have been used or when there are other complicating factors (e.g., coadministration of methoxyflurane).²³ Renal injury probably occurs as a result of inhibition of renal prostaglandin synthesis and altered renal autoregulation during periods of renal stress or insult.²⁴ In animals that have decreased renal perfusion caused by dehydration, anesthesia, shock, or preexisting renal disease, this interference with prostaglandin synthesis can lead to renal ischemia.²⁵ Many cases of renal damage caused by anesthetic-NSAID interactions might be subclinical because of the reserve capacity of the kidney. Widespread nephron damage would be required (approximately 75%) before currently used laboratory benchmarks for renal function (blood urea nitrogen and creatinine) would significantly change.

Additional information is needed with regard to the safety of the effect of currently available COX-2 specific inhibitors on the kidney. Prostaglandins that play an important role in salt and water regulation and renal hemodynamics are synthesized by COX-2 enzymes.²⁶ Constitutive COX-2 is found in various sections of the kidney, and administration of drugs that selectively inhibit COX-2 may adversely affect overall renal function in some situations. Of the currently available NSAIDs, carprofen's effect on renal function has been the most extensively studied. Because carprofen is registered for use in perioperative situations in an injectable formulation, safety studies have been conducted to determine whether there is any evidence of an increased occurrence of renal toxicity with its use in the perioperative period, particularly during anesthesia. In one study, carprofen, ketorolac,

and ketoprofen were examined in healthy dogs undergoing surgery, but without intravenous fluid administration. There were minor increases in renal tubular epithelial cells in urine sediment, but, overall, carprofen had no adverse effect on renal function.²⁷ In contrast, some ketorolac-treated and ketoprofen-treated dogs had transient azotemia. In two similar studies, carprofen administered to anesthetized healthy dogs had no adverse effect on renal function.^{28,29} The renal effects of deracoxib administration have been reported by the manufacturer. At high doses, there is a dose-dependent effect on renal tubules. At up to 10 mg/kg for 6 months, it is well tolerated in most dogs, but there is a potential for a dose-dependent renal tubular degeneration/regeneration at doses of 6 mg/kg or higher with long-term usage. It should be remembered that the clinically approved dose of deracoxib for long-term treatment is only 1 to 2 mg/kg per day. Tepoxalin at a dose of 10 mg/kg (currently registered dose) has been evaluated in anesthetized, healthy, normotensive, normovolemic dogs. It has also been evaluated in dogs receiving ACE inhibitors. In both studies adverse effects on renal function were not detected.³⁰ Despite the apparent safety of perioperative NSAID administration documented by these studies, intravenous fluid administration and vigilant monitoring during prolonged anesthesia are clearly warranted to reduce the risk of either subclinical damage or overt renal complications.

Gastrointestinal Interactions with NSAIDs

In the gastrointestinal (GI) tract, prostaglandins play an important role in maintaining a healthy mucosa and cytoprotection and in regulation of acid and mucous secretion. Administration of NSAIDs typically alters GI physiology and may increase the risk of GI injury. GI effects range from mild gastritis and vomiting to severe GI ulceration and bleeding and even death. These effects have been documented for the past 3 decades in the veterinary literature. GI toxicity is caused by two main mechanisms: direct irritation of the GI mucosa and prostaglandin inhibition.¹⁵ Direct irritation occurs because an acidic NSAID can become more lipophilic in the acid milieu of the stomach and cause injury by enhancing diffusion into the gastric mucosa. Secondly, prostaglandins have a cytoprotective effect on the GI mucosa, and inhibition of these compounds causes decreased cytoprotection, diminished blood flow, decreased synthesis of protective mucus, and inhibition of mucosal cell turnover and repair. In healthy dogs, COX-1 is the primary COX enzyme that produces prostaglandins (primarily prostaglandin E₂).³¹ An examination of published reports of GI toxicity from the administration of an NSAID in animals indicates that the most serious problems are caused from doses that are higher than recommended, but toxicity has been observed also from relatively mild doses in susceptible individuals. Some factors may increase the risk of GI toxicity, including concurrent corticosteroids and other GI diseases. Corticosteroids in particular are known to increase the risk of GI toxicity caused by NSAIDs.^{25,32,33} Even meloxicam, which is relatively COX-1 sparing in the canine GI tract, has been associated with increased risk of GI mucosal injury when administered with a corticosteroid.³² Other events that stress the gastric mucosa, such as decreased perfusion caused by shock, anesthesia, or

dehydration, increase risk of damage.³⁴ Clinical observations suggest that, although gastric ulceration can be significant with the administration of NSAIDs in some patients, catastrophic perforating ulceration can occur also in the proximal duodenum, especially in dogs.³⁴ Further investigation into the actions of NSAIDs on the duodenal mucosa are needed.

Opioid Interactions

Opioids are often administered with general anesthetics to provide analgesia and enhance their anesthetic action.³⁵ They are also commonly coadministered with sedative and tranquilizing agents to enhance sedation and analgesia. Clinical and research observations strongly support the concurrent use of opioids and anesthetic and anesthetic-adjunctive drugs; however, there is some evidence that this practice may actually decrease the magnitude and duration of opioid analgesic efficacy in some situations.^{36,37}

As discussed previously in this chapter, there is a specific interaction between MAO inhibitors and meperidine described in people. The use of these drugs together has caused an unpredictable and sometimes fatal reaction, which includes excitation, sweating, rigidity, coma, and seizures. This reaction seems to be rather specific for meperidine because it is caused by one of its metabolites. If animals receive MAO inhibitors and another opiate, it is suggested first to administer a test dose of the opiate and observe the animal carefully. If there is no adverse reaction, subsequent doses can probably be administered safely. Although nonspecific MAO inhibitors are rarely used for treatment of depression in animals, other drugs with MAO-inhibiting properties are used in animals. For example, selegiline, a specific MAO type-B inhibitor, is used in dogs to treat canine hyperadrenocorticism and cognitive disorder. Amitraz, which is also an MAO inhibitor, is found in pet collars and dips to prevent and treat mite infestations. Although no adverse reactions in animals have been documented with amitraz or selegiline and opioid analgesic drugs, one should administer these drug combinations cautiously, at least for the first dose.

In recent years, tramadol has become increasingly popular as an oral analgesic medication for managing chronic pain, but its analgesic efficacy may be partially attributed to serotonin reuptake inhibition. The potential to induce CNS excitation and even seizures when tramadol is coadministered with known CNS stimulants, such as the tricyclic antidepressants, the SSRIs such as fluoxetine, and mood-altering herbal medication such as St. John's wort, should be appreciated by veterinarians. These combinations should be administered to animals with caution.

Interactions Among Opioid Drugs

In recent years, there has been some confusion as to whether the administration of opioid agonists with opioid agonist/antagonists will produce an interaction that diminishes the analgesic effect of the combination. In theory, drugs such as butorphanol and pentazocine have antagonistic properties on the μ receptor, so they should partially reverse some effects of μ -receptor agonists when administered together. The clinical significance of this antagonism has been debated, however. In dogs, for example, although butor-

phanol reverses some respiratory depression and sedation produced by pure agonists, the analgesic efficacy may be preserved.³⁸ Similarly, in dogs given butorphanol for postoperative pain associated with orthopedic surgery, there was no diminished efficacy with subsequent administration of oxymorphone.³⁹ However, in another study, dogs that had not responded to butorphanol after shoulder arthrotomy responded to subsequent administration of oxymorphone, but the oxymorphone dose required to produce an adequate effect was higher than what would be required if oxymorphone was used alone, suggesting that some antagonism of analgesia may have been present.⁴⁰ When butorphanol and oxymorphone have been administered together to cats, a greater efficacy has been reported than when either drug was used alone.^{41,42} These clinical observations taken together suggest that antagonism may indeed occur in some clinical patients, but in other patients coadministration actually results in a synergistic analgesic effect. These divergent results from one individual to the next may be due to a variety of factors, including (a) differences in the pain syndrome being treated, (b) species variation in response to opioids, (c) dosage ratios of the specific opioids being administered and (d) variation in opioid efficacy between genders. For example, when looking at the first of these factors in humans, whether antagonism or synergism occurs with the coadministration of butorphanol and a pure opioid agonist appears to depend on whether somatic pain versus visceral pain is present. These types of studies have not been performed to date in common pet species.

Nomenclature

Commonly used terms to describe drug interactions are addition, antagonism, synergism, and potentiation.

In purely pharmacological terms that have underlying theoretical implications, *addition* refers to simple additivity of fractional doses of two or more drugs, the fraction being expressed relative to the dose of each drug required to produce the same magnitude of response; that is, response to X amount of drug A = response to Y amount of drug B = response to $1/2X_A + 1/2Y_B$, $1/4X_A + 3/4Y_B$, and so on. Additivity is strong support for the assumption that drug A and drug B act via the same mechanism (e.g., on the same receptors). Confirmatory data are provided by in vitro receptor-binding assays. Minimum alveolar concentration (MAC) fractions for inhalational anesthetics are additive.

Synergism refers to the situation where the response to fractional doses as described previously is greater than the response to the sum of the fractional doses (e.g., $1/2X_A + 1/2Y_B$ produces more than the response to X_A or Y_B).

Potentiation refers to the enhancement of action of one drug by a second drug that has no detectable action of its own.

Antagonism refers to the opposing action of one drug toward another. Antagonism may be competitive or noncompetitive. In competitive antagonism, the agonist and antagonist compete for the same receptor site. Noncompetitive antagonism occurs when the agonist and antagonist act via different receptors.

Experimental approaches to determine additivity etc. have included dose-response analysis (Fig. 16.1) and isobolographic analysis (Fig. 16.2).

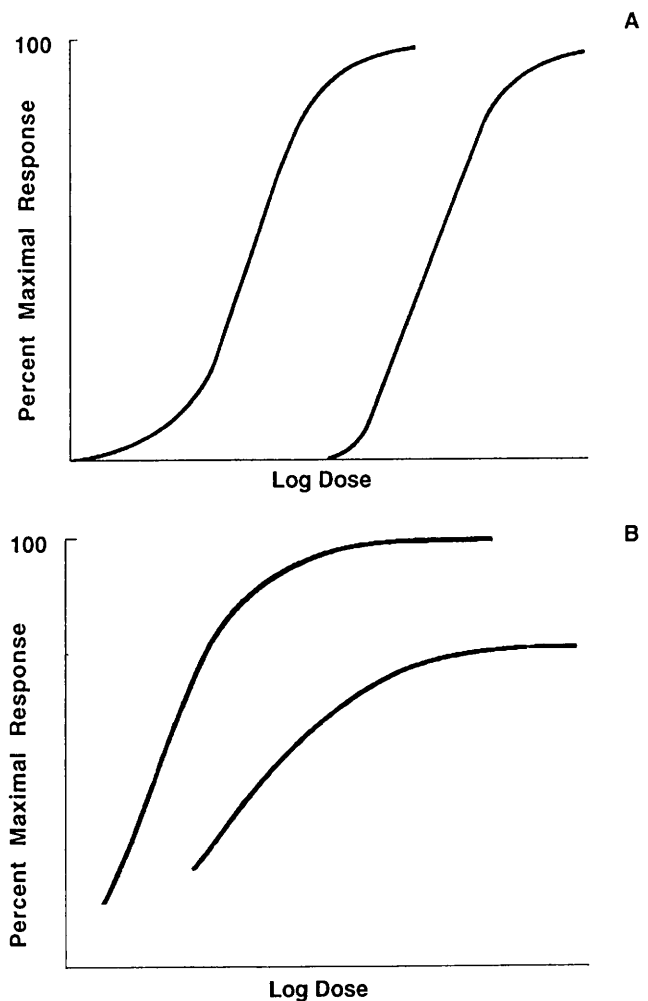

Fig. 16.1. Dose-response curve illustrating competitive antagonism (A) and noncompetitive antagonism (B). In A, the dose-response curve is shifted to the right in the presence of an antagonist, but the shape of the curve is not changed. In B, the dose-response curve is shifted to the right in the presence of an antagonist, and the maximal response to the agonist is reduced.

Anesthetic Drug Interactions

The way anesthetic drugs are usually used raises special considerations with regard to drug interactions. For example, (a) drugs that act rapidly are usually used; (b) responses to administered drugs are measured, often very precisely; (c) drug antagonism is often relied upon; and (d) doses or concentrations of drugs are usually titrated to effect. Minor increases or decreases in responses are usually of little consequence and are dealt with routinely.

Commonly Used Anesthetic Drug Interactions

Two or more different kinds of injectable neuroactive agents are frequently used to induce anesthesia with the goal of achieving the highest quality of anesthesia with minimal side effects. The agents frequently have complementary effects on the brain, but

Fig. 16.2. Isobolograms for the response to mixtures of drugs. The sets of concentrations of drugs A and B, which as mixture produce an effect (e.g., 50% of a maximal response), are plotted. Strict additivity, which means $[A] + [B] = a$ constant, results in a curve of slope -1 (2). If the curve is concave (3), some antagonism is present; if the curve is convex (1), synergism is present.

one agent may also antagonize an undesirable effect of the other. An example of such a combination is tiletamine and zolazepam (Telazol [tiletamine hydrochloride 50 mg/mL and zolazepam hydrochloride 50 mg/mL], an arylcycloalkylamine and a benzodiazepine).

Tiletamine produces sedation, immobility, amnesia, and marked analgesia, but may also produce muscle rigidity and grand mal seizures. Zolazepam produces sedation, reduces anxiety, and prevents muscle rigidity and seizures. Another arylcycloalkylamine-benzodiazepine combination commonly used is ketamine with either midazolam or diazepam. Ketamine is also frequently used in combination with xylazine, a potent sedative with central muscle relaxant and analgesic properties.

Acepromazine is often used as a preanesthetic agent. In addition to calming patients, acepromazine reduces the dose of anesthetic required to produce anesthesia and reduces the sensitivity of the myocardium to catecholamines, thereby reducing the risk of ventricular arrhythmias. On the other hand, acepromazine possesses α_1 -adrenergic blocking activity such that the cardiovascular depressant effects of general anesthetics may interact to produce further vasodilation and hypotension.

Volatile anesthetics may potentiate cardiovascular depression in patients. Because nitrous oxide produces relatively less cardiovascular depression than does an equivalent dose of a volatile agent (it may even stimulate), at any given depth of anesthesia, the amount of cardiovascular depression is less with nitrous oxide plus a volatile agent than with the volatile agent alone at the same depth of anesthesia achieved.

To manage pain associated with surgical procedures better, it is becoming increasingly common to combine the use of regionally administered analgesics and light general anesthesia. An example of such an approach is to administer a local anesthetic alone or in combination with an opioid or an α_2 -adrenergic agonist into the epidural space before or during general anesthesia. Benefits sought with this approach are reduction in the amount of general anesthetic required and the provision of preemptive analgesia. Reducing the amount of general anesthetic required reduces the magnitude of systemic side effects of the general anesthetic.

Introduction

The halogenated hydrocarbon anesthetics are liquids that must be vaporized for administration. These volatile drugs are potent and should be delivered with accuracy. Nitrous oxide (N_2O) is a gas

anesthetic, normally used in high concentrations. It should be administered with enough oxygen to assure an adequate inspired concentration of oxygen. Using contemporary methods, anesthesia machines and breathing systems are required for administration of inhalant anesthetics. Standards for performance and safety of anesthesia machines designed for use in human patients have been published.¹⁻⁴ Newer veterinary anesthesia machines meet some of these standards, but are not required to comply fully with the American Society for Testing and Materials (ASTM) guidelines.

Anesthesia Machines

Anesthesia machines have certain basic components, and are compatible with various breathing systems. An anesthesia machine prepares a precise, but variable, gas mixture (oxygen and anesthetic) for delivery to a breathing system.² The breathing system supplies oxygen and anesthetic to patients, eliminates carbon dioxide from exhaled gases, and provides a means for controlled ventilation. Sources for medical gases (e.g., cylinders for oxygen and N_2O), a regulator and a flowmeter for each gas, and a vaporizer for each volatile anesthetic are fundamental to the operation of an anesthesia machine.⁵

Pressures of gases vary at different locations in an anesthesia machine,^{2,3} and knowledge of these pressures facilitates the evaluation and safe operation of these machines. There are low-, intermediate-, and high-pressure areas. The high-pressure area accepts gases at cylinder pressure and reduces and regulates the pressure; this area includes gas cylinders, hanger yokes, yoke blocks, high-pressure hoses, pressure gauges, and regulators, and the pressure may be as high as 2200 pounds per square inch (psi). The intermediate-pressure area accepts gases from the central pipeline or from the regulators on the anesthesia machine and conducts them to the flush valve and flowmeters; this area includes pipeline inlets, power outlets for ventilators, conduits from pipeline inlets to flowmeters, and conduits from regulators to flowmeters, the flowmeter assembly, and the oxygen-flush apparatus. The pressure usually ranges from 37 to 50 psi, although it may be lower on newer anesthesia machines. The low-pressure area consists of the conduits and components between the flowmeter and the common gas outlet; this area includes vaporizers located outside the breathing system, piping from the flowmeters to the vaporizer, conduit from the vaporizer to the common gas outlet, and conduit from the common gas outlet to the breathing system, and the pressure is only slightly above am-

The primary bank supplies oxygen to the pipeline system until the cylinders are depleted, at which time the system is automatically switched to the reserve bank.

bient. Pressures in the breathing system itself vary, but usually range from 0 to 30 cm of water (cm H₂O) when used with normal, healthy patients.

Medical Gases

An anesthesia machine typically has two sources for each medical gas. First, small compressed-gas cylinders attach to the machine and the hanger yokes, and, second, the hospital's central gas supply enters the machine at pipeline inlets. Ideally, the hospital's pipeline should be the primary source of medical gases, and small cylinders should be reserved for emergencies or transport.⁶ Generally, bulk sources of medical gases are more economic than small cylinders.

The pipeline source for N₂O originates from the bank of large (G or H) compressed-gas cylinders, and oxygen may be supplied similarly (Fig. 17.1). Alternately, the central source of oxygen may emanate from a bulk tank of liquid oxygen (Fig. 17.2) or possibly from an oxygen-concentrating system. The latter will not reliably deliver 100% oxygen. Pipeline systems (Fig. 17.3) convey gases from the central source to terminal units (station outlets) throughout the hospital. A noninterchangeable gas-specific connector at the station outlet accepts only its corresponding connector, which attaches to the pipeline inlet of an anesthetic machine through a flexible, high-pressure hose. The connector may be a threaded diameter index safety system (diss) or a proprietary (manufacturer specific) nonthreaded, noninterchangeable quick connector (Fig. 17.4).³ The high-pressure hose connects to the anesthesia machine at a pipeline inlet, which is usually a diss male connector (Fig. 17.5).

Gases move to and from a cylinder through a brass valve (Fig. 17.6). The valve stem controls flow, and a safety relief device (e.g., a fusible plug with a low melting point) allows emergency escape of gas to prevent bursting of a cylinder during exposure to high temperatures.² The threaded outlets of the valve bodies on

Fig. 17.2. An outside bulk container for liquid oxygen supplying the central medical gas pipeline system of a large hospital.

large cylinders (G and H) are designed to prevent the accidental interchange of oxygen, N₂O, and other gases at regulators or manifolds. The valve bodies of small (E) cylinders of oxygen and N₂O attach directly to anesthesia machines at the hanger yokes, and they use the pin-index safety system (Fig. 17.7) to prevent interchange of oxygen and N₂O. Two pinholes and a port in the valve body correspond to two pins and a nipple on the hanger yoke. Spacing of the pins for each medical gas precludes the interchange of gases under ordinary conditions (Fig. 17.8).

Although the pin-index system is effective, the system has been defeated.² The pins can be removed (Fig. 17.9), bent, broken, or forced deeper into the yoke. The nipple can be stacked with enough washers to allow attachment of the wrong cylinder. Yoke blocks coupled to high-pressure hoses will accommodate alternate gas sources. Some of the older yoke blocks do not have pinholes, and some short blocks can be attached upside down (Fig. 17.9), allowing connection of the wrong gas. Older anesthesia machines should be inspected to assure the integrity of the pin-index system for oxygen and N₂O. Small cylinders should be aligned correctly to the hanger yoke to prevent the creation of a potential hazard. Directing the retaining screw into the safety re-

These valves should be placed strategically throughout the gas distribution system to control the flow of gases during emergencies or maintenance.

Fig. 17.4. A set of proprietary (Ohio or Ohmeda, Madison, WI) quick connects (quick couplers) for oxygen (male and female on the *left*), vacuum (male and female in the *center*), and air (male and female on the *right*). The female connectors are usually present at the site of use (station outlet) for attachment to the male counterparts from the anesthesia machine or other equipment via high-pressure flexible hose. Inadvertent interchange of the gases is prevented by variations in the spacing of corresponding components of the couplers.

lief device instead of the conical depression has caused rapid decompression of a cylinder (Fig. 17.10).^{7,8} If an anesthesia machine has multiple hanger yokes, each yoke should be fitted with a cylinder or a yoke plug (Fig. 17.11) when the machine is in operation.

An oxygen cylinder's service pressure is about 2200 psi. An E cylinder contains about 700 L of gaseous oxygen and an H cylinder about 7000 L (Table 17.1). The pressure is proportional to the contents, and an E cylinder with a pressure of 1100 psi contains about 350 L of oxygen. The pressure in a full N₂O cylinder is

Fig. 17.5. Pipeline inlets for oxygen (*top* connector labeled as O₂) and nitrous oxide (*bottom* larger connector) on a Drager anesthesia machine (North American Drager, Telford, PA). The female diameter index safety system (diss) connectors from the high-pressure hoses couple to the male diss pipeline inlets on the anesthesia machine.

Fig. 17.6. Brass valves on large gas cylinders. The valve outlets on these two cylinders are designed to prevent an inadvertent connection to the wrong cylinder of gases. The valve on the *right* has external threads, whereas the one on the *left* has internal threads. The valve outlet for a large cylinder is distinguished by diameter, number of threads per inch, and type of threads (right hand or left hand and internal or external).

Fig. 17.7. Diagram of the pin-index safety system. The spacing between the valve outlet and the pinholes in the valve bodies for oxygen and nitrous oxide cylinders are illustrated. The pinholes and outlets correspond to the nipple and pins of hanger yokes on anesthesia machines and help to prevent the inadvertent incorrect use of medical gases. Note that pinholes 2 and 5 are used for oxygen, whereas pinholes 3 and 5 are used for nitrous oxide. From Hartsfield.⁵

Fig. 17.9. An oxygen yoke showing a way in which the pin-index system for small gas cylinders can be defeated. The pins have been removed, and a short yoke block has been inserted upside down. Both will defeat the effectiveness of the pin-index system and allow connection to an inappropriate cylinder.

Fig. 17.8. Comparison of the yokes for small cylinders of oxygen (*left*) and nitrous oxide (*right*). The relationship of the pins and the nipple on each yoke show how the inadvertent interchange of oxygen and nitrous oxide cylinders is prevented. From Hartsfield.⁵

about 750 psi at normal room temperature, with N_2O in both liquid and gaseous phases. The vapor pressure of N_2O varies with temperature and determines the pressure in the cylinder. In a full cylinder, 95% of the volume is liquid,⁹ and an E cylinder contains about 1600 L (Table 17.1). As liquid N_2O vaporizes, the cylinder cools, and frosting may occur. The contents of an N_2O cylinder is not directly proportional to the pressure. As pressure starts to decrease after all liquid N_2O has vaporized, about 25% of the original gas content remains. The remaining gas will then be depleted based on rate of flow.¹⁰ Although the amount of N_2O is not directly related to pressure, the content of any cylinder can be de-

Fig. 17.10. The retaining screw of the yoke and a small (E) cylinder of oxygen next to a Vetaflex 5 veterinary anesthesia machine (Pitman-Moore, Washington Crossing, NJ). The retaining screw has been removed from the yoke to illustrate the pointed shape, which is intended to correspond to the conical depression of the cylinder valve and to secure the cylinder in the yoke. If the cylinder is positioned incorrectly in the yoke and the retaining screw is tightened into the fusible plug (the round, slotted device below the conical depression), the cylinder may decompress rapidly.

termined by weight regardless of the state of the material in the cylinder.³

In the United States, the Department of Transportation controls the construction and testing of gas cylinders. The service pressure, defined as the maximum filling pressure at 70°F (22°C),² is typically 1900 to 2200 psi for oxygen. Cylinders are designated alphabetically, size A being the smallest. Sizes E, G,

Fig. 17.11. Preparation for inserting a yoke plug into a yoke intended for a small (E) cylinder prior to use of the anesthesia machine. Since only one cylinder is present, the open yoke should be blocked with a yoke plug to prevent gas leaks, even if a check valve is present immediately upstream from the cylinder.

and H are common for medical oxygen and N₂O (Table 17.1). Permanent markings near the top of the cylinder indicate the Department of Transportation specification number, the type of material used in construction (e.g., steel or aluminum), service pressure in pounds per square inch, serial number, identification of the manufacturer, and testing dates. A five-point star after the last testing date qualifies the cylinder to be retested after 10 years.³

A color-coded label (green for oxygen and blue for N₂O) on the wall of the cylinder indicates the gas contents, warns of potential hazards (e.g., oxidizing agent), and names the manufacturer or distributor (Fig. 17.12). A single word appears on the label: *Danger* means an immediate threat to health or property if gas is released, *warning* indicates a less than immediate threat, and *caution* means no immediate hazard to health or property. A diamond-shaped area on the label indicates the hazard class of

Fig. 17.12. Small (E) cylinders of oxygen and nitrous oxide, with labels and warnings. The diamond-shaped figure on each cylinder's label indicates the hazard class of the contents (yellow for oxygen, an oxidizer; and green for nitrous oxide, a nonflammable gas).

Table 17.1. Characteristics of medical gas cylinders³

Size	Gas	Gas Symbol	Color Code (U.S.)	Capacity and Pressure (at 70°F)	Empty Cylinder Weight (pounds)
E	Oxygen	O ₂	Green	660 L 1900 psi	14
E	Nitrous oxide	N ₂ O	Blue	1590 L 745 psi	14

psi, pounds per square inch.

the gas by words (oxidizer, nonflammable, or flammable) and color code (yellow, green, and red, respectively).³ Distributors often attach a color-coded tag to the valve body, identifying a cylinder's contents. Tags incorporate sequential perforated tabs imprinted with the terms *full*, *in use*, and *empty* to track the use of the cylinder.

Extensive descriptions of the appropriate handling, storage, and use of compressed gas cylinders have been published.^{2-4,8,11} Briefly, cylinders should not be stored near flammable materials and should be properly secured at all times, even during transport. Cylinders should be stored in a cool, dry, clean, well-ventilated room that is constructed of fire-resistant materials.³ Before using a cylinder, the contents should be clearly identified from the label. The valve port should be pointed away from the operator, opened briefly to clear possible debris, and then closed before connection to a hanger yoke, regulator, or manifold. A sealing washer should be placed between a small cylinder valve and the hanger yoke. The valve should be opened slowly to pressurize the regulator and then opened fully.^{2,3} Defective cylinders should not be used.

Pressure Gauges

Each compressed gas supplied to an anesthesia machine should have a corresponding pressure gauge (Fig. 17.13)¹⁻³ that is attached to the regulators for large cylinders and to manifolds for banks of cylinders. The gauge indicates pressure on the cylinder side of the regulator. Gauges are identified by the gas's chemical symbol or name and are usually color coded. The scale is graduated to indicate the units of measure in kilopascals (kPa) and pounds per square inch.¹ Bourdon tube-type gauges are typical for anesthesia machines.¹² Earlier standards for anesthesia machines required that the gauge's full-scale reading should be at least one-third greater than the maximum cylinder pressure, and that, on a given anesthesia machine, all gauges should displace a similar arc from the lowest to highest readings.² Pressure gauges are also incorporated into pipeline distribution systems at various locations. In addition, pressure gauges may be used on anesthesia machines to report pipeline pressure.^{1,3} Pressure gauges do not accurately report the quantitative contents of a cylinder containing liquid gas.¹

Regulators

An anesthesia machine should have a regulator for each medical gas supplied to the machine (Fig. 17.14).¹ The pressure in a gas cylinder varies with its content and temperature, and the pressure in a full cylinder is relatively high (e.g., 2000 psi in an oxygen cylinder). A regulator reduces the high and variable storage pressure to a lower and more constant pressure that is appropriate for the anesthesia machine.⁶ By reducing and controlling pressure as gas exits a cylinder, a regulator maintains constant flow to the flowmeter, even though the pressure in the cylinder decreases as the contents are depleted.

Although regulators on newer anesthesia machines designed for human patients may be quite sophisticated, a simple regulator has a high-pressure chamber separated by a valve port from a low-pressure chamber (Fig. 17.15).¹² Movement of a flexible di-

Fig. 17.13. Pressure gauges for oxygen (1900 psi) and nitrous oxide (750 psi) on a veterinary anesthesia machine.

Fig. 17.14. Pressure regulator on a Pitman-Moore 970 veterinary anesthesia machine (Pitman-Moore, Washington Crossing, NJ). The triangular shaped regulator for oxygen is shown in-line between the yoke for the oxygen cylinder and the small-diameter oxygen line to the flowmeter. The pressure gauge indicates the pressure in the cylinder, and the pressure downstream from the regulator is reduced to 50 psi by the regulator.

aphragm opens or closes the valve, regulating a variable opening, and consequently the pressure in the low-pressure chamber. Increasing pressure on the low-pressure side tends to close the valve. The amount of pressure required to close the valve depends on a spring opposite the diaphragm. The exact construction varies among regulators, but the function is consistent. Regulators are designed for safety relief (at two to four times the pressure in the low-pressure chamber) in order to protect equipment and personnel.^{3,12}

Regulators produce a safe operating pressure, prevent flowmeter fluctuations as cylinders empty, and decrease the sensitivity of the flowmeter indicator to slight movements of the control knob. The ASTM standard requires that regulators on anesthesia ma-

Fig. 17.15. A simple pressure regulator for oxygen that has been separated into its component parts. chines be set so that the pipeline gases are used preferentially.¹ Therefore, regulators may be set at about 45 psi (if a power outlet is present for a ventilator) or at 37 to 42 psi (without a power outlet), since pipeline pressure is usually 50 psi. Older anesthesia machines that have regulators set at 50 psi and open E cylinders located on the machine can allow E cylinder gas flow rather than pipeline gas flow when a pipeline check valve is not present, possibly depleting gases from the cylinder that should be saved for emergency situations (e.g., pipeline failure). Contemporary anesthesia machines designed for human patients have additional regulators (second stage) that deliver gases to the flowmeters at much lower pressures (e.g., 12 to 16 psi) to increase the constancy of the flowmeter.^{3,6}

Flowmeters

Flowmeters for medical gases are positioned downstream from the regulators for each corresponding gas, and the portion of the flowmeter that is downstream from the flow-control valve is part of the low-pressure system of an anesthesia machine. A flowmeter measures and indicates the rate of flow of gas,³ and enables precise control of oxygen or N₂O delivery to an out-of-system vaporizer and to the common gas outlet.

Gas moves through the flow-control valve to enter the bottom of the glass tube (i.e., Thorpe tube) of the flowmeter assembly. The gas then courses around a movable indicator (float) in the annular space between the indicator and the wall of the tube, and exits at the top of the tube (Fig. 17.16). The tube is larger at the top than at the bottom, and a greater volume of gas moves around the indicator as it rises.² The scale associated with the tube indicates rate of gas flow in milliliters per minute (mL/min) or in liters per minute (L/min). Some flowmeters, especially those on older anesthesia machines, have double tapers (Fig. 17.16). A slight taper in the lower part of the tube promotes accuracy at low flows (mL/min), and a greater taper at the top allows higher flow

Fig. 17.16. Flowmeter diagram illustrating gas flow from bottom to top through flowmeters with single and double tapers. As the indicator (*black dot*) rises, flow increases because orifice size increases. The double taper tube allows increased accuracy at the lower end of the tube while accurately metering higher flow rates at the top. From Hartsfield.⁵

rates (L/min). The current machine standard requires that the scale be on the glass tube itself or be located to the right of the tube (viewed from the front of the anesthesia machine).¹ The scale may be on the left in older anesthesia machines, and the operator should assure the proper adjustment of flowmeter control knobs when older equipment is used.³

Flowmeters are calibrated at 760 mm Hg and 20°C, and accuracy may change under other conditions.³ Generally, the effects of temperature on flowmeter function are minimal, but changes in barometric pressure may be significant, producing a higher flow than indicated at lower barometric pressure (altitude) and a lower flow at high pressure (i.e., in a hyperbaric chamber).³ Since a flowmeter (tube, indicator, and scale) is calibrated as a unit, parts from different flowmeters should not be interchanged. If a flowmeter fails, the glass tube, indicator, and scale should be replaced as a unit. The lowest mark on the scale is the first accurate setting, and extrapolation to lower flow rates is unreliable.² A flowmeter's indicator should be read at the top (Fig. 17.17), except for a ball-type float, which is read at the center (Fig. 17.18). The point of reference for reading the indicator should be shown on the flowmeter assembly.¹ Flowmeters should be used in the position on the machine as originally designed (e.g., vertical on newer machines or slanted in some older machines).

The flow-control knob for oxygen on contemporary anesthesia machines should be as large or larger than other flow-control knobs, it should have a fluted profile (Figs. 17.17 and 17.18) as dictated by the ASTM standard, and it should project beyond the control knobs for other gases.¹ This enables the operator to “feel” which gas is being adjusted (“touch coded”).² A control knob is labeled with the gas symbol and is color coded (Figs. 17.17 and 17.18). Good flow controls have fine threads for accuracy and stops to prevent over tightening and damage to flow-control valves.

The size of the flowmeter's indicator in relation to the scale influences accuracy. Float indicators may be longer than 1 cm, and

Fig. 17.17. Oxygen and nitrous oxide flowmeters on a Vetaflex 5 veterinary anesthesia machine (Pitman-Moore, Washington Crossing, NJ). The oxygen flowmeter is located to the right in the cluster, and the indicator should be read at its top (1.5 L/min). The indicator is relatively long compared with the calibrations on the scale. Erroneously reading the bottom of the indicator would result in a flow of oxygen that was 600 mL/min lower than intended. The O₂ flow-control knob is fluted and color coded.

reading the scale at the wrong location may affect the flow rate significantly (Fig. 17.17). Errors in reading the flowmeters for flowmeter-controlled vaporizers such as Copper Kettles and Verni-Trols may dangerously alter the inspired concentration of anesthetic. Dirt, static electricity, or a damaged float may impair movement and cause erroneous readings. The indicator should move freely in the glass tube, and a sluggish or sticking float indicates that it should be cleaned or replaced. A sticking float, which indicated oxygen flow when the oxygen cylinder was empty, has been reported as a cause of hypoxia.^{2,13} Flowmeters should be off when not in use so as to prevent the sudden application of pressure to the glass tube and indicator when a gas cylinder valve is opened. Sudden high pressure may force the indicator upward, damaging the indicator or the stop. The indicator may jam at the top of the tube, where it may go unnoticed.²

Fig. 17.18. Flowmeters for oxygen and nitrous oxide on a Drager anesthesia machine (North American Drager, Telford, PA). The oxygen flowmeter is located to the right of the nitrous oxide flowmeter, and the ball-type indicator should be read in the center (1 L/min). The flow-control knob for oxygen is fluted and color coded and is larger than the flowmeter for nitrous oxide.

The standard for modern anesthesia machines requires the presence of only one flow-adjustment control for each gas delivered to the common gas outlet.¹ Ideally, when there are two flowmeters for one gas, they should be connected in series and controlled by a single flow-control knob.³ Some veterinary anesthesia machines (Fig. 17.19) and older machines for human and veterinary patients may have multiple flow controls for multiple flowmeters with different scales in a parallel arrangement, and the operator should assure proper settings with both control knobs. Similarly, the sequence of flowmeters is important with multiple gases on a single anesthesia machine. The machine standard requires that oxygen be delivered downstream of other gases when all gases use a common manifold.¹ If oxygen enters the manifold upstream from the other gases, the possibility exists for delivering hypoxic mixtures, which is a complication that has

Fig. 17.19. Double oxygen flowmeters on a Matrix Spartan V.M.C. veterinary anesthesia machine (Matrix, Orchard Park, NY). One flowmeter (*left*) is graduated from 0 to 1000 mL/min, whereas the other is graduated from 0.2 to 4.0 L/min. The intent is to increase accuracy at lower flow rates. Two flow-control knobs in parallel offer an opportunity for setting an incorrect flow of oxygen. With two flowmeters in parallel, the total flow is the sum of the flow rates set from each flowmeter.

been reported several times.² The U.S. and Canadian standard locates the oxygen flowmeter to the right in a cluster of flowmeters as viewed from the front of the anesthesia machine. If a specific flowmeter for a vaporizer is required, it should be to the right of the cluster, at least 10 cm from the oxygen flowmeter,² although flowmeter-controlled vaporizers are no longer covered in the ASTM standard.¹ For flowmeter-controlled vaporizers, this arrangement standardizes the location of control knobs and decreases the likelihood of adjusting the incorrect flowmeter. Standardization of location of the flowmeters for oxygen delivery and for vaporizers along with requiring touch-coded flow-control knobs for oxygen flowmeters are intended to reduce errors in oxygen flow rates. Locating the oxygen flowmeter to the right in a cluster of flowmeters is a North American standard, and the location may vary on older machines and in machines manufactured in other countries.³ Other arrangements of flowmeters may exist in older anesthesia machines (e.g., oxygen flowmeter located to the left, to the right, or in the center in a cluster). The danger of delivering hypoxic mixtures by adjusting the wrong control knob when using both N₂O and oxygen must be guarded against.

The arrangement of flowmeters on older models of Drager anesthesia machines allowed delivery of hypoxic mixtures if both oxygen and N₂O were used and a leak developed at the base of the oxygen flowmeter (Fig. 17.20). This malfunction caused the death of a horse.¹⁴ Similarly, cyanosis and light anesthesia were produced shortly after intubation and attachment of a dog

Fig. 17.20. Flowmeters for oxygen (*left*) and nitrous oxide (*right*) on a Drager Narkovet Stand Model anesthesia machine (North American Drager, Telford, PA) for small animals. A leak at the seal created by the nut below the flowmeter could result in delivery of a low or hypoxic concentration of oxygen to the breathing system.

to an anesthesia machine;¹⁵ evaluation of the oxygen flowmeter revealed a leak at its base caused by a faulty seal with a folded washer. Because of this flowmeter's design, the indicator showed a correctly adjusted flow rate for oxygen, although total gas flow to the vaporizer and breathing system was very low. Leaks associated with flowmeters can occur at several locations, including cracks in the glass tube, as well as problems with O-rings and gaskets.⁶ Leaks in the flowmeter should be detected by leak tests performed on the low-pressure area of an anesthesia machine.¹⁶

Flowmeters should be adjusted to assure an adequate total volume and an appropriate concentration of each medical gas. Flow rates should meet or exceed the patient's oxygen consumption and deliver an adequate inspired-oxygen concentration (usually a fraction of inspired oxygen [F_IO₂] ≥ 0.3). Delivery of an appropriate concentration of oxygen, as well as an adequate quantity of oxygen, is essential for saturating hemoglobin and for supplying the patient's metabolic needs. Accuracy becomes especially important with the administration of N₂O and with closed and low-flow breathing systems. The accuracy of flowmeters signifi-

cantly decreases with flows lower than 1 L/min.² With low-flow systems, scrutiny of $F_{I}O_2$ becomes important; continuous monitoring of oxygen concentration on the inspiratory limb of the breathing system has been recommended. Indeed, to meet the ASTM standard, an oxygen analyzer is a required component of the anesthesia machine.^{1,6}

Safety Devices for Oxygen Pressure and Flow

Anesthesia machines may be designed to alert the operator to a dangerously low pressure of oxygen flow.^{3,4} When the oxygen pressure reaches a certain value, the machine may alert the user with an alarm, or the machine may be engineered to cut off the supply of all other gases (e.g., N_2O) to prevent the delivery of hypoxic mixtures. In addition, some anesthesia machines incorporate proportioning devices to assure that oxygen is flowing at some preset minimum portion of the total fresh gas flow. Dupaco anesthesia machines were once popular in veterinary anesthesia and incorporated an audible alarm if the pressure of oxygen became dangerously low. The Metomatic veterinary anesthesia machine reduces the flow of other gases (i.e., flow through the Verni-Trol) if oxygen flow is reduced. These safety mechanisms may malfunction, and continuously monitoring gases on the inspiratory limb of the breathing system is a more reliable way to assure the delivery of an adequate concentration of oxygen.

Flush Valves

Oxygen is supplied at approximately 50 psi to the flush valve of an anesthesia machine. The flush valve delivers a high, but unmeasured, flow (35 to 75 L/min is the ASTM standard)¹ of oxygen to the common gas outlet or directly to the breathing system in some simple veterinary machines (e.g., Matrx small animal anesthesia machine). The contemporary machine standard does not allow piping of oxygen from the flush valve through the vaporizer. However, older anesthesia machines, especially those with precision vaporizers added after the machine was manufactured, may increase oxygen flow through the vaporizer, with the potential for increased output of anesthetic.⁶

At a flow rate of 50 L/min, oxygen from the flush valve can quickly fill the breathing system. In general, pediatric breathing systems (i.e., pediatric circles, Mapleson systems, or valved non-breathing systems) should not be filled via the flush valve because of the danger of overpressurizing a patient's respiratory system. Current machine standards require that the actuating device for the flush valve be recessed to prevent inadvertent activation and delivery of a high volume of gas to the breathing system (Fig. 17.21).¹ Other problems involving the flush valve include leaks in the flush-valve assembly and sticking of the flush valve in the on position.³ A leak at the flush valve reportedly resulted in loss of anesthetic and oxygen at flow rates of less than 1 L/min, making it impossible to maintain surgical anesthesia with the typical fresh gas flow rates used with a semiclosed circle breathing system.¹⁷

Vaporizers

Except for N_2O , modern inhalant anesthetics are delivered with vaporizers. Concentration-calibrated, variable-bypass vaporizers,

Fig. 17.21. Flush valve and common gas outlet on a veterinary anesthesia machine. The flush valve (labeled on the machine) is protected from inadvertent activation by a circular stainless-steel guard. The common gas outlet (open hole) received a connector to link the anesthesia machine through a rubber hose to the fresh gas inlet of the breathing system.

which are temperature, flow, and back-pressure compensated, are standard in human anesthesia and are recommended for delivery of volatile inhalant anesthetics to veterinary patients. However, nonprecision, uncompensated vaporizers (e.g., Stephens vaporizer) have also been marketed to veterinarians as a part of a complete anesthesia machine. In addition, an older vaporizer designed for less volatile inhalant anesthetics (Ohio #8 glass bottle), when modified by removal of the wick, has been evaluated for the delivery of halothane or isoflurane to veterinary patients.^{18,19} Administering highly volatile, highly potent inhalant anesthetics with nonprecision, uncompensated vaporizers is associated with a high degree of risk unless instrumental monitoring (e.g., of inspired or expired anesthetic concentration) is available.

A vaporizer is designed to change a liquid anesthetic into its vapor and to add a specific amount of vapor to the gases being delivered to a patient.² Carrier gas, oxygen alone or with N_2O , passes through the vaporizer to acquire anesthetic vapor. Because the saturated vapor pressures of most inhalant anesthetics are significantly greater than the partial pressures required for clinical anesthesia (i.e., significantly greater than the minimum alveolar concentration [MAC]), a vaporizer should deliver a concentration that is close to the setting on the vaporizer control dial. Otherwise, the inspired concentration of anesthetic should be monitored. In general, the design of precision vaporizers allows dilution of a high concentration of anesthetic vapor from the vaporization chamber to a clinically usable and safe concentration.

Physics of Vaporizer Design and Function

Several principles of physics are involved in the function of a vaporizer for inhalant anesthetics.²⁻⁴ Heat is required for vaporization of liquid anesthetics; the *latent heat of vaporization* is de-

defined as the number of calories required to change 1 g of liquid into its vapor. This heat requirement causes liquid anesthetic to cool during vaporization. The vapor pressure of an anesthetic is the partial pressure of the anesthetic gas above the liquid at equilibrium, and vapor pressure varies directly with temperature. Thus, uncontrolled cooling limits a vaporizer's maximum output. A vaporizer made of a substance (e.g., copper) with a high *specific heat* (the quantity of heat required to raise the temperature of 1 g of the substance 1°C) supplies heat to the liquid anesthetic during vaporization, retarding the cooling process. If a vaporizer is constructed of a material with a high *thermal conductivity* (the rate at which heat flows through a substance), such as copper, heat flows from warmer ambient air into the vaporizer to impede cooling. Materials including copper and bronze are used in the construction of vaporizers because of favorable values of these metals for specific heat and thermal conductivity. More recently, stainless steel has been used in the construction of vaporizers.⁴ The output of concentration-calibrated vaporizers is generally expressed as volume percent of anesthetic vapor in the gases exiting the vaporizer. This relative value changes with variation in barometric pressure.

Compensatory Mechanisms for Vaporizers

The conditions of use affect the performance of vaporizers and must be stated in the operation manual for a concentration-calibrated vaporizer to meet the ASTM standard.¹ The effects of changes in carrier-gas flow, temperature, ambient pressure, and back-pressure should be delineated. Vaporizers compensate in various ways for changes in flow, temperature, and pressure.²⁻⁴

Compensation for variations in temperature of the liquid anesthetic during vaporization can be accomplished by several mechanisms. As previously mentioned, copper and bronze materials with high specific heat and thermal conductivity values supply and conduct heat efficiently to the liquid anesthetic to promote a relatively constant temperature. This "heat sink" mechanism attenuates changes in temperature, producing a degree of thermostability. Bimetallic strip valves in Tec vaporizers, a gas-filled bellows linked to a valve in the bypass gas flow in Ohio calibrated vaporizers, and an expansion member (silicone cone) in Vapor/vaporizers that expand(s) and contract(s) with temperature changes, alter(s) carrier-gas flow through the vaporization chamber and controlling anesthetic output.⁴ Manual adjustments in carrier-gas flow are required to compensate for temperature variations in measured-flow vaporizers (e.g., Verni-Trol vaporizer) and older Vapor vaporizers. Other vaporizers are electrically heated, and the mechanism for control of the temperature of the anesthetic is supplied heat (e.g., Verni-Trol vaporizer on the Ohio DM 5000 anesthesia machine). The Tec 6 vaporizer for desflurane is electrically heated and thermostatically controlled at 39°C.¹⁶

Differences in carrier-gas flow rates alter the output of uncompensated vaporizers. Modern flow-compensated vaporizers produce relatively accurate anesthetic concentrations over an approximate range of 250 mL/min to 15 L/min.⁶ The *splitting ratio* (ratio of the bypass to the gas passing through the vaporization

chamber) determines the output of vapor,⁴ and the resistance to flow through each of the two channels in the vaporizer allows the splitting ratio to be maintained at various rates of flow.³ Below 250 mL/min and above 15 L/min, the output from most concentration-calibrated vaporizers is variable, and performance data outside that range may not be available. Output from older variable-bypass vaporizers (e.g., Fluotec Mark 2) may vary significantly from the setting on the control dial at flow rates less than 4 L/min. Measured-flow (flowmeter controlled) vaporizers (e.g., Copper Kettle) require adjustments in the flow of oxygen to the vaporization chamber when the total flow of gas is changed.

Vaporizer output may vary with the composition of the carrier gas; the output of anesthetic with oxygen as the carrier gas may differ from the output with a combination of oxygen and N₂O as the carrier gas.^{2,4} The magnitude of effect is variable, depending on the specific vaporizer. With N₂O, newer vaporizers initially deliver concentrations that are less than the control-dial setting. With the Fluotec Mark 3, N₂O has little effect on output. However, N₂O as the carrier gas in the Fluotec Mark 2 increases the output of halothane.²

Back-pressure compensation is a design feature of modern vaporizers. Intermittent pressure transmitted to a vaporizer during activation of the flush valve and during application of positive-pressure ventilation may increase vaporizer output compared with output of anesthetic during free flow of gases through the vaporizer.⁶ Newer vaporizers prevent or minimize this "pumping effect" by use of small vaporization chambers (e.g., Tec), long spiral tubes at the inlet to the vaporization chamber (e.g., Vapor), pressure-check valves just downstream from the vaporizer, and relief valves at the vaporizer outlet.^{2,3,6}

Effects of Barometric Pressure on Vaporizer Function

Variations in barometric pressure (e.g., high altitude or hyperbaric chambers) alter vaporizer output expressed in volume percent. A specific partial pressure of inhalant anesthetic (e.g., 1 MAC) represents the same anesthetic potency (partial pressure) at various barometric pressures.²⁰ However, anesthetic concentration is expressed as volume percent on most vaporizers, and MAC expressed as volume percent increases as barometric pressure decreases. Changing the barometric pressure also alters the viscosity and density of gases flowing through vaporizers and flowmeters and affects the output concentration.²⁰ The ASTM standard states that the effects of barometric pressure on the performance of a vaporizer must be described in catalogs and operation manuals.^{1,3}

With decreasing barometric pressure, most concentration-calibrated vaporizers (e.g., Fluotec Mark 3) are considered "self-compensating" and deliver about the same partial pressure, but an increasing volume percent of anesthetic.^{3,20} Basically, the vaporizer can be set normally in volume percent even though the volume-percent setting on the control dial is inaccurate.²⁰ In theory, a halothane vaporizer at an ambient pressure of 500 mm Hg should deliver twice the concentration on the control dial in volume percent and approximately 1.3 times the dialed concentra-

tion in terms of MAC or potency.⁴ Since variations in resistance of flow through the vaporizer at differing ambient pressures cause small changes in concentration output,³ the best approach is to measure partial pressure of anesthetic in inspired or expired gases when working at atypical barometric pressures.

With measured-flow vaporizers (e.g., Copper Kettle), changes in barometric pressure affect both partial pressure and volume percent of the delivered anesthetic.²⁰ If barometric pressure is low, the output expressed as volume percent and as partial pressure increases. When the barometric pressure is high, measured-flow vaporizers deliver a lower anesthetic concentration, expressed as either volume percent or partial pressure. Temperature, barometric pressure, and vapor pressure of the anesthetic all affect the final anesthetic concentration, but the greatest effects are on anesthetics with low boiling points and with vapor pressures that are near the barometric pressure.^{3,20}

Changes in barometric pressure also affect the function of flowmeters. Actual flow increases, becoming higher than the indicator and scale of the flowmeter show, as barometric pressure decreases.²⁰ In contrast, a flowmeter will deliver less flow than indicated when ambient pressure is higher than the barometric pressure at which the flowmeter was calibrated.³

Potential Problems with Vaporizers

The arrangement of vaporizers on anesthesia machines and how vaporizers are maintained affect their safety under clinical conditions. Filling errors, improper transport, using vaporizers in series, and improperly connecting a vaporizer to a machine may cause significant variations in output.

Veterinary practices often stock more than one inhalant anesthetic, and a vaporizer may be inadvertently filled with the wrong drug, especially if the vaporizer has a screw-cap filler port in contrast to a keyed filler port. Keyed filler systems are designed to prevent the introduction of the wrong anesthetic into a vaporizer (Fig. 17.22). However, they are more inconvenient, and screw-cap filler ports and a simple bottle adapter will decrease spillage (Fig. 17.23). Admittedly, there is an increased chance for incorrect filling of vaporizers (Fig 17.24). If an agent-specific vaporizer for a drug with a lower vapor pressure (e.g., methoxyflurane) is filled with a potent, highly volatile anesthetic, dangerously high concentrations may be produced. If this occurs, the vaporizer should be decontaminated before it is used for a patient. The best approach is to have the vaporizer serviced by a qualified vaporizer technician. For Ohio calibrated vaporizers, service is required because the paper wicks must be replaced. For a contaminated Tec vaporizer, an option is to drain the vaporizer, flush it with an oxygen flow of 5 L/min for 45 min or until no trace of a contaminant is present, allow it to stabilize thermally for about 2 h, and refill it with the appropriate anesthetic. Vaporizers contaminated with a nonvolatile contaminant (e.g., water or thymol) should be drained and serviced.⁴

Filler ports and sight glasses are designed to preclude overfilling of modern vaporizers, primarily to prevent liquid anesthetic from entering the fresh gas line of the vaporizer (Fig. 17.25). Recent designs for some vaporizers prevent liquid from entering the fresh gas line even during tipping or inversion. However, tip-

Fig. 17.22. Bottle adapter for halothane vaporizers with keyed filler systems. Such systems reduce the likelihood of introducing an inappropriate anesthetic into an agent-specific vaporizer. The larger end (*left*) of the device attaches to a bottle of halothane, and the opposite end corresponds to the vaporizer filler receptacle. A screw in the receptacle enables a tight seal to be created during the filling process. Bottles of inhalant liquid have a color-coded collar to accept only the correct bottle adapter (see Fig. 17.23).

ping of certain vaporizers may introduce liquid anesthetic into the bypass channel.³ If this occurs, a high concentration of anesthetic vapor may be delivered: Tipping a vaporizer that was not securely attached to an anesthesia machine has reportedly caused a human patient's cardiac arrest.²¹ Also, moving a vaporizer on a mobile anesthesia machine may alter vaporizer output if the machine is tipped or liquid anesthetic is sloshed as the machine is moved over doorway thresholds. Generally, vaporizers should be emptied before transport. Even portable anesthesia machines should be moved with care. If tipping occurs, a high flow of oxygen through the vaporizer for 20 min with the control dial at a low setting has been recommended, but servicing may be required.²

One anesthesia machine may be fitted with multiple vaporizers (Fig. 17.24). Modern anesthesia machines designed for use in human patients are equipped with interlocking mechanisms that do not allow two vaporizers to be on simultaneously.⁶ Few veterinary practices have the luxury of owning anesthesia machines with interlocking vaporizers. In-line, noninterlocked vaporizers offer the possibility of operating two vaporizers concurrently, conceivably producing an excessive depth of anesthesia.² The simultaneous use of more than one vaporizer in series also increases the probability of contaminating a vaporizer with an inappropriate agent. If vaporizers are placed in series, the best order is methoxyflurane, sevoflurane, isoflurane, and halothane from upstream to downstream: This reduces the chance of contamination by taking into account both vapor pressure and po-

Fig. 17.23. Bottle adapter (Southmedic, Beaumont, TX) for filling isoflurane vaporizers with screw-cap filler ports. The isoflurane bottle has a color-coded collar corresponding to the color on the bottle's label and the color of the bottle adapter. This type of bottle adapter is intended to reduce spillage during the filling of vaporizers with screw-cap filler ports.

tency.^{3,4} Anesthesia machines with vaporizers in series should be used carefully if an interlocking mechanism is not in place.

Occasionally, veterinarians will use a freestanding, concentration-calibrated vaporizer that is periodically connected between the common gas outlet and the breathing system or between the outlet of another vaporizer and the breathing system. Also, freestanding vaporizers are commonly used with pump oxygenators for cardiopulmonary bypass procedure.⁴ A freestanding vaporizer offers a greater opportunity for tipping. The flow through the vaporizer might be inadvertently reversed when vaporizer connections are changed periodically, and oxygen may be forced through the vaporizer with the flush valve if the vaporizer is located downstream from the flush valve. All of these situations lead to a significant increase in the output concentration.⁶ Use of a freestanding vaporizer is not the safest approach for access to a second inhalant anesthetic.

In anesthesia machines designed for veterinary use, a concentration-calibrated vaporizer can be connected in reverse, even though the connections are labeled and different sizes. In this configuration, the vaporizer output can potentially be twice that indicated on the control dial.⁶

Classification of Vaporizers

Vaporizers have been classified according to several major characteristics:

1. Method of output regulation
2. Method of vaporization

Fig. 17.24. Filling a vaporizer with a screw-cap filler port. Halothane is about to be poured into an isoflurane vaporizer, illustrating the possibility of filling a vaporizer with a screw-cap filler port with the wrong anesthetic. Tec 3 vaporizers for halothane (Fluotec Mark 3) and isoflurane (Isotec 3) are shown in series. The ideal order would be to reverse these vaporizers with the isoflurane immediately downstream from the flowmeters, followed by the halothane vaporizer (see the text for explanation).

Fig. 17.25. Screw-cap filler system and sight glass for a Fluotec Mark 3 vaporizer. The location of the filler port prevents the operator from filling the vaporizer excessively because liquid will overflow if the maximum level on the sight glass is exceeded significantly. The plastic tubing on the bottom of the filler system facilitates drainage of the vaporizer.

3. Location
4. Mechanism of temperature compensation
5. Agent specificity
6. Resistance

Even though some authors have used only one feature in classifying vaporizers, such schemes are incomplete because of the variations among vaporizers.³ As examples of classification

Table 17.2. Classification characteristics of some vaporizers used in veterinary anesthesia²⁻⁴

Vaporizer	Method of Output Regulation	Method of Vaporization	Location	Temperature Compensated	Resistance	Specificity
Ohio #8	VBP CC-	FO/wick	VIC	No	Low	No
Stephens	VBP CC-	FO/wick	VIC	No	Low	No
Tec 2	VBP CC+ ^a	FO/wick	VOC	Yes	High	Yes
Tec 3	VBP CC+	FO/wick	VOC	Yes	High	Yes
Vapor	VBP CC+	FO/wick	VOC	Yes	High	Yes
Vapor 19.1	VBP CC+	FO/wick	VOC	Yes	High	Yes
Ohio Calibrated	VBP CC+	FO/wick	VOC	Yes	High	Yes
Siemens	NA CC+	Inject	VOC	No	High	Yes
Copper Kettle	MF CC-	Bubble-through	VOC	Yes	High	No
Verni-Trol	MF CC-	Bubble-through	VOC	Yes	High	No

CC+, concentration calibrated; CC-, not concentration calibrated; FO, flow-over; MF, measured flow through the vaporizer; NA, not applicable; VBP, variable bypass; VIC, vaporizer in circuit (i.e., in the breathing system); VOC, vaporizer out of circuit (i.e., out of the system).

^aA Tec 2 vaporizer is concentration calibrated at higher flows of carrier gas, but output varies with low flows.

nomenclature, the characteristics of several vaporizers are summarized in Table 17.2.

1. Regulation of Output

Anesthetic output is regulated in volume percent by variable-bypass or measured-flow mechanisms.^{3,4} With variable-bypass vaporizers, all fresh gas flows into the vaporizer, part being directed through and part bypassing the vaporization chamber. The gases rejoin before exiting the vaporizer, establishing the anesthetic concentration dialed with the control knob. The standard for these vaporizers is for the control dial to be turned on in a counterclockwise direction.¹ Concentration-calibrated variable-bypass vaporizers are quite accurate (e.g., Tec's), but uncalibrated variable-bypass vaporizers (e.g., Ohio #8) are inaccurate.

Measured-flow (flowmeter controlled) vaporizers are considered non-concentration-calibrated.⁴ They route a small flow of carrier gas (i.e., oxygen) through the vaporizer, and this gas becomes fully saturated with anesthetic. A second source of gas (i.e., oxygen and possibly N₂O) that never enters the vaporizer dilutes the saturated gas to the desired concentration. Calculations are necessary to determine the concentration of anesthetic that is delivered to the common gas outlet and breathing system.

2. Method of Vaporization

The method of vaporization can be flow-over, bubble-through, or injection.²⁻⁴ *Flow-over* vaporizers direct carrier gas over the surface of the liquid anesthetic. The surface area may be increased with wicks to improve the efficiency of vaporization (Figs. 17.26 and 17.27). The Stephens vaporizer can be used with or without a wick, depending on the anesthetic and the decision of the anesthetist.²² The *bubble-through* method of vaporization delivers carrier gas below the surface of the liquid through a diffuser (a sintered bronze disk in the Copper Kettle) that disperses bubbles of carrier gas through the liquid anesthetic to increase the liquid-gas interface.⁴ Efficiency of vaporization increases with smaller

Fig. 17.26. Ohio calibrated vaporizer with paper wicks and copper spacers. The wicks function to increase the surface area for vaporization of inhaled anesthetic.

bubbles, deeper bubble dispersion, and slower carrier-gas flow.² *Injection* vaporizers deliver a known amount of liquid anesthetic or pure vapor into a known volume of gas to deliver an accurate concentration.³

3. Vaporizer Location

In relation to the breathing system, a vaporizer may be located either out of the system (vaporizer out of circuit [VOC]) (Fig. 17.28) or in the system (vaporizer in circuit [VIC]) (Fig. 17.29).² High-resistance vaporizers are used as VOC units, and low-resistance vaporizers are necessary for VIC use (because the patient must inspire through the vaporizer). Traditionally, highly potent, highly volatile anesthetics have been administered with VOC vaporizers. However, some VIC vaporizers have been used for delivery of isoflurane and halothane. VIC-type vaporizers have been characterized as being unpredictable in output.^{3,23}

Fig. 17.27. Fluotec Mark 3 vaporizer with cloth wicks. The wicks function to increase the surface area for vaporization of inhalant anesthetic. From Hartsfield.⁵

4. Temperature Compensation

As discussed previously, heat is required to vaporize liquid anesthetics. To prevent or compensate for cooling that alters the rate of vaporization of the liquid anesthetic, heat must be supplied to maintain the temperature of the liquid anesthetic, or the flow of

carrier gas through the vaporizer must be adjusted to account for the changing rate of vaporization. Heat may be supplied from the vaporizer itself if it is made of a material with high specific heat and high thermal conductivity (thermostability).⁴ Electric heaters and warm-water jackets were used to supply heat for older vaporizers, and an electric heating device has been incorporated into newer vaporizers (e.g., the Tec 6) designed for desflurane.¹⁶ In other vaporizers, alternative thermostatic mechanisms (e.g., a change in carrier gas flow through the vaporization chamber) have been used to counterbalance changes in temperature and vaporization. Manual adjustments of flow through the vaporization chamber are made to offset variations in temperature that occur with measured-flow vaporizers.

5. Agent Specificity

Vaporizers can be either *agent specific* (designed for a particular inhalant anesthetic) or *multipurpose* (used with any volatile liquid anesthetic).² A vaporizer that is designed and used for multiple agents should be clearly labeled with the name of the agent currently in the vaporizer. If the anesthetic is changed, the vaporizer should be cleared of the original anesthetic before another anesthetic is introduced into the vaporizer, and draining alone may not eliminate all of the original anesthetic.³ The trend for vaporizer type has been toward agent-specific, concentration-calibrated vaporizers.

Fig. 17.28. Diagram of a vaporizer located outside the breathing system (vaporizer out of circuit [VOC]) and its relationship to the other basic components of the anesthesia machine and circle system. From Hartsfield.⁵

Fig. 17.29. Diagram of the vaporizer located inside the breathing system (vaporizer in circuit [VIC]) and its relationship to other basic components of the anesthesia machine and circle system. From Hartsfield.⁵

6. Resistance

Vaporizers have been classified according to resistance to flow.³ Plenum-type vaporizers are high-resistance vaporizers designed for location outside of the breathing system, and high resistance is characteristic of contemporary concentration-calibrated, variable-bypass vaporizers. Low-resistance vaporizers are those designed for incorporation into the breathing system³ and include the Ohio #8 and the Stephens vaporizers.

In-circuit Vaporizers (VICs)

Nonprecision, draw-over, VIC vaporizers were commonly used in veterinary anesthesia for many years. Until the introduction of halothane into veterinary anesthesia, perhaps the most widely used vaporizer for veterinary patients in the United States was the Ohio #8 glass bottle. Although it is no longer manufactured, it was the basic vaporizer on many veterinary anesthesia machines (Pitman-Moore models 960 and 970) sold in the 1970s for administration of methoxyflurane. In the 1990s, the Stephens vaporizer was also marketed for use in veterinary patients. Nevertheless, for safety reasons, VIC vaporizers have generally been recommended for use only with anesthetics of low potency (e.g., ether) or low vapor pressure (e.g., methoxyflurane). In human patients, the Ohio #8 glass bottle was used mostly for administration of diethyl ether and, to a lesser extent, methoxyflurane. The use of halothane and isoflurane in nonprecision vaporizers located within the circuit has been described specifically when used with low-flow or closed breathing systems.²⁴

With VIC vaporizers, the inspired anesthetic concentration varies with a patient's respiratory minute volume, use of positive-pressure ventilation, changes in carrier-gas flow rate, and variations in temperature. At a given vaporizer setting, increased spontaneous ventilation, positive-pressure ventilation, and lower fresh gas flows increase the inspired anesthetic concentration. As has been stated specifically for the Ohio #8 vaporizer, "The delivered concentration is unknown and changes unpredictably with use."²³ Without instrumental monitoring of the inspired or expired anesthetic concentration, the anesthetist is completely dependent on the response of the patient to determine appropriate settings for the vaporizer. This is often referred to as *qualitative anesthesia* in contrast to *quantitative anesthesia*, where a known concentration of inhalant (with knowledge of its potency [i.e., MAC value]) is continually delivered to a patient.

Ohio #8 Glass-Bottle Vaporizer

The Ohio #8 vaporizer is classified as variable bypass, flow-over with wick, non-temperature-compensated, VIC, low resistance, and multipurpose.² It is designed very simply: The vaporization chamber is made of glass, and a cloth wick creates a large surface area for vaporization (Fig. 17.30). The vaporizer is not calibrated; thus, it is considered nonprecision. The vaporizer has no method of controlling the temperature of the liquid. Its low resistance allows it to be situated in the breathing system (VIC), usually on the inspiratory side of the circle. If positioned on the expiratory limb, the vaporization chamber may become contaminated with water condensing from expired gases. The control

Fig. 17.30. Partially disassembled Ohio #8 glass bottle vaporizer. The cloth wick (left) functions to increase the surface area for vaporization of the anesthetic.

arm of the lever is adjustable from zero, corresponding to no gas flow through the vaporization chamber, to 10, corresponding to total inspiratory flow through the vaporization chamber (Fig. 17.31). The possibility of diverting all gas flow through the vaporization chamber makes the use of highly volatile anesthetics particularly dangerous, especially if the wick is in place. The concentration delivered is unknown and may change unpredictably. The function of this vaporizer is probably best summarized by the following statement: "Because of the variability associated with an in-system vaporizer, it is not possible to give performance data."² The Ohio #8 vaporizer is no longer being manufactured, and finding expertise and parts for repairing it may be difficult.

The Ohio #8 vaporizer, modified by the removal of the wick, has been proposed as an inexpensive alternative for administration of isoflurane¹⁸ and halothane.¹⁹ Use of an Ohio #8 vaporizer for administration of halothane or isoflurane with the wick in place is dangerous owing to the high concentration of anesthetic that may be delivered in the inspired gases, especially if all carrier gases are diverted through the vaporization chamber. Even with the wick removed, recommendations for using the Ohio #8 vaporizer for isoflurane include familiarity with guidelines for its use and understanding of its limitations.¹⁸ The Ohio #8 vaporizer

Fig. 17.31. Control lever for the Ohio #8 jar vaporizer set at position 2. The numbered positions (0 to 10) on the vaporizer correspond to increasing flow of carrier gas through the vaporization chamber. At the closed position (0), all gas entering the vaporizer should bypass the vaporization chamber, and, at full open (10), all gas entering the vaporizer should move through the vaporization chamber.

Fig. 17.32. Underside of the head of an Ohio #8 vaporizer showing valves and seats through which gases enter and leave the vaporization chamber. The integrity of these valves in the off position may be lost because of wear or corrosion leading to carrier-gas flow through the vaporization chamber, even when the control lever is in the zero or off position.

also has potential for leaking anesthetic into the breathing system when the control lever is off.² With age, the vaporizer's valves may not seat properly (Fig. 17.32), allowing continuous passage of fresh gases through the vaporization chamber and production of anesthetic-rich gases.

Stephens Vaporizer

The Stephens vaporizer is classified as variable bypass, flow-over, non-temperature-compensated, VIC, low resistance, and multipurpose. It is not a precision vaporizer. The vaporizer's low resistance allows it to be located within the breathing system on the inspiratory side. The vaporization chamber is made of glass

Fig. 17.33. Stephens anesthesia machine and vaporizer (Henry Schein, Port Washington, NY). The glass vaporizer can be set at the off and full-on positions with incremental settings marked in eighths. This vaporizer has been used with methoxyflurane (with a wick in place) and for halothane or isoflurane with the wick removed.

(Fig. 17.33), and a wick is provided for administration of methoxyflurane. The wick should not be used for administration of halothane or isoflurane.²² The vaporizer is not calibrated and has no method for controlling the temperature of the liquid. The control knob is adjustable from the off position to the full-on position in increments of eighths. The off position indicates no flow through the vaporization chamber, and the on position corresponds to complete flow through the vaporization chamber. The Stephens vaporizer is intended for use in a low-flow circle breathing system.²²

Out-of-circuit Vaporizers (VOCs)

Modern concentration-calibrated vaporizers located outside of the breathing circuit are considered precision vaporizers: Any volatile liquid anesthetic can be administered safely with a concentration-calibrated, agent-specific, VOC vaporizer. Several brands of VOC-type vaporizers are common in veterinary anes-

Table 17.3. Approximate output (vol%) from a Fluotec Mark 2 vaporizer at various flow rates and dial settings¹⁵

Dial Setting	1 L/min	2 L/min	3 L/min	4 L/min	6 L/min	8 L/min
0.5%	0	0	0	0.5	0.5	0.5

4.0%	6.5	5.0	4.1	4.0	4.0	4.0

thetia. Many older models of vaporizers, although no longer being manufactured, remain serviceable and may be purchased as used equipment. Newer VOC-type vaporizers are temperature, flow, and back-pressure compensated. The performance of older VOC-type vaporizers varies with changes in temperature, flow, and back-pressure, and performance data should be reviewed before using them. The concentration control dial and the vaporizer output generally are linear over a wide range of flow rates and temperatures in newer VOC-type vaporizers. The following discussion, though not exhaustive, includes information about several out-of-circuit vaporizers commonly used in veterinary anesthesia.

Tec Vaporizers

Tec vaporizers specifically designed for halothane or isoflurane vaporization, particularly the Fluotec Mark 3 and Isotec 3, are commonly used in veterinary anesthesia. They are considered reliable because they are temperature, flow, and back-pressure compensated under normal operating conditions. The Fluotec Mark 3's predecessor, the Fluotec Mark 2, is no longer being manufactured, but may still be available as used equipment. In some veterinary practices, Fluotec Mark 2 vaporizers remain in use. Tec 4, 5, and 6 vaporizers have superseded the Tec 3 vaporizers for use in contemporary human anesthesia machines.^{6,16} Although these vaporizers have not been as commonly used in veterinary anesthesia, various publications and the specific operation manuals offer information about their use and performance.^{3,4,6,16}

Fluotec Mark 2

This vaporizer (Fig. 17.34) is classified as variable bypass, flow-over with wick, VOC, temperature compensated, high resistance, and agent specific.² Temperature compensation is with a bimetallic strip valve at the outlet to the vaporization chamber.³ Performance data show that the Mark 2 becomes imprecise at flow rates below 4 L/min, and inaccuracy increases distinctly below 2 L/min.² At flow rates and dial settings likely to be selected for small veterinary patients, the Mark 2's actual output tends to be lower than control-dial settings of less than 2% and higher than dial settings of 2% or greater (Table 17.3).

At the very low flow rates required for closed and low-flow maintenance techniques, the Mark 2's output may decrease to zero or increase to concentrations much higher than the dial set-

Fig. 17.34. Fluotec Mark 2 vaporizer. The performance characteristics for variations in carrier-gas flow are included on the plastic card attached to the vaporizer (see Fig. 17.35).

tings. Because of its unpredictable output characteristics, the Mark 2 has been categorized as unsuitable and unreliable for use with low fresh gas flow rates.^{2,22,25} Back-pressure (e.g., positive-pressure ventilation) increases the output of the Mark 2 dramatically at flow rates less than 2 L/min.^{2,26} A pressurizing valve was developed for the Mark 2 to minimize the effects of back-pressure,² but it may not be present on all Mark 2 vaporizers. The operator should fully understand the Mark 2's relatively poor performance characteristics before using the vaporizer clinically, and the output diagram for the Mark 2 should be available for consultation during clinical use (Fig. 17.35).

Tec Mark 3 Vaporizers

These vaporizers are classified as variable bypass, flow-over, temperature compensated, agent specific, high resistance, and

Fig. 17.35. Performance diagram for a Fluotec Mark 2 vaporizer. The diagram indicates expected output of halothane in volume percent for specific control-dial settings at specific carrier-gas flow rates.

VOC.^{2,3} This model type includes the Fluotec Mark 3, the Pentec Mark 2, and the Isotec 3 vaporizers (Fig. 17.24). The Tec 3 vaporizer is temperature compensated with a bimetallic, temperature-sensitive element associated with the vaporization chamber. Output from the Tec 3 vaporizer is nearly linear over the range of concentrations and flow rates that would typically be selected for veterinary patients (250 mL/min to 6 L/min). Back-pressure compensation is accomplished in the internal design of the vaporizer with a long tube leading to the vaporization chamber, an expansion area in the tube, and exclusion of wicks from the area of the vaporization chamber near the inlet.²

Vapor Vaporizers: Vapor 19.1 and Vapor

The Vapor 19.1 vaporizer (Fig. 17.36) is classified as variable bypass, flow-over with wick, temperature compensated, high resistance, agent specific, and VOC.^{2,3} Specific vaporizers are available for isoflurane and halothane administration. Temperature compensation is automatic with an “expansion member” that varies the flow of gas through the vaporization chamber with changes in temperature. Pressure compensation is accomplished by the presence of a long spiral inlet tube to the vaporization chamber.⁴ This vaporizer is accurate from 0.3 to 15 L/min of fresh gas flow at the lower settings on the control dial, but complete saturation may not occur at higher settings with higher flows. The vaporizer is designed for operation (temperature compensation) in the range of 10° to 40°C.²

The Vapor vaporizer (Fig. 17.37) preceded the Vapor 19 and 19.1, and has been called “semiautomatic” because manual adjustments are required for complete temperature compensation (Fig. 17.38).⁵ The unit is no longer being manufactured, but some vaporizers may still be in operation in veterinary practices. The vaporizer was available for both methoxyflurane and halothane administration. It is classified as variable bypass, flow-over with

wick, VOC, temperature compensated by manual flow alteration, high resistance, and agent specific, and is considered to be very accurate.² It was designed for thermostability and is constructed of a large mass of copper as a heat sink to prevent excessive cooling during vaporization.^{2,27} The concentration dial must be manually adjusted to the temperature chamber within the vaporizer and the liquid between 16° and 28°C (Fig. 17.38).²⁸ The unit is flow compensated over a wide range (approximately 250 mL/min to 10 L/min), with some deviation at high concentrations at high flows. The mechanism for back-pressure compensation involves a long coiled tube at the inlet to the vaporization chamber.²

Other Vaporizers

Ohio Calibrated Vaporizer

This vaporizer (Fig. 17.26) has been available for veterinary use and was commonly employed on human anesthesia machines for many years. This vaporizer is classified as variable bypass, flow-

Fig. 17.37. A halothane Vapor vaporizer (North American Drager, Telford, PA).

over with wick, automatically temperature compensated, agent specific, VOC, and high resistance.^{2,3} Specific units are manufactured for isoflurane, halothane, and sevoflurane administration. These vaporizers were designed for accuracy at fresh gas flows between 0.3 to 10 L/min, and temperature compensation occurs between 16° and 32°C. Tilting these vaporizers up to 20° while in use or up to 45° when not in use does not cause problems. Greater tipping of the vaporizer may cause delivery of high concentrations. Between paper wicks, the vaporizer has plastic spacers that may react with enflurane or isoflurane to cause discoloration of the liquid anesthetic, apparently without significant consequences.³

Siemens Vaporizer

This vaporizer is a concentration-calibrated, injection-type, non-thermocompensated, agent-specific, and plenum (high resistance) unit.³ It has not been used extensively in clinical veterinary anesthesia, except in laboratory-animal facilities associated with hospitals for human patients. The vaporizer was designed to couple with a specific Siemens ventilator. The function and evaluation of this vaporizer have been reviewed elsewhere.³

Measured-Flow Vaporizers

Verni-Trols and Copper Kettles (Fig. 17.39) are flowmeter-controlled vaporizers that formerly were popular for use in anesthesia of human patients.²⁻⁴ Copper Kettles were the first devices

Fig. 17.38. Vapor vaporizer with a control-dial setting of 2% at 28°C. The thermometer (*left*) indicates the temperature within the vaporizer (liquid anesthetic). The control dial is used to manually align the curved line corresponding to the desired anesthetic concentration with the temperature of the liquid anesthetic (the vertical line with hash marks) within the vaporizing chamber. From Hartsfield.⁵

to enable precise vaporization of liquid anesthetics.² These flowmeter-controlled vaporizers are classified as measured flow, bubble-through, high resistance, VOC, temperature compensated (thermally stable with manual flow adjustments based on temperature of the liquid anesthetic), and multipurpose. They have been classified as saturation vaporizers. These vaporizers are constructed of copper (Copper Kettle) or silicon bronze (Verni-Trol) for thermostability. Back-pressure compensation mechanisms are present on more recent models and can be fitted on older models (e.g., check valves). These vaporizers are no longer being manufactured and are not covered by the ASTM standard of 1989.⁶ However, they are available on used anesthesia machines and have been purchased for veterinary patient use. Since these vaporizers are multipurpose or universal, they can accurately vaporize halothane, isoflurane, sevoflurane, or methoxyflurane, and should be clearly labeled for the agent in use.

With measured-flow vaporizers, manual adjustments in flow rates are required to account for variations in total gas flow, day-to-day changes in temperature, and changes in liquid temperature during use, especially with high fresh gas flow rates. In most cases, a calculator (Fig. 17.40) is supplied with each vaporizer for determining proper flow rates. Anesthesia machines with measured-flow vaporizers have oxygen flowmeters for two purposes: One flowmeter routes all of its oxygen through the vaporization chamber, where it is fully saturated with anesthetic; the other flowmeter supplies oxygen that bypasses the vaporizer and supplies oxygen to meet the patient's requirements. Both gas sources combine at a mixing valve to achieve the proper anesthetic concentration before gases enter the breathing system.

Since the output of a measured-flow vaporizer is oxygen fully saturated with anesthetic, the concentration of halothane or isoflurane approaches 32%. Dangerously high concentrations of anesthetic can be delivered to the breathing system if flowmeters

Fig. 17.39. Copper Kettle vaporizer (Foregger, Allentown, PA). The vaporization chamber (copper kettle) with its thermometer is behind the table top (*right rear*), and the vaporizer circuit control valve is attached to the left front corner of the tabletop. The flowmeter cluster from *left to right* includes the oxygen flowmeter to the vaporization chamber (black scale), two bypass oxygen flowmeters (green), and one nitrous oxide flowmeter (blue). This cluster does not meet recent standards for the arrangement of flowmeters. From Hartsfield.⁵

are set carelessly or if the diluent flow is not turned on. It is also possible to misread the calculator and set incorrect flows.² Because such high concentrations can be achieved and because errors in adjustment of flowmeters are possible, the use of continuous monitoring of the inspired anesthetic agent concentration has been recommended.⁴

In addition to using a calculator, the output from measured-flow vaporizers can be calculated or estimated. Methods, including formulas, for calculating flow requirements for measured-flow vaporizers have been reviewed.²² As previously stated, the vaporization chamber produces an anesthetic concentration equal to the anesthetic's saturated vapor pressure. Thus, if halothane's vapor pressure is 243 mm Hg at 20°C, approximately 32% halothane is delivered to the mixing valve. This concentration is diluted by bypass gases to an appropriate concentration for the patient.

Fig. 17.40. A circular slide rule for calculation of oxygen flow rates for an anesthetic machine with a measured-flow vaporizer. The rule can be used for several different anesthetics at various total flow rates over a range of temperatures. This circular slide rule shows that 120 mL of oxygen must be supplied to the vaporizer to produce 3% halothane at a total gas flow rate of 2 L/min at a vaporizer temperature of 23°C.

If a patient is to be maintained with a total gas flow of 2 L/min and a halothane concentration of 1.5%, then 30 mL/min of halothane vapor ($1.5\% \times 2000 \text{ mL} = 30 \text{ mL}$) must be delivered to the breathing system along with 1970 mL/min of oxygen. About 64 mL of oxygen must enter the vaporization chamber each minute to produce an output of 30 mL/min of halothane: $30 \text{ mL} = 32\% \cdot X$, where X is the total gas flow exiting the vaporization chamber; thus, $X = 94 \text{ mL}$, and $94 \text{ mL} - 30 \text{ mL} = 64 \text{ mL}$. The bypass oxygen flow must equal $2000 \text{ mL/min} - 94 \text{ mL/min}$ or 1906 mL/min. In all calculations, the total gas flow to the patient must be considered, including oxygen, N_2O , and vaporizer flows, for determination of anesthetic requirements.

Using similar computations for methoxyflurane administration at 20°C (vapor pressure = 23 mm Hg), a maximum vaporizer output of 3% can be predicted. Thus, with 2 L/min of total fresh gas flow to the breathing system and a desired concentration of 1%, 20 mL/min of methoxyflurane ($1\% \times 2000 \text{ mL} = 20 \text{ mL}$) must be delivered to the breathing system. About 647 mL of oxygen must enter the vaporization chamber to deliver 20 mL/min of methoxyflurane vapor to the breathing system: $20 \text{ mL} = 3\% \cdot X$, where X is the total gas flow exiting the vaporization chamber; thus, $X = 667 \text{ mL}$, and $667 \text{ mL} - 20 \text{ mL} = 647 \text{ mL}$. Therefore, 647 mL/min of oxygen must be delivered to the vaporization chamber to produce a total output of 667 mL/min, including 20 mL of methoxyflurane. The bypass flow must then be equal to 1333 mL/min, for a total flow of 2 L/min to the breathing system.

Most of the hazards associated with measured-flow vaporizers relate to incorrect use, including errors in calculation of the out-

put of vapor, failure to turn on the vaporizer flowmeter or the vaporizer circuit control valve, and careless handling of the vaporizer during filling and transport. With tipping, liquid anesthetic may enter the discharge tube of the vaporizer, ultimately delivering very high concentrations of anesthetic to the breathing system. Overfilling is also possible in older models.² Older vaporizers may not be equipped for back-pressure compensation, and application of positive-pressure ventilation may significantly increase the concentration delivered.² An inflowing gas leak at a faulty O-ring on the base of a sidearm Verni-Trol has reportedly caused reduced oxygen concentration and hypoxia in human patients.²⁹ Later models of the same machine incorporated a check valve to prevent loss of fresh gas flow. Finally, flow rates below the lowest mark on the scale for the vaporizer's flowmeter should not be extrapolated.

Some measured-flow vaporizers, including the Verni-Trol on the Ohio DM 5000 anesthesia machine² and the vaporizer on the old Pitman-Moore 980 veterinary anesthesia machine (Fig. 17.41), designed specifically for methoxyflurane,^{22,30} were calibrated for the vaporizer flowmeter to be measured in cubic centimeters (milliliters) per minute of anesthetic vapor rather than in milliliters per minute of oxygen flow to the vaporizer. Consequently, using the flow-rate calculation derived from calculators accompanying Copper Kettles or other Verni-Trol-type machines with these two machines will result in erroneously high delivered concentrations to the anesthetic circuit.^{22,31} Volatile anesthetics other than methoxyflurane should not be used in the Pitman-Moore 980 machine's vaporizer.^{22,30}

Maintenance of Vaporizers

Vaporizers should be conscientiously maintained. In general, the best policy is to follow the manufacturer's guidelines for care and servicing of vaporizers. Recommendations for maintenance vary. Returning a vaporizer to the manufacturer yearly for cleaning and calibration has been suggested.³² One source recommends calibration and testing for leaks every 3 to 6 months.³ Maintenance should be performed on a vaporizer if, based on the responses of patients, the dialed anesthetic concentration is suspected to be erroneous or if any of the components of the vaporizer function improperly (e.g., the control dial is difficult to adjust). Servicing, as recommended by the manufacturer, includes an evaluation of operation, cleaning, changing of filters, replacement of worn parts, and recalibration.² Halothane and methoxyflurane contain preservatives (thymol and butylated hydroxytoluene, respectively) that do not vaporize and thus collect in the vaporization chambers and on the wicks, potentially affecting anesthetic output. Vaporizers should be periodically drained to eliminate these preservatives. Vaporizers should not be overfilled or tipped when filled. Vaporizers should be emptied before removal from the anesthesia machine for service. In the past, flushing a vaporizer with ether to dissolve preservatives that collect in it has been recommended. Owing to the flammability and explosiveness of ether, extreme caution should be exercised. Flushing the vaporizer does not eliminate the need for regular service by a certified vaporizer technician.

Fig. 17.41. Pitman-Moore 980 veterinary anesthesia machine (Pitman-Moore, Washington Crossing, NJ). This machine includes a Verni-Trol vaporizer with the oxygen flowmeter (*left*, white background) to the vaporization chamber calibrated in milliliters per minute of methoxyflurane vapor. From Hartsfield.⁵

Use of the Wrong Anesthetic in an Agent-Specific Vaporizer

Using an agent-specific vaporizer for an anesthetic for which the vaporizer is not calibrated is problematic, especially if the introduction of an anesthetic is unintentional (i.e., the operator does not realize the mistake). A low output of anesthetic is the expected result if an anesthetic with a lower vapor pressure is placed into a vaporizer designed for a drug with a higher vapor pressure. Conversely, a highly volatile anesthetic in an agent-specific vaporizer designed for a drug with a lower vapor pressure is likely to produce a high, potentially lethal concentration. The differential potencies of the drugs in question would be expected to affect the depth of anesthesia in either situation.

During the introduction of isoflurane into veterinary anesthesia, it was commonly administered with agent-specific, halothane vaporizers that were not recalibrated for isoflurane. Because the vapor pressures of halothane and isoflurane are similar, the out-

Fig. 17.42. Common gas outlet on a Drager anesthesia machine. The retaining device designed to prevent an accidental disconnection at the common gas outlet is in the closed down position.

Fig. 17.43. Common gas outlet on a Drager anesthesia machine. The retaining device designed to prevent an accidental disconnection at the common gas outlet is in the open horizontal position.

put was not expected to differ greatly from the control-dial setting. Indeed, halothane vaporizers produce concentrations of isoflurane that are reasonably close to the dial setting for halothane.³³ Nevertheless, current manufacturer recommendations are against the use of isoflurane in halothane-specific vaporizers and vice versa.³ Depending on the vaporizer and conditions of operation, isoflurane in a halothane vaporizer may produce 25% to 50% more vapor than expected, and halothane in an isoflurane-specific vaporizer usually delivers a concentration that is lower than expected.³ If isoflurane is to be used in an agent-specific halothane vaporizer, the vaporizer should be serviced and completely recalibrated for isoflurane. Complete calibration implies that the vaporizer has been tested for accuracy with an anesthetic-gas analyzer at various carrier-gas flows and various temperatures to assure reliable function.

Fig. 17.44. The outlet hose on a Fluotec Mark 3 vaporizer mounted onto a small animal anesthesia machine. The vaporizer outlet connector is attached to a rubber hose that directs anesthetic and carrier gas to the circle system. Alternatively, the rubber hose could be attached to one of the Mapleson systems. A faulty connection to the vaporizer or disconnection of the rubber hose could be responsible for interfering with the delivery of oxygen and anesthetic to the breathing system.

Common Gas Outlet

This outlet is the site from which gases that have passed through the flowmeter, vaporizer (VOC), and flush valve exit the anesthesia machine on the way to the breathing system. Typically, there is a 15-mm internal diameter (ID) opening to which a fitting with rubber tubing attaches (Fig. 17.21). The other end of the tubing connects to the fresh gas inlet of the breathing circuit. In some simple veterinary anesthesia machines with VOC vaporizers, all gases flow directly from the vaporizer outlet to the fresh gas inlet of the breathing system.

Disconnections at the common gas outlet, the vaporizer outlet, or the fresh gas inlet can cause loss of gas flow to the breathing system. The ASTM standard requires that the common gas outlet incorporate a retaining device to prevent accidental disconnection (Figs. 17.42 and 17.43).¹ Disconnects should be detected during the checkout of the machine and breathing system before each case, but disconnects can occur during use of the machine if a retaining mechanism is not present.

A disconnection from the common gas outlet or from the outlet of the vaporizer (Fig. 17.44) during an anesthetic procedure may not be recognized immediately in a spontaneously breathing patient. With a circle system and a VOC, low inspired-oxygen fraction, increased respiratory efforts, and light anesthesia are likely. Some circle systems (Matrx VMS small animal circle) incorporate an air-intake valve (negative-pressure-relief valve [Fig. 17.45]) to entrain room air when the fresh gas flow is inadequate. With a non-rebreathing system and an outlet disconnect, exhaled carbon dioxide will be rebreathed, low F_{iO_2} is probable, and the patient will appear lightly anesthetized with increased respiratory efforts. The use of an oxygen analyzer for continuous evaluation of inspired gases enables early detection of this problem.

Fig. 17.45. Air-intake valve (negative pressure relief valve) on the dome of the inspiratory one-way valve of a circle system on a Fraser Harlake small animal anesthesia machine. The valve is designed to entrain room air if the supply of fresh gas to the circle breathing system is interrupted. In addition, the pop-off valve is attached to the expiratory one-way valve.

Breathing Systems

Anesthetic breathing systems deliver anesthetic gases and oxygen to the patient, remove carbon dioxide from exhaled gases, and usually provide a means to manually support ventilation. Spontaneously breathing patients inhale and exhale through the breathing system, and the breathing system should be able to supply enough gases to meet the peak inspiratory demands of the patient.

The breathing system adds resistance to the flow of gases, and the diameter of the breathing tubes and other conduits is a major factor in determining the amount of resistance. Doubling the radius decreases the resistance 16 times. Halving the length of the circuit halves the resistance. Changing the direction of gas flow or routing gases through restrictive orifices creates turbulent flow and increases resistance. Therefore, breathing systems should be as short as practical, with maximum diameters in the conduits and the fewest bends and restrictions in the path of gas flow.² Generally, the endotracheal tube has the smallest luminal diameter of the breathing apparatus, and the largest tube that is practical should be selected.

Classification of breathing systems has been called a favorite pastime among anesthesiology personnel.³ Most systems of classification are confusing, not exclusive, and thus not helpful to veterinary students or personnel. When referring to a breathing system in the veterinary or medical literature, the system should be named and physically described, the fresh gas flow rates should be stated, and the patient's body weight and/or oxygen consumption should be listed.^{5,34} This eliminates the need for cumbersome, obscure classification systems.

Systems Using Chemical Absorption of Carbon Dioxide

Circle and to-and-fro breathing systems use a chemical absorbent for exhaled carbon dioxide. They are termed *rebreathing* systems

because part or all of the exhaled gases, after extraction of carbon dioxide, flow back to the patient. In contrast to *non-rebreathing* systems, rebreathing systems conserve anesthetic, oxygen, heat, and moisture, but impart more resistance to ventilation. Rebreathing systems are relatively expensive to purchase, but comparatively economic to operate.

Circle Systems

Pediatric, standard adult (small animal), and large animal circles differ primarily in their IDs and volumes. Arbitrarily, pediatric circles have been recommended for veterinary patients weighing less than 6.8 kg (15 lb), standard adult circles for patients between 6.8 kg and 135 kg (300 lb), and large animal circles for larger patients.⁵ However, choosing the size of circle system for a veterinary patient may be influenced by the species, the practical availability of equipment, the type of ventilation used, and the veterinarian's preferences. In the anesthesia of human patients, a *pediatric circle* usually refers to a standard (adult) absorber assembly, short breathing tubes of small diameter (15 mm ID), and a small bag.³

All circle systems have the same basic components, arranged so that gases move in only one direction (Figs. 17.28 and 17.29). Exhaled gases enter the Y piece and flow through the expiratory breathing tube and the expiratory one-way valve. Gases may enter the reservoir bag before or after coursing through the carbon dioxide-absorbent canister. On inspiration, gases exit the reservoir bag and travel through the inspiratory one-way valve, the inspiratory breathing tube, and the Y piece to the patient.

Components of the Circle System

Y Piece This is usually constructed of plastic and unites the endotracheal tube connector and the inspiratory and expiratory breathing tubes. The Y piece contributes to the system's mechanical dead space, but a septum may be present in the Y piece to decrease dead space. It has been argued that the amount of dead space in a standard, adult (small animal) Y piece is not significantly greater than that in a non-rebreathing system.³⁵ A standard adult Y piece has a 15-mm female port for the endotracheal tube connector, and this port may have a 22-mm outer diameter (OD) to accept a mask. The two 22-mm male ports connect to the breathing tubes. Disposable systems may have the Y piece and breathing tubes permanently attached to each other. The dimensions of the Y piece in large animal circles vary among manufacturers, but approximate 50 mm (2 inches).

Breathing Tubes These tubes are usually made of rubber or plastic, and serve as flexible, low-resistance conduits between the Y piece and the one-way valves. Corrugations reduce the likelihood of obstructions if the tubes are bent. Breathing tubes add length and volume to the system, and increase resistance to ventilation; the tubes should have an ID larger than the ID of the patient's endotracheal tube. Standard adult breathing tubes have a 22-mm ID and have been recommended for small animals weighing more than 7 kg.³⁶ For smaller patients, 15-mm-ID tubes are available, whereas 50-mm-ID (2 inch) breathing tubes are used with large animal circle systems. Breathing tubes do not

Fig. 17.46. Components of a unidirectional valve (North American Drager, Telford, PA) of a circle breathing system. From the *left*, the plastic dome, the retaining ring for the dome, the valve itself, and the valve housing are depicted. From Hartsfield.⁵

contribute to mechanical dead space if the one-way valves are functional.

One-way (Unidirectional) Valves These paired valves direct gas flow away from the patient on expiration and toward the patient on inspiration, preventing the rebreathing of exhaled gases before they pass through the absorbent canister. Gases enter a unidirectional valve from below, raise the disk, and pass under the dome (Fig. 17.46) to the reservoir bag, the absorbent canister, or the inspiratory breathing tube, depending on the location of the valve and the design of the circle. The one-way valves are usually attached to the canister on modern circle systems, but some older systems located the one-way valves within the Y piece, where they were more likely to become incompetent. Valves contribute to the resistance of breathing and should be inspected regularly to assure proper function.

Fresh Gas Inlet This inlet is the location at which gases from the common gas outlet of the anesthesia machine or from the outlet of the vaporizer enter the circle system. The fresh gas inlet is located on the absorbent canister near the inspiratory one-way valve or on the inspiratory one-way valve. Entry of fresh gases on the inspiratory side of the circle minimizes dilution of fresh gases with exhaled gases with a VOC, prevents absorbent dust from being forced toward the patient, and reduces loss of fresh gases through the pop-off valve.

Pop-off Valve This valve (adjustable pressure-limiting valve, relief valve, or overflow valve [Fig. 17.47]) vents gases to the scavenger system to prevent the buildup of excessive pressure within the circle, and it allows rapid elimination of anesthetic gases from the circle when 100% oxygen is indicated. The exhaust port of the pop-off valve through which overflow gases enter the scavenger system is designated to have a 10- or 30-mm male connector according to ASTM standards,^{1,3} although older

Fig. 17.47. Pop-off valve and manometer on a circle breathing system of a VMS anesthesia machine. The exhaust port (19-mm outer diameter) of the pop-off valve is attached to clear corrugated tubing, which directs waste gases to the scavenging system. The air-intake valve is mounted on the top of the dome for the inspiratory (*right*) one-way valve and functions to entrain room air if the fresh gas supply to the circle system fails.

overflow valve ports were sized at 22 mm OD. A pop-off valve should vent gases at pressures of 1 to 2 cm H₂O when it is fully opened. Several types of pop-off valves are available, but those with a spring-loaded disk are common. The pop-off valve is most convenient and relatively conservative with absorbent if it is located between the expiratory one-way valve and the absorbent canister. This location limits waste of fresh gases during exhalation. The pop-off valve is a major safety feature of a circle breathing system regardless of the mode of operation of the circle (e.g., closed, low-flow, or semiclosed fresh gas flow rates). The pop-off valve is designed to prevent the inadvertent buildup of pressure, and it should remain open except during the administration of positive-pressure ventilation.

Reservoir Bag This bag is located on the absorber side of the circle, either upstream or downstream from the canister, depending on the manufacturer. The reservoir bag, which attaches to the bag port, has an outside diameter of 22 mm for small animal circles and 50 mm (2 inches) for large animal circle systems. Gas from an appropriately sized reservoir meets the patient's peak inspiratory flow demands and provides compliance in the system during exhalation.³ The bag also provides a mechanism for assisted or controlled ventilation. Excursions of the bag during spontaneous ventilation enable the anesthetist to assess respiratory rate and to roughly estimate the tidal volume. In addition, if the pop-off valve is inadvertently left closed, the bag provides a compliant area of the system to prevent the immediate buildup of excessive pressure. Ideally, the bag should not allow pressures to exceed 60 cm H₂O.³ The minimum size of the reservoir should be six times the patient's tidal volume, but as a matter of practicality, the bag's volume should exceed the patient's inspiratory capacity. Therefore, a spontaneous deep breath should not empty

the bag.⁴ For small animal circle systems, 1-, 2-, 3-, and 5-L bags are common, whereas 15-, 20-, or 30-L bags are used for large animals. An optimally sized bag enables the anesthetist to manually support ventilation comfortably and to observe ventilatory excursions. An unnecessarily large bag is cumbersome, impairs monitoring, and slows changes in the inspired anesthetic concentration when settings on an out-of-circuit vaporizer are increased or decreased.

Manometer This device (Fig. 17.47) is a pressure gauge that is usually attached to the top of the absorber assembly. It is calibrated in centimeters of water (cm H₂O), although it may have a scale in kilopascals or in millimeters of mercury (mm Hg). Primarily, manometers are used to assess pressures during assisted or controlled ventilation.

Air-Intake Valve This valve (negative-pressure-relief valve) is included on some veterinary anesthesia machines (Matrx VMS small animal) (Fig. 17.47). Located on the dome of the inspiratory one-way valve in these small circle systems, the valve will entrain room air in emergencies (i.e., absence of fresh gas inflow). If fresh gas flow is interrupted, the valve allows ambient air (21% oxygen) to enter the circle and prevents the patient from inspiring against a negative pressure and becoming hypoxic.

In-circuit Vaporizers Vaporizers can be located within the breathing system (Fig. 17.29), the Ohio #8 glass bottle and the Stephens being the most likely vaporizers located in this position. The primary requirement is that the in-circuit vaporizer be of a low-resistance type, because patients must inspire through the vaporizer.

Absorber This assembly, which contains the canister for the chemical absorbent for carbon dioxide, is located between the one-way valves, on the side of the circle opposite the patient (Fig. 17.48). The canister is usually one plastic container or two stacked plastic containers. For a specific patient, the canister should be large enough to contain an airspace between chemical granules that is equal to or greater than the patient's maximum tidal volume. The intergranular space is approximately 50% when a canister is filled with standard absorbent (4- to 8-mesh size).⁴ Exhaled gases may enter the top or bottom of a canister, and baffles or annular rings (Fig. 17.49) in many absorbers move gases toward the center of the canister to compensate for lower resistance to gas flow near the canister wall. Without baffles or annular rings, channeling of gases and inefficient absorption of the carbon dioxide may occur. Internal tubes for gas return from an absorber may enhance the wall effect and gas channeling.² Some absorber units, especially those for large animals, have drain in the bottom to discharge water that condenses from exhaled gases.

The canister filled with absorbent, besides being a source of resistance during ventilation, is an important area for malfunctions in circle systems. The canister is removed regularly to change the absorbent, and failure to create a seal adequately when replacing the canister causes leaks. Normal wear and tear may damage the canister, the caustic effects of soda lime may

Fig. 17.48. Absorber assembly for a Matrx (Orchard Park, NY) large animal circle breathing system. Attached to the absorber canister are the unidirectional valves, the manometer, the ports for the breathing hoses and reservoir bag, and the pop-off valve.

Fig. 17.49. An absorber assembly with an annular ring. The ring diameter, being smaller than the canister diameter, promotes dispersion of gases throughout the canister and helps to prevent preferential flow of gases next to the walls of the canister leading to the development of dead space.

corrode metal parts, and aging causes gaskets to deteriorate. Simply leaving soda lime granules on the gaskets can make a tight seal impossible. One report described the bypass of soda lime with resultant hypercarbia because of the disconnection of the diffuser foot from the conduction tube in the canister on a veterinary anesthesia machine.³⁷ Newer circle systems are constructed with materials less vulnerable to the effects of soda lime.

Some circle systems were designed with a mechanism for purposely bypassing the absorbent canister (Fig. 17.50). The bypass was intended for use during the changing of soda lime and for intentionally elevating the inspired concentration of carbon dioxide.² If these obsolete systems are used in veterinary practices, the operator should understand the function of the bypass and its control apparatus and should not operate the circle in the bypass mode.

Fig. 17.50. The top of an absorber from an obsolete circle breathing system. The control on the absorber functions to direct exhaled gases through one or both chambers of the canister. With both indicators in the closed position, exhaled gases bypass the carbon dioxide absorbent completely.

Chemical absorption of carbon dioxide is a fundamental function of circle and to-and-fro breathing systems. Depending on the fresh gas inflow, all or part of the exhaled carbon dioxide may be absorbed chemically. If the fresh gas flow approximates the patient's oxygen consumption, almost all exhaled carbon dioxide will be chemically neutralized. Chemical absorption of carbon dioxide allows lower fresh gas flows, reduces wastage of anesthetics and oxygen, and lowers the cost for anesthesia. With high fresh gas flows, much of the exhaled carbon dioxide escapes through the pop-off valve and into the scavenger system, and the dependence on chemical absorption of carbon dioxide is decreased.

Chemical Absorption of Carbon Dioxide

Calcium hydroxide is the primary component of soda lime and barium hydroxide lime, the two most common absorbents for carbon dioxide. Small amounts of sodium and potassium hydroxide in soda lime activate the reaction, and silica and kieselguhr are included to give hardness to the granules.^{2,3} Barium hydroxide lime is inherently hard owing to bound water molecules and does not require silica.² For optimal absorption of carbon dioxide, 14% to 19% H₂O is required in soda lime. Water formed during granule reactions with carbon dioxide can be useful in humidifying dry gases from the fresh gas inlet, but does not participate in the reactions of chemical absorption of carbon dioxide. The overall chemical reaction of carbon dioxide with soda lime includes multiple steps (e.g., carbon dioxide first reacts with water to form carbonic acid), but can be summarized as follows:

(CaCO₃, calcium carbonate; Ca[OH]₂, calcium hydroxide; H₂CO₃, carbonic acid; Na₂CO₃, disodium carbonate; and NaOH, sodium hydroxide)

Fig. 17.51. Evaluation of the consistency of soda lime granules. Functional granules are relatively soft and easily crushed, whereas expended granules are hard.

The granule size for chemical absorbents is typically 4 to 8 mesh and represents a compromise between absorptive activity and airflow resistance.² Small granules offer the most surface area for chemical reactions, but large granules impose less resistance to gas flow through the canister. Proper packing of a canister is necessary to prevent flow of gases over a single pathway in the canister, creating excessive dead space. Gentle shaking of the canister upon filling it with an absorbent will avoid loose packing and reduce channeling. Packing too tightly should be avoided to prevent formation of dust and increased resistance to ventilation.⁴

During evaluation of a rebreathing system, the anesthetist should confirm that the absorbent is functional. Fresh granules of calcium hydroxide are soft enough to be easily crushed, whereas expended granules have chemically changed to calcium carbonate and are hard (Fig. 17.51). Indicators of pH are added to absorbents to show color changes as chemical reactions proceed. Soda lime changes from white to violet as the granules are exhausted. The violet may revert to white during storage, but will reappear when the granules are exposed to carbon dioxide again. Newer CO₂ absorbents will maintain this color change and are less reactant producing less heat, carbon monoxide, and compound A. The absorption of carbon dioxide is an exothermic reaction, and a "heat line" should be detectable on the wall of the canister if carbon dioxide absorption is effective. Heat is particularly notable in canisters for large animals. The amount of carbon dioxide absorption is about 26 L/100 g,⁴ but efficiency may vary, depending on the design of the canister and the method of packing. When using a circle system with a chemical absorbent, the inspired carbon dioxide should be near zero.² Measuring the concentration of carbon dioxide in inspired gases, with 0.1% to 1.0% being acceptable^{38,39} is the most accurate way to determine whether the absorbent is functional.^{2,3} Without such measurements, the absorbent should be exchanged when the color reaction is apparent in approximately two-thirds of the absorbent.^{2,36}

Fresh Gas Flows for Circle Breathing Systems

Fresh gas flow–rate recommendations for circle systems are somewhat controversial. Semiclosed, low-flow, and closed circles are the options, and when all factors are considered, a veterinarian's personal preference usually determines the flow of fresh gas. Nevertheless, there are differing advantages to the various fresh gas flow rates discussed. The terms *closed*, *low-flow*, and *semiclosed* are often used in reference to circle breathing systems and refer to the fresh gas–inflow rate compared with the metabolic needs of the patient. The terms do not denote any structural differences among the breathing systems, and they do *not* relate any information about the state of the pop-off valve (open or closed).

Closed Circle System

Closed-system anesthesia occurs when there is a low flow of anesthetic gases and oxygen to the patient and system.³ Thus, the oxygen flow into a closed circle approximates the patient's oxygen consumption, which varies with the patient's metabolic rate. Metabolic rate and oxygen consumption are influenced by the patient's body weight and body-surface area, its temperature, its state of consciousness, and the type of anesthetic. Table 17.4 lists values for oxygen consumption in dogs as reported in several publications. Table 17.5 includes published recommendations for fresh gas flows for closed circle systems in dogs, and all fall within the minimum and maximum rates of oxygen consumption reported for dogs as listed in Table 17.4. In practice, observation of the reservoir bag enables the anesthetist to adjust the fresh gas flow to approximate the patient's uptake of gases when using a closed system.

Although a patient's oxygen consumption is used to guide the rate of fresh gas flow into a closed system, the minimum flow of carrier gas for accurate function of the vaporizer should be considered. Concentration-calibrated, variable-bypass vaporizers (VOCs) require a certain minimum flow to assure proper performance, and flow below the minimum may cause erratic output of anesthetic. With a vaporizer, the lowest flow known to produce a reliable output should be the minimum acceptable flow for the breathing system. Strategies for using closed-system anesthesia with both in-circuit and out-of-circuit vaporizers have been reviewed.²⁴

Generally, N₂O is not used in a closed breathing system because of the potential for developing hypoxic gas mixtures with low inflow of oxygen. If N₂O is administered in a closed system, continuous monitoring of F_IO₂ is imperative. With closed systems, denitrogenation of the system by emptying the reservoir bag through the pop-off valve and refilling the system with fresh gas should be done two to four times during the first 15 min of anesthesia and each 30 min thereafter to prevent exhaled nitrogen from diluting oxygen in the system.^{31,40} A closed system is completely dependent on chemical carbon dioxide absorption, and the quality of the absorbent should be assured before each use. Ideally, the inspired concentration of carbon dioxide should be monitored to assure proper function of the absorbent. Closed systems are more economic, retain more heat and humidity, and are less likely to produce operating-room pollution than other systems.

Table 17.4. Values reported for consumption of oxygen in dogs

Oxygen Consumption (mL · kg ⁻¹ · min ⁻¹)	Conditions	Reference
6 to 8 mL · kg ⁻¹ · min ⁻¹	Anesthetized	Soma ⁴⁶
10 to 11 mL · kg ⁻¹ · min ⁻¹	Anesthetized	Soma ⁴⁶
4 to 8 mL · kg ⁻¹ · min ⁻¹	Awake, resting	Haskins ⁶³
9 to 14 mL · kg ⁻¹ · min ⁻¹	Ketamine anesthesia	Haskins ⁶³
3 to 7 mL · kg ⁻¹ · min ⁻¹	Barbiturate and inhalant anesthesia	Haskins ⁶³
4 to 7 mL · kg ⁻¹ · min ⁻¹	Basal metabolic rate	Wagner and Bednarski ²⁴

4.4 to 11 mL · kg ⁻¹ · min ⁻¹	Muir and Hubbell ⁴¹
4 to 7 mL · kg ⁻¹ · min ⁻¹	Wagner and Bednarski ²⁴
4.4 to 6.6 mL · kg ⁻¹ · min ⁻¹	Muir and Hubbell ³²

Low-Flow Circle System

Low-flow anesthesia for small animals has been defined as an oxygen flow rate greater than the patient's oxygen consumption (4 to 7 mL · kg⁻¹ · min⁻¹) but less than 22 mL · kg⁻¹ · min⁻¹.²⁴ In the definition, 22 mL · kg⁻¹ · min⁻¹ was used because it is the lower limit of the traditional range of flow for a semiclosed circle system.⁴¹ The advantages of a low-flow system are similar to those for a closed system, including economy, reduced waste gas, and some retention of heat and moisture.⁴² The primary disadvantage of low-oxygen-flow techniques relates to the inadequate delivery of anesthetic from a concentration-calibrated, variable-bypass vaporizer during mask induction or during the transition from a short-acting injectable anesthetic induction to the maintenance of inhalant anesthesia. The suggested solution for this problem is the use of higher fresh gas flow rates for the first 15 to 30 min of anesthesia, followed by a change to low-flow technique after the uptake of inhalant anesthetic by the patient has decreased.²⁴ Similarly, changing depth of anesthesia is slower with low fresh gas flow rates. To increase anesthetic concentration in the system with a concentration-calibrated, out-of-circuit vaporizer, the fresh gas flow should be increased temporarily to speed the process. To lower the anesthetic concentration, the concentration setting on the vaporizer should be decreased and fresh gas inflow increased with either an out-of-circuit or in-circuit vaporizer location. For small animals, 10 to 15 mL · kg⁻¹ · min⁻¹ has been suggested as an appropriate flow rate for a low-flow system.²⁴

Semiclosed Circle System

This terminology describes a system in which the fresh gas inflow exceeds the uptake of oxygen and anesthetic by the patient.

Fig. 17.52. Diagram of a to-and-fro rebreathing delivery system showing the component parts: patient connector, pop-off valve, fresh gas inlet, canister, and reservoir bag. From Hartsfield.⁵

Traditional flows for semiclosed circle systems range from 22 to 44 mL · kg⁻¹ · min⁻¹.^{24,41} A significant quantity of excess gas must be eliminated through the pop-off valve. The choice of flow rate for a semiclosed circle is based primarily on personal preference, but the patient's oxygen consumption times three has been a common guideline. For example, if a dog's oxygen consumption is 7 mL · kg⁻¹ · min⁻¹, the fresh gas flow would be 21 mL · kg⁻¹ · min⁻¹. Use of N₂O will increase total gas flow requirement. For a 50% N₂O mixture, oxygen flow would equal 21 mL · kg⁻¹ · min⁻¹, and N₂O flow would equal 21 mL · kg⁻¹ · min⁻¹, with a total fresh gas flow of 42 mL · kg⁻¹ · min⁻¹. With a semiclosed circle, nitrogen accumulation within the system is not significant because gases are rapidly eliminated through the pop-off valve. N₂O can be used safely, the inspired anesthetic concentration can be changed rapidly, and dependency on the carbon dioxide absorbent is less because carbon dioxide is partly eliminated through the pop-off valve into the scavenging system. However, the retention of heat and humidity is lessened, and economy is less, compared with closed and low-flow systems.

Breathing systems that produce the least resistance to gas flow should be chosen for spontaneously breathing patients. Resistance to gas flow through a circle breathing system is influenced primarily by the pop-off valve, unidirectional valves, and carbon dioxide absorbent canister.² The total resistance in a circle system varies with the fresh gas flow rate and the type of ventilation. High fresh gas flow rates can increase flow through the pop-off valve and therefore may increase resistance to ventilation. The ventilation pattern affects the flow rate and therefore the resistance through the soda lime canister and the unidirectional valves.²

Resistance to breathing has been cited as a reason for not using adult circle systems for pediatric patients. However, Dorsch and Dorsch² suggest that the use of circle systems in spontaneously breathing pediatric patients may not be contraindicated solely on the basis of resistance. For veterinary patients, it has been recommended that circle breathing systems are appropriate for healthy animals weighing as little as 2.5 to 3.0 kg.^{24,43,44}

Resistance to constant flow in large animal breathing circuits has been assessed.⁴⁵ Greater resistance occurs with higher flows through all of the breathing circuits. The Drager and Fraser Sweatman circuits were intermediate in total resistance when nine different circuits were compared, and each circuit had individual parts that contributed significantly to resistance in at least one of the circuit types. Since low resistance is considered an advantage, it has been suggested that most larger animal breathing circuits be redesigned to help minimize resistance.

To-and-Fro System

This type of rebreathing system (Fig. 17.52) is much less popular than the rebreathing circle and Mapleson systems. The to-and-fro system has a carbon dioxide-absorbent canister located between the endotracheal tube connector and a reservoir bag. A pop-off valve and the fresh gas inlet are positioned between the canister and the endotracheal tube connector. A to-and-fro system is suitable for both large and small animals if proper canisters are available.^{28,46} With low flows approximating the patient's oxygen consumption, carbon dioxide removal depends on chemical absorption. With higher flows, part of the expired carbon dioxide is vented through the pop-off valve.

Portability, simplicity, and ease of disassembly for cleaning are advantages of the to-and-fro system. Disadvantages are related to the position of the system, including the canister, next to the patient. Heat produced during carbon dioxide absorption may be transferred to the patient during inspiration, there is greater potential for inhalation of alkaline dust from the absorbent than with a circle system, and the system is quite cumbersome. Over time, channeling of gases through the canister may create dead space in the absorbent, causing inefficient absorption of carbon dioxide. The horizontal position of the canister is probably less desirable than the vertical position used in most circle rebreathing systems.⁴ As with circle systems, denitrogenation during the early phases of anesthesia is required to prevent hypoxia, especially with lower fresh gas flows.

Mapleson Systems

Breathing systems that use no chemical absorbent for carbon dioxide, but depend primarily on high fresh gas flow rates to flush exhaled carbon dioxide from the system, have been classified as Mapleson systems. They have been called *non-rebreathing systems* as a group, though this terminology is technically incorrect because some rebreathing of exhaled gases occurs in most of these systems, especially with lower recommended flow rates.⁵

The Mapleson systems are simple and easy to use, are easily cleaned and sterilized, are lightweight and compact, can be positioned conveniently, have few moving parts, are relatively inexpensive, impart little resistance to respiration, do not require carbon dioxide absorbents, add minimal mechanical dead space, and allow the inspired concentration of anesthetic to be changed rapidly. The main disadvantages of using Mapleson systems is the requirement for higher flow rates of fresh gas, which decreases temperature and increases cost. Higher flow rates promote hypothermia and drying of the respiratory tract. The Mapleson sys-

Table 17.6. Characteristics of the Mapleson breathing systems

Class	Fresh Gas Inlet	Overflow Location	Presence of a Reservoir	Corrugated Tubing	Example System
A	Near the reservoir	Near the patient	Yes	Yes	Magill
B	Near the patient	Near the patient	Yes	Yes	a
C	Near the patient	Near the patient	Yes	No	a

MD ^c	Near the patient	Away from the patient	Yes	Yes	Bain
E	Near the patient	Away from the patient	No	Yes	T-piece
F	Near the patient	Away from the patient ^b	Yes	Yes	Jackson-Rees

^aNo system in this classification is commonly used in veterinary anesthesia.

^bThe overflow may be located between the reservoir and the corrugated tubing of the system.

^cMD, modified Mapleson D system.

Fig. 17.53. Diagrams of each of the Mapleson breathing systems (A–F, Mapleson systems). From Rayburn.⁶⁴

tems are diagramed in Fig. 17.53, and characteristics of the Mapleson systems are listed in Table 17.6.

Magill System

The Magill system (Fig. 17.54) is classified as a Mapleson A system and is characterized by a fresh gas inlet, an overflow valve near the patient, and a corrugated tube connecting the patient end of the system to a reservoir bag.⁴⁶ Fresh gas flows continuously

into the reservoir bag and into the corrugated tubing, moving carbon dioxide-rich gases through the overflow valve. The system is efficient during spontaneous ventilation, but, during controlled ventilation, some rebreathing of expired gases occurs. Fresh gas inflow should approximate the patient's minute volume,⁹ with flows less than 0.7 of minute volume leading to some rebreathing.² The N₂O flow should be calculated as a part of the total fresh gas inflow. The volume of the corrugated tubing and the reservoir bag should be equal to or greater than the patient's tidal volume. Because of the location of the overflow valve, the system is relatively cumbersome during controlled ventilation.

Bain Coaxial System

This system (Fig. 17.55) is classified as a modified Mapleson D design. It is configured as a tube within a tube.⁹ The internal tube (0.7 mm ID) supplies fresh gases to the patient end of the system (Fig. 17.56), minimizing mechanical dead space. The Bain system accepts an endotracheal connector (15 mm) or a mask (22 mm). The external corrugated tube conducts exhaled gases from the patient to a reservoir bag. The reservoir bag may attach directly to the corrugated tubing, in which case the pop-off valve is built into the bag, or the corrugated tubing may attach to a metal head with drilled channels and accommodations for the reservoir bag, the overflow valve, and optionally a manometer.^{2,3}

Recommendations for total fresh gas flow into a Bain system are variable for both human and animal patients. Recommendations have been based on minute volume, body weight, and body surface area.² During spontaneous ventilation, 200 to 300 mL · kg⁻¹ · min⁻¹ has been recommended for anesthesia of human patients.⁹ Fresh gas flows from 100 to 150 mL · kg⁻¹ · min⁻¹ have been recommended for veterinary patients.^{36,47} Some investigators⁴⁸ have suggested a fresh gas flow rate of 200 mL · kg⁻¹ · min⁻¹ for patients weighing less than 7 kg, whereas others have recommended a flow rate of 220 to 330 mL · kg⁻¹ · min⁻¹.³² The fresh gas flow that will eliminate rebreathing during spontaneous ventilation with a Bain system differs significantly from patient to patient. After reviewing numerous references, Dorsch and Dorsch³ concluded that most studies recommended fresh gas flows of 1.5 to 3.0 times minute volume. Less than two to three

Fig. 17.54. Diagram of a Magill system illustrating the basic components and the entry of fresh gases. From Hartsfield.⁵

Fig. 17.55. Diagram of a Bain coaxial system attached to an anesthesia machine. Fresh gas flows from the outlet of the vaporizer or the common gas outlet of the anesthesia machine to enter the Bain system near the reservoir. Moving through the Bain's inner tube, fresh gas is delivered near the patient end of the system. Exhaled gases flow through the corrugated tubing to the reservoir and the overflow to the scavenging system.

Fig. 17.56. The two ends of a Bain coaxial system showing the location for attachment of the reservoir bag (*top left*) and the endotracheal tube (*bottom right*). Fresh gases enter at the reservoir end (Y connection at the *top right*) and move through the small inner tube to the patient end of the system (triangular supports). From Hartsfield.⁵

times the minute volume will result in some rebreathing of carbon dioxide, but the end-tidal carbon dioxide concentration may remain normal even with some rebreathing of carbon dioxide.³ For spontaneously breathing patients, 440 to 660 mL · kg⁻¹ · min⁻¹ may be used for maintenance of anesthesia with the Bain system to assure that rebreathing of exhaled gases does not contribute to increases in arterial carbon dioxide partial pressure. Without regular monitoring of carbon dioxide tensions or expired carbon dioxide values, the exact flow requirements are difficult

to define for an individual patient. Minute volumes for dogs and cats range from 170 to 350 mL · kg⁻¹ · min⁻¹ and 200 to 350 mL · kg⁻¹ · min⁻¹, respectively.⁴⁹ Using these values for minute volume, an argument can be made for even higher flows than 660 mL · kg⁻¹ · min⁻¹. In general, a total fresh gas flow of less than 500 mL/min or more than 3 L/min with a Bain system is not recommended for animals that weigh less than 6.8 kg. With controlled ventilation, 100 mL · kg⁻¹ · min⁻¹ is apparently an adequate flow for fresh gases.⁵⁰ For larger patients maintained with an adult Bain system, lower total fresh gas flow (e.g., 100 mL · kg⁻¹ · min⁻¹) may be appropriate. Use of Bain systems has been effective in dogs weighing up to 35.5 kg.⁴⁷ Fresh gas flows higher than usually recommended are indicated in situations of increased carbon dioxide production, increased dead space, and decreased minute ventilation.³ Flow rates of two to three times minute volume have been recommended for hypoventilating animals in which controlled ventilation was not corrective.⁴⁷

During spontaneous ventilation, a Mapleson D system has been shown to function identically to a Mapleson F system.² The Bain's coaxial design has been shown to be effective in reducing loss of heat and humidity,² although the overall benefit is questionable in small veterinary patients maintained with relatively high fresh gas flow rates.

Ayre's T-Piece and Norman Mask Elbow Systems

Ayre's T-piece and Norman mask elbow systems (Fig. 17.57) equipped with an expiratory limb (corrugated tubing) and reservoir bag are classed as Mapleson F systems.² Without a reservoir bag, they are Mapleson E systems. The T piece itself is a T-shaped tube with a 1-cm ID. Fresh gas enters the tube from the side, perpendicular to the direction of gas flow during ventilation

Fig. 17.57. Diagrams of Norman Mask Elbow system (*bottom*) and Ayre's T-piece system (*top*). From Hartsfield.⁵

(Fig. 17.57). One end of the tube attaches to the endotracheal tube connector, and the other end attaches to an expiratory arm (corrugated tubing equivalent to one-third of the patient's tidal volume) to which a reservoir bag may or may not be attached. The reservoir bag has an overflow valve. An Ayre's T piece with an expiratory tube and reservoir is a Rees modification of an Ayre's T piece or a Jackson-Rees system.²

During spontaneous ventilation, fresh gas flows to the patient during inspiration; during expiration and prior to the next inspiration, gas flows toward the reservoir. Gas flow follows the path of least resistance. Inspiratory flow requirements in excess of the fresh gas flow are obtained from the expiratory arm and reservoir. During expiration and before inspiration, high gas flow clears exhaled gases from the expiratory tube and washes out carbon dioxide. Such a system should have an ID of at least 1 cm to minimize resistance.

Generally, two to three times the patient's minute volume is recommended to prevent dilution of the inspired anesthetic concentration and rebreathing of carbon dioxide with Mapleson F systems. If N_2O is used, the desired concentration is calculated using N_2O as a portion of the total fresh gas flow. Variable recommendations for the most appropriate flow rates to use with these systems exist in the veterinary literature.

In a Norman mask elbow system, the direction of gas flow into the system is parallel to the flow of gases into the endotracheal tube during inspiration and expiration (Fig. 17.57). The fresh gas inlet is located in the center of the patient end of the system. This location probably reduces dead space slightly more than the Ayre's T-piece system. Also, the patient end of the elbow accepts a standard mask (22 mm). Recommendations for flow rates, tube sizes and volumes, and reservoir sizes and volumes are similar to those for the Ayre's T-piece system. Controlled ventilation can be used with either system by closing the overflow valve and compressing the reservoir bag. To prevent rebreathing during controlled ventilation, the expiratory tube's volume should be greater than the patient's tidal volume.

Resistance to ventilation in the Mapleson systems is minimal,² which may be advantageous for small patients. The advantages of modern "non-rebreathing" systems for very small patients include decreased resistance to ventilation, better gas exchange, greater control of the depth of anesthesia, and fewer mechanical

problems.⁴⁸ Hazards of non-rebreathing systems relate primarily to outflow occlusion, development of excessive airway pressure, and barotraumas to the lungs, including development of pneumothorax.

Care in positioning the Mapleson systems and judicious use of overflow valves during positive-pressure ventilation are important considerations. Activation of the flush valve when a non-rebreathing system is being used can overpressurize the respiratory system, causing volutrauma (rapid overexpansion of the lungs) and subsequent pneumothorax. Therefore, the machine's flush valve should not be used when one of the Mapleson systems is connected to a patient.

Systems with Non-rebreathing Valves

Numerous non-rebreathing valves (e.g., Stephens-Slater, Fink, and Digby-Leigh) have been designed for anesthesia breathing systems, but they are not commonly used today.³ These breathing systems with one-way valves were cumbersome, and essentially have been replaced by the Mapleson and circle systems. Presently, non-rebreathing valves are used most in self-inflating bags for resuscitation or transport of patients requiring manual ventilation.

Stephens-Slater System

This system (Fig. 17.58) was in common use in veterinary anesthesia in the 1970s, but today is mainly of historical interest. The system was designed with two one-way valves, one directing gas from the reservoir to the patient and blocking exhaled gases from the reservoir and a second valve directing exhaled gases away from the system and preventing entry of ambient gases during inspiration. Fresh gases enter the system through the reservoir bag and move through the inspiratory valve to the patient. The recommended total fresh gas flow is equal to the patient's minute volume.^{2,46} The flow of N_2O , if used, is calculated as a part of the total fresh gas flow. Since the valves are located near the patient, the system is cumbersome, especially with manual ventilation, during which the exhalation valve is held closed while the reservoir bag is compressed. The reservoir must be monitored closely to assure sufficient gas to meet inspiratory demands. This valved system added minimal dead space and resistance to respiration. However, the valve flaps could stick and obstruct ventilation. The

Fig. 17.58. Diagram of a Stephens-Slater system. From Hartsfield.⁵

system was popular prior to the advent of scavenging, which presents some difficulty with the Stephens-Slater system.

Resuscitation Bags

These self-inflating bags incorporate non-rebreathing valves. As an example, an Ambu bag (a bag valve mask) facilitates resuscitation and transport of apneic or anesthetized patients. Oxygen can be delivered into the reservoir bag to increase $F_I O_2$. When the bag is compressed, the increase in pressure closes the exhalation port and gases enter the patient's respiratory system. When pressure on the bag is released, gas flows from the patient's respiratory system through the exhalation port. With spontaneous breathing, the Ambu valve allows the patient to inhale room air only. The Ambu E2 is a modification that allows the patient to inhale both from the reservoir and from the exhalation port, creating a mixture of fresh gas and air. During controlled ventilation, all gases originate from the reservoir.²

Closed Containers and Masks

Closed Containers

Closed containers are used for oxygenation and inhalant inductions in small veterinary patients. Inhalant inductions have decreased in popularity because of the difficulty associated with scavenging of waste gases, especially as an anesthetized patient is removed from the chamber. Perhaps, the only completely effective way to assure elimination of waste anesthetic gases with this system is the concurrent use of a fume hood. The primary advantage of induction in a closed container is the reduced requirement for physical restraint of the patient. Induction in a closed container is very effective for aggressive cats and for some laboratory and small wild or exotic species. Often, the container can be placed over the animal, eliminating the need for any physical contact and restraint.

Most containers for inhalant inductions are constructed of glass, Plexiglas, or other clear plastic materials (Fig. 17.59), allowing the patient to be observed during induction. Since the airway might become obstructed during a closed-container induction, ventilatory efforts should be monitored throughout the process. The chamber should be no larger than necessary, but the animal should be able to lie in lateral recumbency without having to flex its neck. A chamber that is too small for the patient promotes airway obstruction. Excessive chamber volume slows the rate of rise of anesthetic concentration and the onset of induc-

Fig. 17.59. Closed container for oxygenation and inhalant inductions in small patients. The container is clear so that the animal can be monitored during the induction process. The ports for the entrance of fresh gases and for attachment of a scavenging system are on the lid.

tion. When the patient is induced and is manageable, it should be removed from the chamber, and the induction should be completed by mask.

Relatively high flows of fresh gas facilitate inductions in closed containers. The outlet of the chamber should be attached to a scavenger system when anesthetic is being administered. Chamber inductions should be done in a well-ventilated area, ideally, under a fume hood that vents all waste gases from the working environment. Depending on the size of the chamber and the body weight of the patient, total flow of fresh gas into the chamber should be approximately 2 to 5 L/min.⁵¹ Low flow rates of fresh gases slow induction and contribute to the development of excitement. Oxygen should be administered for about 5 min before the introduction of inhalant anesthetic. Then, the concentration of the inhalant should be increased at 0.5% increments every 10 s until 4% to 4.5% sevoflurane or isoflurane is being administered. Unless N_2O is contraindicated because of patient pathology, it can be used in concentrations of 60% to 70%.

Masks

Mask inductions (Fig. 17.60) are facilitated by anesthetic concentrations and fresh gas flows that are similar to those for closed containers. Mask inductions are smoothest in depressed, tranquilized, or sedated patients. Masks should fit snugly over the muzzle to minimize dead space, and the appropriate size for the patient should be used. A tight-fitting mask promotes a rapid induction and minimal contamination of the workplace with waste gases. A clear mask with a rubber diaphragm (Fig. 17.61) enables visualization of the nares and mouth during induction and creates a good seal around the animal's muzzle. The mask should be attached to a breathing system to provide a reservoir of gases to meet the patient's peak inspiratory flow demands, which may exceed the inflow of fresh gases. Most excess gases can be scavenged through the pop-off valve of the breathing system, but

Fig. 17.60. Masking a tranquilized potbellied pig with isoflurane in oxygen administered with a transparent veterinary mask. The rubber diaphragm enables a good seal between the patient's snout and the mask, minimizing leakage.

masking procedures should be done in a well-ventilated environment. High fresh gas flows (e.g., 3 to 5 L/min for most dogs and cats) during masking supply the oxygen demands of the patient, dilute and eliminate exhaled carbon dioxide, and provide inhaled anesthetic concentrations equivalent to the vaporizer setting (3% to 5% for isoflurane or 4% to 6% for sevoflurane) for a relatively rapid induction.

Scavenging Waste Anesthetic Gases

Over the last two decades, the exposure of medical and veterinary personnel to waste anesthetic gases has become a significant concern. A bulletin from the American Veterinary Medical Association's Liability Insurance Trust has stated the following: Numerous studies in the United States and abroad have found no conclusive evidence that waste gases or trace amounts of waste gas cause specific health problems. There is evidence, however, to suggest that removal of gases from veterinary facilities will likely improve the occupational health of the veterinary staff.⁵²

At present, the Occupational Safety and Health Administration (OSHA) has no set limits for exposure to anesthetics, but OSHA can enforce recommendations of the National Institute for Occupational Safety and Health (NIOSH) under the general duty clause: The general duty of an employer is provision of a work environment that is free of recognized hazards that are likely to cause death or serious physical harm.^{53,54} The recommended exposure limits from NIOSH vary from a maximum of 2 parts per million (ppm) for halogenated hydrocarbon anesthetics like halothane and isoflurane to an 8-h time-weighted average exposure to N₂O of 25 ppm. Used together, 0.5 ppm is the limit for the halogenated agent, with 25 ppm being the limit for N₂O.⁵⁵ The American Conference of Governmental Industrial Hygienists has recommended threshold-limit values of 50 ppm for halothane and N₂O as 8-h time-weighted averages.⁵⁶

Fig. 17.61. Small animal masks of varying sizes. The clear masks with rubber diaphragms facilitate monitoring during the masking procedure, and they enable a good seal around the muzzle. A conical rubber mask of the correct size minimizes dead space under the mask. From Lumb and Jones.³¹

Recommendations for Controlling Waste Gases

Veterinary workers should be aware of potential risks so that they can take steps to minimize their exposure to the inhaled anesthetics. Women in the first trimester of pregnancy, individuals with hepatic or renal disease, and persons with a compromised immune system appear to be at greater risk.⁵⁷ The following considerations are important in regard to managing waste anesthetic gases:

1. All personnel should be educated about the potential health hazards associated with exposure to waste anesthetic gases.
2. Scavenger systems should be used with all anesthesia machines and breathing systems.
3. All rooms in which anesthetic gases are used should be well ventilated with an appropriate number of air exchanges (e.g., 15 air exchanges per hour).
4. Anesthetic machines and breathing systems should be maintained as leak free as possible, and the leakage tolerances should comply with established criteria (e.g., less than 300 mL/min at 30 cm H₂O for a circle breathing system with the pop-off valve closed).³
5. A log documenting the performance and maintenance procedures for anesthesia machines, vaporizers, and breathing systems should be maintained.

6. Personnel should minimize spillage when filling vaporizers, and keyed filling mechanisms should be considered.
7. Anesthetic concentrations in induction, operating, and recovery rooms should be periodically monitored to assure the efficacy of scavenging and other efforts to reduce contamination in the workplace.

Several ways of decreasing contamination of the occupational environment with anesthetic gases have been suggested. They include the following:

1. Avoid spills when filling vaporizers.
2. Start gas flows only after intubation of the patient.
3. Use endotracheal tubes with inflated cuffs.
4. Occlude the Y piece of the circle or the patient end of a Mapleson system if the system is disconnected from the patient.
5. Use a scavenging pop-off valve.
6. Discharge all gases through an effective scavenger system.
7. Flush breathing systems with oxygen before disconnecting the patient.
8. Use the minimum gas flow that promotes safe anesthesia.
9. Minimize the use of masks and closed containers. When using masks, be sure that they fit well, and use closed containers only in well-ventilated areas. Ideally, masks should be used under a fume hood.
10. Maintain proper ventilation in work areas and minimize exposure to exhaled gases during the initial phases of the recovery period whenever possible.

Having anesthetic machines and breathing systems properly outfitted and functional for administration of anesthetic gases is essential for assuring the minimum amount of environmental pollution. Each machine should be leak free, and each machine-breathing system combination should connect with a functional scavenger system. An efficient scavenging system is the most important factor in reducing trace anesthetic gases, because it will lower ambient concentrations by as much as 90%.³

Scavenging Systems

A scavenging system collects waste gases from the anesthetic breathing system and eliminates them from the workplace.^{3,57} The scavenger system is composed of a gas-collecting assembly, an interface, and a disposal system (Figs. 17.62 and 17.63). Depending on the system, various types of tubing connects these parts.

The Gas-Collecting Assembly

This assembly gathers waste gases from the breathing system. At present, the exhaust outlet from the pop-off valve (Fig. 17.47) on a circle system must be either 19 mm or 30 mm in outside diameter. On older anesthesia machines, 22-mm connectors were used, which enabled the inadvertent interchange of scavenging hoses and breathing tubes. Depending on the location of the overflow in Mapleson systems (e.g., the Bain system), devices connecting the tail or the side of the reservoir bag serve as the gas-collecting assembly and attach to transfer tubing leading to the interface.

Fig. 17.62. A scavenging system (Vetroson; Summit Hill Laboratories, Navesink, NJ) on a veterinary anesthesia machine showing the pop-off valve of the circle breathing system attached to the corrugated tubing of the scavenging system that directs waste gases to the disposal system. The T-shaped component includes air-intake valves and is part of the interface that assists in the pressure regulation in the scavenging system.

Fig. 17.63. A scavenging system including the pop-off valve, which is connected to a canister containing activated charcoal (F/air, Omnicon; Critical Care Products, Houston, TX). This system can be used for halogenated hydrocarbon anesthetics, but not for nitrous oxide.

The Interface

The interface is intended to prevent the transfer of pressure changes in the scavenging system to the breathing system. The inlet to the interface should be 19 or 30 mm OD, and the outlet can be of variable diameter (not 15 or 22 mm). Various interfaces are available (Fig. 17.62). An interface should provide positive-pressure relief to protect the patient from occlusions of the scavenging system, negative-pressure relief to limit the pressure effects of an active disposal system, and a reservoir for excess waste gas for use with active disposal systems. Interfaces may be opened or closed.³

The Disposal System

Disposal systems can be passive or active. Passive systems include non-recirculating ventilation systems, piping directly to the atmosphere, and absorption devices. Active systems include piped-vacuum and active duct systems. A non-recirculating ventilation system for the room allows the discharge of waste gases through an exhaust vent or grille. Discharging waste gases directly to the atmosphere is suitable for many veterinary hospitals because the distance from the gas-collecting assembly on the breathing system to the outside can be relatively short. Such systems can be affected by wind currents and should be designed so that water, wind, dust, and insects and other pests cannot enter the system from the outside.

Canisters containing activated charcoal (Fig. 17.63) will absorb halogenated hydrocarbon anesthetics with a varying degree of efficiency. The canisters are simple to use and portable. The effectiveness of absorption varies with different brands, styles of canisters, and rates of flow through the canisters. These devices must be changed regularly, making them rather expensive to use, and they do not absorb N₂O.³ In general, other methods for scavenging waste gases are preferable, with absorption systems reserved for situations where more reliable methods are not accessible.

Central vacuum systems provide convenient anesthetic-gas disposal for hospitals with such systems already in place. The system should be able to create a flow of at least 30 L/min and functions best when the operator can manually adjust the flow.³ The location for discharge of waste gases must be in an appropriate location and not situated where waste gases can reenter the ventilation system of the hospital. Ideally, a central vacuum system dedicated to scavenging, with another system to provide suction for other hospital needs (e.g., surgical suction), is most desirable.

An active duct system with a high volume of flow and a low negative pressure provides an excellent means of gas disposal (Fig. 17.64). Negative pressure is generated by a fan, pump, or other device in a large duct that is connected to smaller ducts that open into the room at the site of use. Such systems are effective, but regular maintenance is required to assure that the fan or pump is operational. This system is not affected by wind currents. With any disposal system, the ultimate elimination of gas must be at a point that prevents reentry of gases to any area of the hospital. The discharge site should be located away from any air-intake vents of the building, and the prevailing winds should not direct exhausted gases toward the air-intake vents of the building.

Fig. 17.64. Corrugated tubing from the pop-off valve of a circle breathing system attached to a high-volume, low-pressure scavenging system (an active duct system). Air is constantly entrained on each side of the stainless-steel plate, whereas waste gas from the breathing system enters the scavenging system through the corrugated tubing.

Anesthesia Apparatus: Checkout Recommendations

Evaluation of anesthesia machines and breathing systems is important to ensure safety for personnel and patients. For patients, delivery of appropriate concentrations and amounts of oxygen and anesthetics is essential. For personnel, the machine and breathing system should be maintained to prevent contamination of the workplace with anesthetics. The Food and Drug Administration has published “Anesthesia Apparatus Checkout Recommendations” for anesthesia-gas-delivery systems and recommends that this checkout or a reasonable equivalent be conducted before administering anesthesia. The intent is to improve patient safety.^{58,59} Recommendations for checkout of veterinary machines have been published.⁶⁰

The high-, intermediate-, and low-pressure areas of the anesthesia apparatus should be evaluated.¹⁻³ The high-pressure area includes gas cylinders, hanger yokes, yoke blocks, high-pressure hoses, pressure gauges, and regulators. These components are exposed to pressures up to 2200 psi for oxygen and up to 745 psi for N₂O. Testing should include inspection for loose connections and audible leakage, pressure checks (loss of pressure when cylinder valves are open and flowmeters are off), and use of soapy water solutions to “snoop” for leaks (creation of bubbles) especially at joints (Fig. 17.65). The intermediate-pressure area (approximately

Fig. 17.65. Searching for leaks in the gas piping system of an anesthesia machine. With the cylinder valve on and pressure on the system, soapy water is applied to areas with potential for leaks. Bubbles will form if leaks are present.

40 to 50 psi) includes pipeline inlets, conduits from pipeline inlets to flowmeters, and conduits from regulators to flowmeters, the flowmeter assembly, and the oxygen-flush apparatus. Tests include visual inspection, listening for leaks, and use of soapy water solutions. The low-pressure area includes the vaporizer(s), conduits from the flowmeters to the vaporizer, a conduit from the vaporizer to the common gas outlet, and a conduit from the common gas outlet to the breathing system. Pressures are slightly above atmospheric. Routing tests include visual inspection and pressure checks with the breathing system. In many anesthesia machines, pressure applied to the breathing system affects the low-pressure area of the machine. Some newer anesthesia machines have check valves near the common gas outlet.

A universal negative-pressure leak test has been proposed for contemporary anesthesia machines to evaluate the low-pressure area. The test requires a simple suction bulb.¹⁶ The flowmeters and vaporizers are off during the test. The suction bulb is attached at the common gas outlet and squeezed until the bulb fully collapses, creating a vacuum in the low-pressure areas (Fig. 17.66). If the bulb reinflates in less than 10 s, a significant leak is present. The test is repeated with the control dial of the vaporizer on to detect any internal leaks that might not be found with the vaporizer off. This test differentiates between leaks in the low-pressure area of the machine (vaporizer) and the breathing system. The test can detect leaks as small as 30 mL/min and has been described as extremely reliable.

Anesthetic machines should be checked out each day before anesthetizing the first patient, and the breathing system should be evaluated before each patient. The operation manual for individual anesthesia machines gives specific guidelines for evaluation and checkout, and machines with special features require individualized attention. Ventilators on anesthesia machines and monitoring equipment should also be evaluated before beginning anesthesia. The following procedures are modified from the

Fig. 17.66. Universal negative-pressure leak test. With all gases off and the vaporizer off, a compressed rubber bulb is attached to the common gas outlet of the anesthesia machine. The bulb should not reinflate in less than 10 s. The test should be repeated with the vaporizer control on. From Andrews.¹⁶

“Anesthesia Apparatus Checkout Recommendations” from the FDA’s Center for Devices and Radiological Health¹ and are appropriate for evaluation of anesthesia machines and breathing systems before the first case of the day:

1. Check central oxygen and N₂O supplies for adequate quantities of gases and pipeline pressures.
2. Inspect the flowmeters, vaporizers, gauges, and supply hoses. Assure correct mounting of cylinders in the hanger yokes; the presence of a wrench for cylinder valve; and a complete, undamaged breathing system with adequate absorbent for carbon dioxide.
3. Assure that the waste-scavenging system is connected to the pop-off valve and is working properly. Leak tests for the scavenger system have been recommended.³ If a charcoal canister is being used, confirm that it is not exhausted.
4. Turn off the flow-control valves for the flowmeters.
5. Assure that the vaporizer is properly filled, with the filler cap sealed and the control dial off.
6. Check oxygen cylinders on the machine. With the pipeline supply disconnected, oxygen cylinder valve off, and pressure gauge at zero, slowly open the valve to check the pressure (500 psi) and determine the presence of leaks (a slow drop in pressure on the gauge) (Figs. 17.67 and 17.68). With multiple oxygen cylinders, each cylinder should be checked.
7. Check the N₂O supply (if present) as in step 6. If they are present, test the fail-safe devices to assure that N₂O cannot be delivered without an adequate amount of oxygen.
8. Test the flowmeters for each gas. With the flow-control valve off, the float should rest at the bottom of the glass tube. Adjust flow through the full range to assure proper function (no sticking or erratic movements).
9. Test the central pipeline supplies of oxygen and N₂O. With small (E) cylinders off and pipeline inlets connected to the cen-

Fig. 17.67. Oxygen cylinder with the pressure gauge reading 2000 psi. An oxygen cylinder should have at least 500 psi before the cylinder and anesthesia machine are used with a patient. With oxygen flowmeters off, the cylinder valve should remain on to allow evaluation of the machine for slow leaks.

Fig. 17.69. Checking the function of the expiratory one-way valve of a circle system. Wearing a surgical mask, the evaluator exhales through the Y piece and observes the expiratory one-way valve to ensure that the valve disk moves appropriately. The reservoir bag should expand as air moves through the valve.

Fig. 17.68. Oxygen cylinder with the pressure gauge reading at 1700 psi after 15 min with the cylinder valve open. If the cylinder pressure was 2000 psi at the start of the test and the flowmeters were off, a significant leak is present and should be corrected before the anesthesia machine is used with a patient.

tral gas supply, adjust flows to a midrange and assure that supply pressures remain near 50 psi.

10. With the vaporizer off, no odor of anesthetic should be present when the oxygen flowmeter is on.

11. For a circle system, test the function of the unidirectional valves. Wearing a surgical mask (Fig. 17.69), exhale through the exhalation limb to check the exhalation valve, and compress the reservoir bag (pop-off valve closed and Y piece open) to check the inhalation valve (Fig. 17.70). Valve disks should be present and should rise and fall appropriately.

12. Test for leaks in the circle breathing system and the anesthesia machine. Close the pop-off valve, occlude the Y piece, fill the system with oxygen, and turn the oxygen flow to 5 L/min. As the pressure in the system reaches 20 cm H₂O, reduce the flow until the pressure in the system (manometer) no longer rises. The oxygen flow should be negligible; a high leakage rate is unacceptable. Squeeze the reservoir bag to create a relatively high pressure (40 to 50 cm H₂O) and assure a tight system. In check-

Fig. 17.70. Checking the function of the inspiratory one-way valve of a circle system. With the pop-off valve closed, the reservoir bag is compressed, and the valve disk of the inspiratory one-way valve should move appropriately.

ing the circle system for leaks, one recommendation is to fill the circle (pop-off valve closed and Y piece occluded) to a pressure of 30 cm H₂O and assure that the leak rate is less than 250 mL/min³⁹ or that the pressure drop is less than 5 cm H₂O in 30 s or that the pressure remains at 30 cm H₂O for at least 10 s (Fig. 17.71).³ Others have recommended similar testing procedures with slightly different values for testing pressures and acceptable leak rates.^{61,62}

13. Open the pop-off valve slowly and observe the release of pressure. Occlude the Y piece and verify that only a negligible positive or negative pressure develops with an oxygen flow rate of zero or 5 L/min.

14. Assure that the pop-off valve provides relief of pressure when the flush valve is activated.

15. Similar to the circle system, non-rebreathing systems should be tested before use. For a complete system check of a Bain system, the patient port should be occluded, the relief valve closed, and the reservoir bag distended. The bag should remain

Fig. 17.71. Evaluation of the integrity of a circle breathing system. The pop-off valve is closed, the patient port is occluded, and the system is filled to a pressure of 30 cm H₂O for at least 10 s, or the leak as determined by use of the oxygen flowmeter should be less than 250 mL/min.

Fig. 17.72. Evaluation of a Bain breathing system (Kendall, Boston, MA) with a complete system check. With all gas flows off, the overflow valve is closed and the patient port is occluded. The bag is filled with the flush valve to a pressure of 30 cm H₂O, and a leak-free system should maintain this pressure for at least 10 s. If a leak is present, it can be quantified with the oxygen flowmeter and should not exceed 300 mL/min. From Dorsch and Dorsch.³

fully distended, and pressure within the system should not decrease (Fig. 17.72). The complete system check does not assure a leak-free inner tube of the coaxial system. Therefore, the inner tube is evaluated by temporarily occluding the inner tube at the patient end with oxygen flowing at approximately 1 to 2 L/min (Fig. 17.73). During a short period of occlusion with an instrument such as the plunger of a syringe, the float in the oxygen flowmeter should fall (Fig. 17.74).^{2,3} The complete system check will usually suffice for other non-rebreathing systems (e.g., Norman mask elbow and Ayre's T-piece systems).

Fig. 17.73. Evaluation of the inner tube of a Bain breathing system. The first step is to turn on the oxygen flowmeter. In this example, the flow of oxygen was set at 1 L/min.

Fig. 17.74. Evaluation of the inner tube of a Bain breathing system. The second step is to occlude the patient end of the inner tube. If the inner tube is intact, the oxygen flowmeter's indicator (e.g., ball or bobbin) should fall (stop flow). From Dorsch and Dorsch.³

The tests mentioned here should be considered the minimum. The operation manual for a specific anesthesia machine usually provides appropriate per-use checkout procedures, and numerous other tests have been described to evaluate anesthesia apparatus.³ Depending on the type of anesthesia machine, breathing system, ventilator (manual or mechanical), and monitoring equipment, other tests may be indicated. Veterinarians should familiarize themselves with the evaluation procedures that are most appropriate for their specific anesthesia apparatus.

Introduction

Safe anesthesia includes establishment of a patient airway with assurance of adequate ventilation and oxygenation. If spontaneous ventilation is insufficient, the anesthetist should provide supplemental oxygen during the preanesthetic, induction, maintenance, and recovery phases of anesthesia.

Endotracheal Intubation

Indications

Indications for endotracheal intubation include maintenance of a patent airway, protection of the airway from foreign material, application of positive-pressure ventilation, application of tracheal

or bronchial suction, administration of oxygen, and delivery of inhalant anesthetics. Placement of an endotracheal tube also reduces anatomical dead space if the tube is of the correct size and correctly positioned. For maintenance of inhalant anesthesia, an endotracheal tube should create a seal with the trachea to prevent leakage of anesthetic gases into the environment. An endotracheal tube is basic for endotracheal intubation, but ancillary equipment may be required in certain species. Intubation can be accomplished through the oral cavity, nasal passages, an external pharyngotomy, or tracheostomy.

Endotracheal Tubes

Murphy-type and Cole-type endotracheal tubes are commonly used in veterinary anesthesia. Uniquely, the Murphy tube has an opening, called a *Murphy eye* or *side hole*, in the wall opposite the bevel (Fig. 18.1); this hole allows gas flow, even if the end hole is occluded.¹ Characteristics of cuffed Murphy endotracheal tubes designed primarily for human patients are diagrammed in Fig. 18.2; such tubes are used in most veterinary patients for which appropriate sizes are available.

Cole tubes are uncuffed and are characterized by a shoulder near the distal end (Figs. 18.3 and 18.4); the diameter of the patient end of the Cole tube is smaller than the remainder of the tube.¹ Only the smaller portion of the tube should fit into the larynx and trachea. Although fitting the sloping shoulder of the Cole tube against the arytenoid cartilage creates a seal,² Dorsch and Dorsch indicate that, to avoid pressure against the laryngeal cartilages and to prevent laryngeal dilation, the shoulder should not contact the larynx.¹ The diameter of the tube should be such that the laryngotracheal part of the tube creates a seal, which guards against egress of gas and aspiration of foreign material. An effective seal can be established in veterinary patients of various sizes.^{2,3}

Endotracheal tubes are made of polyvinyl chloride (PVC), rubber, silicone, and occasionally other plastic or rubberized materials. The most common tubes for human use are made of PVC,¹ many of which are used in small animals. Some endotracheal tubes, designed specifically for veterinary patients, are made of silicone rubber (Fig. 18.5). In general, endotracheal tubes should be clear so that they can be inspected for cleanliness or obstructions before each use. Red rubber tubes have been advertised for veterinary patients; such tubes are opaque, prone to cracking, and difficult to clean and disinfect.

Cuffed endotracheal tubes (Fig. 18.6) designed for human patients consist of a connector to fit the breathing system (15 mm

Fig. 18.1. A Murphy endotracheal tube characterized by a side hole (Murphy eye) opposite the bevel at the distal end of the tube. The inflatable cuff, pilot balloon, self-sealing inflation valve, and syringe for inflation of the cuff are shown. The parts and characteristics of a Murphy tube are diagrammed and labeled in Fig. 18.2.

OD [outer diameter]), the tube itself, and a cuff system (inflating valve, inflating tube, and pilot balloon). Labels on these tubes may include the manufacturer's name, internal and external diameters in millimeters, markings in centimeters indicating the

Fig. 18.3. A 10-French Cole endotracheal tube appropriate for small veterinary patients. Note the smaller diameter of the laryngotracheal portion of the tube (distal end of the tube, right side of the photograph).

length of the tube from the patient (distal) end, and IT, which indicates that the tube has been implantation tested. In addition, tubes labeled with either F29 or Z79 indicate that the tube material has been tested for tissue toxicity.^{1,4} The terms *oral* and/or *nasal* may appear beside the tube's size for internal and external diameters, respectively. Some endotracheal tubes have the size in French units (French size = external diameter in millimeters times pi), which indicates the outside diameter of the tube. Radiopaque markers are embedded in some endotracheal tubes.

Inflation of the cuff of an endotracheal tube applies pressure to the tracheal mucosa. The perfusion pressure of the tracheal mucosa ranges from 25 to 35 mm Hg. A cuff pressure on the tracheal wall of 20 to 25 mm Hg will usually not interfere with tracheal mucosal blood flow.⁵ Greater pressures in the cuff can lead to is-

Characteristics of Common Endotracheal Tubes

Fig. 18.2. Diagram illustrating the parts and desirable characteristics (e.g., radius of curvature and angle of the bevel) of a Murphy endotracheal tube. OD, outer diameter. From Dorsch and Dorsch.¹

Fig. 18.4. Three sizes of Cole endotracheal tubes appropriate for large veterinary patients. Note the smaller diameter of the laryngotracheal portion of each tube (distal ends of the tubes, *left* side of the photograph). The proximal ends of the top two tubes are designed to fit the outside diameter of the Y piece of a circle breathing system for large animals.

Fig. 18.5. Silicone rubber endotracheal tubes designed for veterinary use. The proximal end of the top tube has been fitted with a connector that will conform to the outside diameter of a Y piece of a circle breathing system for large animals.

Fig. 18.6. A Murphy endotracheal tube designed for human patients, but commonly used for small animals. Numbers and markings indicate the internal (5.0 mm) and external (8.0 mm) diameters, the length (13, 15, 17, 19, 21, and 23 cm) of the tube from the patient end, the manufacturer (Sheridan), and tissue toxicity testing (Z79). The internal diameter (5.0 mm) and manufacturer are also shown on the pilot balloon.

chemic injury, mucosal damage, and ultimately tracheal strictures in serious cases. Therefore, the design of contemporary human endotracheal tubes includes a high-volume, low-pressure cuff that creates a good seal between the tracheal mucosa and the cuff wall when the cuff is properly inflated. The intent of the high-volume nonelastic cuff is to distribute the low-pressure seal over a relatively large area of the tracheal mucosa.⁴ A cuff should be inflated with the smallest amount of air that will provide effective protection of the airway. A general recommendation is that pressure on the lateral wall of the trachea exerted by the cuff be maintained between 25 and 34 cm H₂O.¹ Generally, a leak should occur around the cuff when pressure equal to approximately 25 cm H₂O is applied to the airway.

Armored or reinforced endotracheal tubes (Fig. 18.7) are specially designed with helical wire or plastic implanted within the wall of the tube to prevent kinking of the tube and obstruction of the airway when the patient's head and neck are flexed. Such tubes are useful for ophthalmic surgery, cervical spinal taps, myelograms, oral surgery, and head and neck surgery. Armored tubes have thicker walls than standard tubes, causing them to have smaller internal diameters than standard tubes of equivalent external size.⁴ Therefore, resistance to gas flow is increased, and reinforced tubes should not be used unnecessarily. Typically, these tubes are very flexible and more difficult to insert than standard PVC tubes. A stylet or guide tube will facilitate insertion of an armored tube into the larynx, but a stiff stylet should not extend past the distal end of the endotracheal tube.

Endotracheal intubation through a tracheostomy is sometimes necessary to provide a patent airway. Cuffed tracheostomy tubes with 15-mm-OD (outer diameter) connectors (Fig. 18.8) are available for use in human patients. However, standard endotracheal tubes for both large and small animals may be placed via

Fig. 18.7. An armored endotracheal tube with a spiral wire embedded in the wall of the tube: the endotracheal tube connector, bite guard near the proximal end of the tube, inflatable cuff, pilot balloon, inflation line, and self-sealing inflation valve.

Fig. 18.9. A silicone rubber endotracheal tube placed through a tracheostomy site to facilitate inhalant anesthesia for oral and nasal surgery in a foal.

From *left to right* are the cuffed tracheostomy tube with inflation line and pilot balloon, a removable lumen for the tube, an obturator to facilitate insertion of the tube, and another removable lumen.

Fig. 18.10. An endotracheal tube placed by external pharyngotomy in a small dog to facilitate oropharyngeal surgery. From Hartsfield.¹⁹

tracheostomy to facilitate general anesthesia (Fig. 18.9). Endotracheal tubes are also recommended for intubation by external pharyngotomy (Fig. 18.10).⁶

Normally, endotracheal intubation is accomplished in anesthetized patients. Forced intubation in awake or lightly anesthetized patients should be avoided unless dictated by special circumstances. Traumatic intubation can produce laryngeal edema, laryngeal spasm, hemorrhage, and vagal stimulation leading to bradycardia and other arrhythmias. Direct application of a local anesthetic (e.g., lidocaine [Fig. 18.11]) to the larynx may prevent laryngeal spasms in susceptible animals (e.g., cats and swine). The local anesthetic can be sprayed into the larynx, applied with a cotton swab, or squirted from a syringe and hypodermic needle.

When using a syringe, the hypodermic needle must be firmly attached to prevent its dislodgment and entrance into the larynx. The total dose of local anesthetic should not approach a toxic dose, based on the patient's species and body weight. In very small patients, spraying local anesthetic onto the larynx can easily exceed a toxic dose.

Endotracheal and tracheostomy tubes should be cleaned thoroughly after use. The tubes should be gently scrubbed with a soft brush, rinsed, dried, and sterilized or disinfected. If ethylene oxide is not available, chemical disinfectants can be used; glutaraldehyde has been recommended.⁷ After disinfection, tubes should be rinsed thoroughly, according to recommendations for use of the disinfectant, and dried. If tubes are inadequately

Fig. 18.11. Lidocaine as a spray (*left*) or as a liquid (applied with a cotton swab or delivered by squirting it with a syringe and needle) can be applied topically to the larynx to facilitate endotracheal intubation in various species. With either method of delivery, the anesthetist should keep the total dose of lidocaine less than the toxic dose for the patient and species involved.

rinsed, tissue reactions to the disinfectant can occur. Ethylene oxide sterilization should be performed according to the manufacturer's recommendations for the product and its sterilization equipment. Endotracheal tubes should be clean and dry before they are sterilized with ethylene oxide. Appropriate aeration time should be allowed between sterilizing a tube and its use in a patient: typically 2 days at 120°F (49°C) in an aeration chamber or 14 days if no aeration chamber is available. Failure to allow sufficient aeration time can cause serious respiratory complications.⁸ Most endotracheal or tracheostomy tubes should not be autoclaved; however, silicone rubber tubes can be steam autoclaved.^{7,9}

Laryngoscopy is required for endotracheal intubation of some species. Often, the laryngoscope's light source is the main benefit of laryngoscopy, but the blade can be used to manipulate the tongue, soft palate, and epiglottis to view the glottis (Fig. 18.12). Useful blades include the Miller, the McIntosh, and the Bizarri-Guiffrida (Figs. 18.13 and 18.14), and other blades are available. Different lengths of blades are needed for various species. As examples, very short blades designed for human infants are useful in rabbits, and blades up to 205 mm designed for human adults are appropriate for large dogs. Specially designed, very long (350 to 450 mm) blades can be purchased for veterinary use and may be needed in llamas, cattle, swine, and other species.

Techniques of Endotracheal Intubation

Dogs

For most dogs, an endotracheal tube and adequate lighting are the only necessities for intubation of the trachea. However, the use of a laryngoscope, a stylet to stiffen the endotracheal tube, a guide tube (Fig. 18.15), sterile water-soluble lubricant, a mouth speculum, and local anesthetic may be desirable and even necessary under certain circumstances.

Fig. 18.12. Diagram of the correct positioning of a laryngoscope blade for maximum visualization of the larynx. Note that the dog's mouth is opened widely, its tongue is extended from its mouth maximally, and the tip of the laryngoscope blade is positioned at the base of the epiglottis.

Fig. 18.13. From *left to right*, an adult Miller laryngoscope blade, an adult Bizarri-Guiffrida blade, a pediatric Miller blade, and a pediatric Bizarri-Guiffrida blade on a laryngoscope handle. The Bizarri-Guiffrida blades allow the maximum field of view without the interference of a flange.

Fig. 18.14. End-on view of Miller (*left*) and Bizarri-Guiffrida (*right*) laryngoscope blades. The Bizarri-Guiffrida blade allows maximum space for passage of the endotracheal tube, and the Miller blade provides a flange to elevate redundant tissue (e.g., soft palate).

Fig. 18.15. Photograph of a silicone rubber endotracheal tube with a 10-French canine polyethylene urinary catheter preplaced for use as a guide tube. The guide tube will pass easily through the larynx and into the cranial part of the trachea to facilitate passage of the endotracheal tube.

Fig. 18.16. Diagram of the correct placement of an endotracheal tube in a dog. Note that the connector is located near the incisor teeth to minimize mechanical dead space and that the cuffed end of the tube is in the cervical trachea near the thoracic inlet.

Sizes of endotracheal tubes for canine patients range from 1.5 mm to approximately 15 mm ID (internal diameter).² It is difficult, if not impossible, to find cuffed tubes smaller than 3.0 mm ID. There are breed differences that preclude generalizations about the choice of tube diameter based on a patient's body weight or some other arbitrary guide. For example, a 25-kg English bulldog usually accepts only about a 7.5-mm-ID endotracheal tube, but a 25-kg mixed-breed dog may easily accept a 10-mm tube. Most tubes designed for human patients are too long for dogs and should be cut at the proximal end to fit the patient; the connector should be positioned at the level of the dog's incisors, and the distal end should be located in the trachea near the thoracic inlet (Fig. 18.16).

After induction of anesthesia, the dog is positioned in sternal recumbency for intubation. An assistant holds the dog's head with one hand, placing the finger and thumb behind the maxillary canine teeth and pulling the dog's lips upward to create the best field of view. With the other hand, the assistant opens the dog's mouth widely and extends its tongue. The assistant should not

Fig. 18.17. An endotracheal tube secured to a dog's maxilla with a piece of rolled gauze. Note that the gauze is tied tightly around the tube without constricting the lumen, that the connector is at the level of the incisor teeth, and that the gauze is positioned immediately caudal to the maxillary canine teeth and tied in a bow.

put pressure under the dog's neck because the view of the larynx will be obstructed by the soft palate. With a good light source, most dogs can be intubated without a laryngoscope. If an assistant is unavailable, an oral speculum will keep the dog's mouth open during intubation. In small patients, dogs with oral or pharyngeal lesions, and brachycephalic dogs, a laryngoscope facilitates intubation and should always be available if difficulty should arise. The endotracheal tube should be secured to prevent its dislocation during anesthesia. Using a piece of rolled gauze, the tube can be tied to the maxilla (Fig. 18.17), the mandible, or behind the head, depending on the breed, the type of surgery, the presence and condition of the canine teeth, and the anesthetist's preference.

Extubation should be done when the dog's oral and pharyngeal reflexes have returned. The tube should be pulled directly between the upper and lower incisor teeth. If a tube is allowed to deviate laterally, the dog may shear the tube. This damages tubes and creates the potential for aspiration or ingestion of a part of the tube.

Cats

The primary equipment required for feline intubation are an endotracheal tube and a light source. However, a laryngoscope, a stylet to stiffen the endotracheal tube, a guide tube (canine polyethylene urinary catheter), sterile water-soluble lubricant, a mouth speculum, and local anesthetic may be useful. If a wire stylet is used to stiffen the tube, the stylet should not extend past the distal end of the tube to avoid injury to the trachea.² Inadequate depth of anesthesia is probably the most common reason for difficult intubation.

Sizes of endotracheal tubes for domestic cats range from 1.5 mm to approximately 5.5 mm ID; most adult cats readily accept 4.0- to 4.5-mm-ID tubes, a range that provides optimal internal diameter with minimal difficulty in intubation. It is difficult to

Fig. 18.18. Illustration of an excellent method of positioning a cat for endotracheal intubation. Note the secure grip on the maxilla with the index finger and thumb caudal to the canine teeth. The tongue is extended, maximizing the field of view.

Fig. 18.19. View of a cat's glottis using the restraint and positioning depicted in Fig. 18.18. The laryngoscope blade is placed on the tongue with the tip just ventral to the epiglottis.

find cuffed tubes smaller than 3.0 mm ID, and such sizes may be needed for small kittens. One option is to use small Cole tubes. Since most endotracheal tubes designed for human patients are too long for cats, the tube should be cut at the proximal end to fit the patient. The proximal end of the tube should be positioned at the level of the cat's incisors, and the distal end should be located in the trachea near the thoracic inlet.

After induction of anesthesia, the cat should be positioned in sternal recumbency. Although not necessary in every case, local anesthetic (0.5% lidocaine) may be applied to the larynx to desensitize the arytenoid cartilage and epiglottis to help prevent laryngospasm during intubation. An assistant holds the head with one hand, placing a finger and thumb behind the cat's maxillary canine teeth and pulling the lips upward to create the best field of view (Figs. 18.18 and 18.19). With the other hand, the assistant extends the cat's tongue. If the tongue is not protruding from the mouth, the laryngoscope blade can be used to manipulate the tongue so that the assistant can grasp it. Neither the anesthetist nor the assistant should put their fingers into a lightly anesthetized cat's mouth. The assistant should not put pressure under the cat's neck because the view of the larynx may be obstructed by the soft palate. As in dogs, with a good light source, most cats can be intubated without the aid of a laryngoscope. However, a laryngoscope is often helpful. The blade should not touch the arytenoid cartilage or the epiglottis (Fig. 18.18) because such stimulation may cause active closure of the glottis. A laryngoscope should always be available for a difficult intubation (e.g., oral or pharyngeal lesions). If an assistant is unavailable, an oral speculum will keep the cat's mouth open while intubation is accomplished. The routine use of a guide tube (5- to 8-French canine urinary catheter) that extends past the cuffed end of the endotracheal tube (Fig. 18.18) for 2 or 3 cm often makes feline intubation easier. As the endotracheal tube is advanced toward the glottis, rotating it from 0° to 90° or greater will facilitate its passage. Rolled gauze can be used to secure the tube behind the

Fig. 18.20. A endotracheal tube (4-mm internal diameter) sheared during extubation of a cat at the time of recovery from anesthesia. Aspiration or ingestion of the smaller piece is possible.

cat's head with a simple bow knot. In cats, the tube should be tied for rapid removal at recovery.

Extubation should be done when the cat's oral and pharyngeal reflexes have returned. The tube should be pulled directly between the upper and lower incisor teeth. If a tube is allowed to move laterally, the cat may shear the tube (Fig. 18.20), which creates the potential for aspiration or ingestion of part of the tube.

Horses

Blind passage of the endotracheal tube in horses can be aided by a mouth speculum. For routine intubation, PVC connectors (10 cm long, variable diameters) for PVC pipe make economic, effective specula that can be placed between the horse's upper and lower incisors to protect the tube. The connectors can be wrapped with adhesive tape to increase friction between the teeth and the speculum.⁷ Other supplies that may be useful for equine intubation under certain conditions include a guide tube (equine stom-

ach tube), sterile water-soluble lubricant, local anesthetic, and a fiber-optic endoscope.

To assure an appropriate range of sizes of endotracheal tubes for equine patients (miniature horses to draft horses), tubes as small as 7 mm ID and as large as 30 mm ID should be available. Larger sizes (e.g., 35 mm ID) have been recommended for large thoroughbred and draft horses.¹⁰ Tube size varies with the size of the patient and with the location of the tube (oral versus nasal intubation). Modern 26-mm-ID silicone rubber cuffed endotracheal tubes are appropriate for a high percentage of adult horses, with 30-mm tubes indicated for very large horses. In general, a tube that is passed nasally should be about two sizes smaller than a tube that is passed orally.⁹

In preparation for oropharyngeal intubation, the horse's mouth should be flushed with water to remove any debris that may be retained in the oropharynx, including the cheek pouches. Horses are positioned in lateral recumbency for intubation with a lubricated endotracheal tube. A sterile water-soluble lubricant should be used; lubricants containing local anesthetic are unnecessary and may irritate airway tissues.^{7,11} The mouth speculum is placed between the upper and lower incisors, the head and neck are extended, and the endotracheal tube is advanced into the pharynx until the tip of the tube touches the larynx. In some patients, the tube enters the larynx without any interference. However, several attempts (a series of 10- to 15-cm advancements and retractions of the tube, with rotation of the tube from 0° to 90° or greater as it approaches the glottis) may be necessary for intubation, even in normal horses. Although the technique is somewhat of an art, intubation can be facilitated by maximally extending the horse's head and neck in a straight line with the its back (best done by an assistant), extending the tongue during intubation, and holding the endotracheal tube so that the proximal end is curved below the mandible during attempts at intubation. In general, an endotracheal tube of proper size can be passed into the larynx with little if any resistance once correct positioning and technique have been established.

For difficult intubation, an equine stomach tube (guide tube) may be passed into the larynx and trachea, over which the endotracheal tube can be manipulated through the larynx and into the trachea. In some instances (e.g., laryngeal or pharyngeal abnormalities), equine intubation may be successful only after visualizing the glottis with a fiber-optic endoscope; this allows adjustments in the position of the endotracheal tube or a guide tube as it approaches the glottis.

A properly positioned endotracheal tube is usually obvious to an experienced anesthetist because of the absence of resistance as the tube enters the larynx and trachea. Air flow into and out of the tube during spontaneous ventilation can be used to verify tube placement. Some veterinarians advocate compression of the thorax to create air flow from a properly placed tube, but this technique may not be foolproof. Finally, water may condense on the inner surface of the tube during exhalation if the tube is placed properly.

Swine

Endotracheal intubation of swine is relatively difficult for several reasons:¹² The distance from the tip of the snout to the larynx is

Fig. 18.21. Sagittal section of a pig's larynx. This illustrates the irregular course that an endotracheal tube must travel as it moves through the larynx and into the cranial trachea: a, tracheal opening; b, dorsal cricoid cartilage; c, arytenoids cartilage; d, ventral cricoid cartilage; e and i, thyroid cartilage; f, entrance to lateral laryngeal ventricle; g, posterior floor of the larynx; h, tip of endotracheal tube; j, middle laryngeal ventricle; and k, and epiglottis. Reproduced by permission of Dr. William Tranquilli.

comparatively long, the mouth does not open widely, the larynx is rather loosely attached, mobile, relatively small, and slopes ventrally, creating a sharp angle for passing an endotracheal tube (Fig. 18.21). In addition, laryngospasm is rather easily induced in lightly anesthetized pigs. An endotracheal tube, a laryngoscope, 2% lidocaine in a syringe, sterile water-soluble lubricant, and a guide tube should be available for intubation of swine.

Compared with other domestic species, swine have small laryngeal and tracheal diameters. Endotracheal tube sizes from 3 mm ID in piglets to 16 mm ID in larger swine may be needed. Mature sows and boars may accept even larger tubes. After induction of anesthesia, the pig is placed in sternal recumbency, an assistant holds the head with a small rope or piece of rolled gauze passed through the mouth, and the pig's tongue is extended. A mouth speculum can be employed, if necessary. Using the appropriate length of blade, the pig's larynx is visualized with the aid of a laryngoscope; this usually requires some manipulation to position the blade for a good view of the glottis, especially in large swine with a narrow pharynx and excessive tissue in the area of the soft palate. Lidocaine can be squirted onto the larynx for desensitization. The guide tube (usually two 10-French canine urinary catheters in tandem) is passed through the larynx and into the trachea; the guide tube should be manipulated through the larynx without excessive force, and best results are obtained by passing the guide tube along the dorsal aspect of the larynx to the midcervical trachea. Then, a well-lubricated endotracheal tube is directed over the guide tube, through the larynx, and into the trachea; firm, gentle advancement of the tube with a simultaneous twisting motion (0° to greater than 90°) is helpful. The tube should be positioned with the connector at the level of the tip of the snout, and the distal end should be near the thoracic inlet. The cuff should be inflated with the minimum amount of air that will

create a seal. The tube can be secured to the snout with adhesive tape or behind the ears with rolled gauze.

Miniature pet pigs are intubated by using the same equipment (smaller sizes) and method just described, but gentle technique should be emphasized. Laryngospasm, laryngeal edema, and death have been associated with traumatic intubation in miniature pigs.¹³

Cattle

The primary implements for endotracheal intubation in adult cattle are endotracheal tube, a mouth speculum (e.g., Bayer dental wedge, Guenther mouth speculum, Weingart mouth speculum, or Drinkwater mouth gag), and an equine stomach tube (two to three times longer than the endotracheal tube) for use as a guide. For smaller cattle, a long laryngoscope blade (e.g., 14, 16, or 18 inches) may be necessary for passage of a guide tube. Sizes of endotracheal tubes ranging from 18 to 30 mm ID may be needed for adult cattle.

After induction of anesthesia, a mouth speculum is positioned to hold the mouth open; this helps to prevent damage to the endotracheal tube cuff and to the anesthetist's hand and arm during intubation. The cow's tongue is extended from the mouth as its head and neck are extended. The anesthetist passes one hand through the cow's mouth and palpates the epiglottis and glottis. The anesthetist passes the guide tube into the pharynx and then slides the tube through the glottis, assuring the tube's proper placement by palpation as it enters the larynx. The guide tube is advanced until its tip is in the midcervical trachea. After the anesthetist's arm is removed from the cow's mouth, the endotracheal tube is advanced over the guide tube and into the cow's larynx and trachea. Rotation of the tube from 0° to greater than 90° as the tube approaches the arytenoid cartilage will help to advance the endotracheal tube into the trachea. The cuff should be inflated immediately to decrease the likelihood of aspiration of regurgitated rumen contents. Should active or passive regurgitation of large quantities of ruminal content occur just before or simultaneously with endotracheal intubation, external pressure applied over the esophagus will halt the flow of ruminal contents. Alternatively, the endotracheal tube can be quickly passed into the esophagus and the cuff inflated, permitting the regurgitant to flow through the endotracheal tube beyond the pharynx and out of the mouth, preventing its aspiration into the lungs. A properly positioned endotracheal tube in a cow is shown in Fig. 18.22.

Bovine intubation can be accomplished without a guide tube. The endotracheal tube is passed beside or under the anesthetist's arm and palpated as it enters the cow's larynx.¹² Alternately, the anesthetists can take the tube into the cow's mouth, cupping the distal end of the tube in the hand.¹⁴ The disadvantage of either method is that the size of the endotracheal tube that can be readily passed is limited, especially if the anesthetist has a large arm.

Small Ruminants

Equipment required for endotracheal intubation in small ruminants includes an endotracheal tube, a laryngoscope, and a guide tube. Endotracheal intubation in small ruminants (sheep, goats, calves, cattle weighing less than about 250 kg, deer, and exotic

Fig. 18.22. A silicone rubber endotracheal tube (26-mm internal diameter) placed in a cow. The tube was passed with the Weingart mouth speculum in place as shown.

ruminants) is best accomplished by direct visualization of the larynx with an illuminated laryngoscope. Sternal recumbency facilitates the procedure, but intubation can be achieved during lateral recumbency. After induction of anesthesia, an assistant holds the animal's head while the anesthetist extends its tongue. The anesthetist passes the laryngoscope blade over the base of the tongue to visualize the glottis, and then passes a guide tube (e.g., a small equine stomach tube in calves or a polyethylene catheter in sheep or goats) into the larynx and into the trachea to about the midcervical area. The laryngoscope is removed, and the endotracheal tube is passed over the guide tube and into the trachea. The cuff is inflated immediately to decrease the likelihood of aspiration of regurgitated rumen contents. The use of a metal rod has been advocated as a guide tube.¹⁴ Excessive force with a metal guide tube increases the risk of damaging the larynx or trachea and is not recommended.

Nasotracheal Intubation

This is commonly used in foals for the administration of inhalant anesthetics during induction.⁹ The technique can be also be used in calves and adult horses, and its use has been described in llamas.¹⁵

The characteristics of an ideal nasotracheal tube include a tube with minimal curvature and extra length (55 cm). The tube should be made of inert material (e.g., silicone rubber) and have relatively thin walls for maximum internal diameter. The tube should resist kinking. Low-volume, high-pressure cuffs may be less traumatic during placement, but high-volume, low-pressure cuffs may be best for longer periods of anesthesia. Tubes as small as 7 mm ID may be necessary for neonatal foals. In general, in any given patient a nasotracheal tube should be one to two sizes smaller than the appropriately sized orotracheal tube.⁹ Once induction is completed using a nasotracheal tube, the nasotracheal tube can be removed and replaced with an appropriately sized orotracheal tube to decrease resistance to gas flow.

Nasotracheal intubation (Figs. 18.23 through 18.26) involves passage of a properly sized endotracheal tube through the nostril

Fig. 18.23. Restraint of a nontranquilized foal for nasotracheal intubation. A lubricated tube is directed through the ventral meatus.

(Fig. 18.23), ventral nasal meatus, and larynx and into the trachea. Lidocaine gel (10%) is a good lubricant for the tube and should be applied to the nostril and rostral portion of the nasal passage before advancing the tube in awake animals. A sterile water-soluble lubricant without lidocaine is appropriate for anesthetized patients. With the patient's head and neck extended, the tube is advanced into the pharynx and passed into the larynx on inspiration. Air moves freely through a correctly placed tube during spontaneous ventilation. Taping the tube to the muzzle is appropriate (Fig. 18.26).

For uncooperative foals and calves, sedation may facilitate nasotracheal intubation. Some awake patients cough and close the glottis in response to the tube contacting the larynx. With the nasotracheal tube positioned with the cuffed end near the larynx, 2% lidocaine solution can be flooded onto the larynx via the tube (Fig. 18.24). This desensitizes the larynx and eases intubation.

Extubation following nasotracheal intubation should be done carefully. After deflation of the cuff, the tube should be withdrawn slowly and deliberately, with the patient's head restrained to avoid any sudden, jerky motions. Rapid, rough extubation may cause unnecessary nasal hemorrhage.

Fig. 18.24. Lidocaine (2%) being injected through the endotracheal tube, the distal end of which is near the foal's glottis. The lidocaine should desensitize the epiglottis and arytenoid cartilages to facilitate passage of the tube through the glottis.

Rabbits and Other Laboratory Animals

Intubation techniques for rabbits and other small laboratory animals have been described.¹⁶ Most techniques for intubation of small laboratory animals include the use of a laryngoscope or a modified otoscope to expose the glottis, a catheter or stylet to serve as a guide tube, a small-diameter lubricated endotracheal tube, and lidocaine to desensitize the larynx before passing the endotracheal tube. In laboratory rabbits weighing about 3.0 kg, the use of 3.5-mm-ID, 14-cm-long endotracheal tubes are appropriate.¹⁷

The rabbit has been described as perhaps the most difficult animal to anesthetize.¹⁸ Undoubtedly, problems with airway management influenced that opinion. However, the technique for endotracheal intubation in rabbits can be mastered with practice when using proper equipment. Guide-tube technique causes minimal trauma during intubation and allows selection of the largest suitable endotracheal tube. Endotracheal intubation in rabbits requires gentle manipulations. Rough technique invariably leads to

Fig. 18.25. A nasotracheal tube is positioned in the trachea and ready to be secured to the patient. The proximal end of the tube extends a few centimeters from the nostril to facilitate taping (see Fig. 18.26).

Fig. 18.26. A nasotracheal tube secured to a foal's muzzle. The cuff has been inflated, and an adult Bain breathing system has been connected to the endotracheal tube to facilitate induction of anesthesia with isoflurane in oxygen.

trauma to the tongue, pharynx, larynx, or trachea. Trauma with associated edema and hemorrhage can cause lethal complications.

Rabbits can be intubated when positioned in sternal recumbency with the head and neck extended and the fleshy tongue gently withdrawn from the mouth (Figs. 18.27 to 18.30). The rabbit's head can be held with a piece of rolled gauze placed caudal to the maxillary incisors. A size-0 Miller laryngoscope blade (75 mm long) is used to expose the glottis; the blade is carefully manipulated lateral to the maxillary incisors, into the mouth, and over the base of the tongue to expose the soft palate, epiglottis, and glottis. All are very fine, but distinct, anatomical structures. The epiglottis may be positioned behind the soft palate. The anesthetist should definitively identify the glottis before proceeding. Then, a guide tube (a 5- to 8-French canine urinary catheter) can be passed through the larynx and into the midcervical trachea, about 2 cm past the glottis (Fig. 18.27). The guide tube should not be forced because the trachea is easily torn, which can eventually lead to subcutaneous emphysema, pneumothorax, pneumomediastinum, pneumoabdomen, or death. The endotracheal tube is passed over the guide tube, through the larynx, and

Fig. 18.27. Endotracheal intubation in a rabbit. The rabbit is positioned in sternal recumbency, the glottis has been exposed with a size-0 Miller blade, and the anesthetist is passing a 7-French canine urinary catheter to serve as a guide tube for intubation.

Fig. 18.28. Endotracheal intubation in a rabbit. The endotracheal tube is advanced over the guide tube and into the mouth (the distal end of the guide tube is located 2 cm caudal to the cricoid cartilage).

Fig. 18.30. Endotracheal intubation in a rabbit. The distal end of the endotracheal tube has been advanced through the larynx to its final position in the midcervical trachea. The anesthetist is preparing to extract the guide tube and secure the endotracheal tube behind the rabbit's ears.

Fig. 18.29. Endotracheal intubation in a rabbit. The distal end of the endotracheal tube is located just rostral to the glottis, the tip of the guide tube is in the cervical trachea, and lidocaine is flushed through the lumen of the endotracheal tube to desensitize the larynx before advancement of the endotracheal tube.

into the trachea. If resistance to passing the endotracheal tube through the glottis is apparent, less than 0.5 mL of 2% lidocaine can be flushed through the endotracheal tube to the larynx. The lidocaine desensitizes the larynx, and intubation usually proceeds uneventfully. The cuff should be inflated minimally, the pilot balloon should remain soft, and a leak around the cuff should occur at an inspiratory pressure of about 15 cm H₂O. The tube should be secured with rolled gauze behind the rabbit's ears. Alternatively, in large rabbits, a blind approach to endotracheal intubation is often successful when the head and neck are maximally extended and the endotracheal tube is advanced into the remiglottis. Intubation of the trachea is expedited at this point by listening for air movement through the tube while gently advancing it beyond the larynx into the trachea.

Birds and Reptiles

Endotracheal intubation in birds and reptiles that are commonly presented for anesthesia is relatively easy. The glottis is usually located on the midline at the base of the tongue and is readily apparent when the patient's mouth is opened. Appropriately sized endotracheal tubes should be selected, and, to avoid damage to the tracheal rings if cuffed tubes are used, the cuff should not be overinflated. Owing to the small size of some birds and reptiles and the propensity for mucus to collect in the distal end of the tube, the anesthetist should be careful to assure a patent airway at all times. The use of lubricating jelly can also cause the obstruction of air flow through small endotracheal tubes.

Special Techniques for Endotracheal Intubation

The common techniques for endotracheal intubation may fail if oropharyngeal pathology is present (Fig. 18.31) or if movement of the temporomandibular joint is impaired. In such patients, "blind" intubation can be performed successfully on occasion. With the patient's head and neck extended, the larynx can be manipulated externally with one hand while the other hand maneuvers the tube through the larynx and into the trachea. However, if this technique is too traumatic or fails completely, other options for intubation are available.

Guide-Tube Technique

In some patients, a laryngoscope blade will allow exposure and illumination of the glottis by diverting the obstruction to one side, enabling direct placement of the endotracheal tube into the larynx. However, it may be easier to pass a small-diameter guide tube (e.g., a canine urinary catheter), rather than an endotracheal tube, through the glottis. Guide-tube technique has been previously described for various species, and it can be beneficial in dogs and cats with oropharyngeal pathology.¹⁹ Once the tip of the guide

Fig. 18.31. In this dog, a pharyngeal tumor is obstructing the larynx and inhibiting passage of an endotracheal tube. Intubation was accomplished by using a laryngoscope blade to expose the glottis enough for a guide tube to enter the larynx, followed by passage of the endotracheal tube over the guide tube. From Hartsfield.¹⁹

tube is situated about half the distance from the cricoid cartilage to the thoracic inlet, the endotracheal tube can be passed into place (Fig. 18.32). Then, the guide tube is removed, and the endotracheal tube is secured as appropriate for the species involved.

Retrograde Intubation

If direct visualization of at least a portion of the glottis is impossible, other techniques of intubation have been advocated.^{19,20} One method—use of a retrograde guide tube or wire—involves passing a hypodermic needle through the skin of the neck and into the trachea at the junction of the second and third tracheal rings. In human patients, the needle is passed through the crico-

thyroid membrane. A guidewire is then maneuvered through the needle cranially into the larynx, pharynx, and oral cavity until it can be used as a guide for passage of an endotracheal tube (Fig. 18.33). After the tip of the endotracheal tube is within the larynx, the needle and the guide tube are removed, and the endotracheal tube is manipulated into its final position with the cuffed end near the thoracic inlet. The cuff should be located caudal to the puncture site of the hypodermic needle to avoid forcing gases subcutaneously or into the mediastinum during positive-pressure ventilation. Subcutaneous emphysema and pneumothorax are possible complications with this technique.

Lateral Pharyngotomy

This technique has been described⁶ and has been advocated for selected canine and feline patients requiring oropharyngeal surgery or orthopedic procedures involving the mandible or maxilla (Fig. 18.10). The major advantages are improved visualization within the operative field during oropharyngeal surgery and normal dental occlusion to aid in the proper reduction of mandibular or maxillary fractures.

The basics of tube placement involve passage of a correctly sized, cuffed endotracheal tube and a routine skin incision made near the angle of the mandible. Then, hemostats are bluntly passed through the skin incision into the caudal part of the pharynx. After the endotracheal tube adapter has been removed, the adapter end of the tube is grasped and pulled from the pharynx, through the subcutaneous tissue, and through the skin incision. The endotracheal tube adapter is replaced, and the tube is reconnected to the breathing system for maintenance. A correctly placed tube should be secured to the skin with tape and several sutures.

Using an Endoscope

Laryngoscopy with a flexible fiber-optic endoscope can be useful for intubation in patients with abnormal anatomy or disease

Fig. 18.32. Diagram illustrating passage of an endotracheal tube into the trachea of a dog by using a guide tube. From Hartsfield.¹⁹

processes involving the pharynx or head and neck. Depending on the species and the specific conditions, the endoscope can be placed inside the endotracheal tube to directly guide intubation passed orally beside the endotracheal tube, or advanced through the nasal passage to view the endotracheal tube entering the glottis. The technique can be particularly advantageous in horses with abnormal oropharyngeal, laryngeal, and/or nasal anatomy, and can be helpful in small laboratory species that are difficult to intubate. The technique is applicable to any species that are difficult to intubate. The technique is applicable to any species in which intubation is impaired by anatomical abnormalities or disease. The technique is illustrated in a normal cat in Figs. 18.34 through 18.36.

Tracheostomy

A temporary tracheostomy can be chosen for airway management in lieu of the techniques suggested earlier for difficult cases. In some patients, the only reasonable option for intubation is tracheostomy, and some patients with airway disease arrive in the induction room with a tracheostomy tube in place. For anesthesia, intubation of the trachea through the tracheostomy site provides all of the advantages of oral intubation or intubation by pharyngotomy. However, tracheostomy has been associated with infection, granulomas, tracheal stricture, cartilage damage, hemorrhage, pneumothorax, tracheocutaneous or tracheo-esophageal fistula, aspiration, dysphagia, and tracheal malacia; thus, tracheostomy should not be considered an innocuous procedure.²¹ Intubation via tracheostomy is generally reserved for patients requiring preoperative or postoperative tracheostomy for airway management. A tracheostomy tube with a replaceable lumen (Fig. 18.8) should be used, if available, but standard endotracheal tubes have been used satisfactorily (Fig. 18.9). Care of the tube is very important. Neglected tubes that are not cleaned regularly can be obstructed by mucus that dries within the lumen of the tube (Figs. 18.37 and 18.38).

Fig. 18.34. Epiglottis, arytenoid cartilages, and glottis of a cat, as viewed through a fiber-optic endoscope.

Changing Endotracheal Tubes

Changing endotracheal tubes during a surgical or diagnostic procedure in an anesthetized animal is occasionally required due to a failing cuff or simply the need for a different size or length of tube. Patients positioned and draped for surgery are generally not ideally situated for intubation. Changing the tube with guide-tube technique is probably the easiest, most efficient way to accomplish the procedure.^{19,22} Depending on the size of the patient and the endotracheal tube, two canine urinary catheters (8 to 10

Fig. 18.35. A polyethylene guide tube (8-French) passing through the glottis and into the larynx and trachea of a cat as viewed through a fiber-optic endoscope. Although not generally necessary for intubation in cats, this technique is effective in other species.

Fig. 18.36. An endotracheal tube passing into the larynx of a cat as viewed through a fiber-optic endoscope. Although not generally necessary for intubation in cats, this technique is effective in other species.

French) connected in tandem, or an equine stomach tube will make an excellent guide tube.

To change endotracheal tubes, the guide tube is inserted through the original endotracheal tube to the area of the midcervical trachea. Next, the endotracheal tube cuff is deflated, and the endotracheal tube is pulled over the guide tube without removing the guide tube from the trachea. Then, the new endotracheal tube is maneuvered through the larynx and into the trachea by using the guide tube to direct its passage. The cuff of the new tube is inflated to protect the airway, and the new tube is secured in the manner appropriate for the specific species.

Tracheal Extubation

Extubation is performed after patients regain the ability to swallow and protect their airways. When the cuff is deflated, the endotracheal tube is removed slowly and deliberately, with care taken to avoid damaging the patient's tissues with the endotracheal tube or damaging the cuff as the tube passes the teeth. After extubation, protection of the airway from foreign material and maintenance of a patent airway remain important. The type of surgical or diagnostic procedure, the species and breed, and pre-existing conditions all affect these considerations.

The anesthetist should be certain that no foreign material remains in the oropharynx before beginning extubation. In dogs and cats, the pharynx should be inspected visually, and any debris should be removed. Specifically, surgery of the mouth and pharynx, dental procedures, and endoscopy promote the accumu-

Fig. 18.37. An endotracheal tube that had been placed through a tracheostomy to maintain an airway in a cat during transport of the cat to a referral center. On presentation, the cat was dyspneic and cyanotic. The tube was filled with dried mucus, and the extent of the occlusion of the lumen is illustrated more dramatically in Fig. 18.38. The tube had not been changed or cleaned for several hours.

lation of blood, fluids, lubricants, tartar, or other materials. Animals anesthetized for gastrointestinal surgery are prone to passive movement of fluid into the pharynx; two examples are dogs with gastric dilation and volvulus (GDV) and horses with colic. Nasogastric or orogastric tubes commonly used in these procedures may promote flow of gastric contents into the pharynx during surgery or when the tube is removed. With either

Fig. 18.38. End-on view of the endotracheal tube in Fig. 18.37 shows that the lumen was almost occluded. The cat was dyspneic prior to removal of the tube from the tracheostomy site.

species, the head should be positioned to allow drainage of fluid from the pharynx during surgery, and removing the endotracheal tube with the cuff inflated is advised.

Assuring a patent airway after extubation is essential, especially in patients with small-diameter upper airways (e.g., kittens, piglets, rabbits, and small brachycephalic dogs). A number of factors can be responsible for postextubation problems. Edema of the upper airway, including the larynx and nasal passages; laryngeal spasm; interference with the integrity of the airway by the soft palate; and laryngeal paralysis are all possible causes of obstructive problems. The anesthetist should be prepared to manage the airway at the time of extubation, knowing that these complications can impair ventilation and oxygenation. In some instances of postextubation airway obstruction, reanesthetizing the patient and reintubation may be the only feasible option.

Techniques of Oxygen Administration

Supplemental oxygen is used in anesthetized and critically ill patients to increase the partial pressure of oxygen in arterial blood (PaO_2) and to promote delivery of oxygen to the tissues. When a patient is breathing room air, values for PaO_2 that are less than 80 mm Hg indicate the potential for hypoxemia. If the PaO_2 decreases to less than 60 mm Hg, the need for supplemental oxygen is indicated.²³ Although ventilation is a factor in maintaining oxygenation, the fraction of oxygen in inspired gases (F_iO_2) plays a significant role in establishing the PaO_2 . As a rule, the PaO_2 value is approximately five times the F_iO_2 value if there are no major abnormalities in the matching of pulmonary ventilation and perfusion. Supplemental oxygen may be the only effective way of correcting hypoxemia in animals with diffusion abnormalities and ventilation-perfusion mismatching. Supplemental oxygen may not significantly improve PaO_2 in patients with pulmonary or cardiac shunts.

Several techniques can be used to administer oxygen to anes-

thetized and critically ill patients. The effectiveness of oxygen supplementation is assessed by evaluation of the patient's clinical responses (e.g., improvement in mucous membrane color and character of ventilation), by measuring the F_iO_2 , and by monitoring of PaO_2 , arterial oxygen saturation (SaO_2), and saturation of peripheral oxygen (SpO_2). Although PaO_2 and SaO_2 data are reliable, they require periodic arterial blood sampling and the use of an acid-base, blood-gas analyzer. The SpO_2 can be conveniently measured by pulse oximetry. Pulse oximetry is a practical method for noninvasive, moment-to-moment estimation of the saturation of hemoglobin with oxygen in anesthetized, recovering, and critically ill patients.^{24,25}

Mask Delivery

Masks for delivery of oxygen to veterinary patients are useful for preoxygenation immediately before induction of anesthesia and for emergency situations in awake patients. The use of masks for oxygenation requires constant attention, and some patients will not accept a mask unless they are sedated. Both factors limit the effectiveness of masks in awake patients. Indeed, some patients object to a mask so vigorously that the increase in oxygen consumption associated with restraint may nullify the benefits of a greater F_iO_2 .

The flow rates generally recommended for increasing F_iO_2 when using masks are variable among species. For example, flow rates of 10 to 15 L/min of supplemental oxygen have been recommended to increase the inspired-oxygen concentration to approximately 35% to 60% in adult horses.²⁶ Flow rates for smaller patients, including dogs and cats, usually range from 3 to 5 L/min. With a tight-fitting mask, higher flow rates of oxygen will produce greater F_iO_2 values and less rebreathing of expired carbon dioxide.

A mask should be used with a breathing system with a reservoir that can meet the patient's tidal volume demands or with a valved system that allows room air to be entrained. As an example, a dog with a tidal volume of 300 mL and an inspiratory time of 1 s has a peak inspiratory gas flow of approximately 18 L/min, which exceeds the practical flow rate for oxygen during masking. High inspiratory flow rates can be provided if the mask is attached to a circle breathing system with a reservoir bag. In addition, a breathing system has an overflow (pop-off) valve that prevents the buildup of excessive pressure with a tight-fitting mask.

Nasal Insufflation

Insufflation involves delivery of oxygen into the patient's airway at relatively high flow rates (Fig. 18.39); the patient inspires both oxygen and room air, the relative proportions of each being determined primarily by the oxygen flow rate and the rate of gas flow during inspiration.

Insufflation can be accomplished by a variety of methods. For horses recovering from anesthesia, oxygen may be delivered from a flowmeter through a delivery tube and into an orotracheal, nasotracheal, or tracheostomy tube. For most awake patients, oxygen is insufflated through a nasal catheter, the tip of which is positioned in the nasopharynx. The catheter is usually made of soft rubber, and the tube should have several fenestrations to pre-

Fig. 18.39. A nasal catheter for administration of oxygen in a dogs. The tube is secured to the muzzle with a suture.

vent jetting lesions from developing in the nasopharyngeal mucosa.²⁷ For awake small animals, instilling 2% lidocaine into the nasal passage with the patient's head and neck extended and held upward may facilitate passage of the tube. Placement involves insertion of the rubber catheter into the nasal passage and the nasopharynx, the distance being approximately the same as from the tip of the nose to the medial canthus of the eye. The external portion of the catheter is secured to the patient's head with tissue adhesive, tape, and/or sutures. A flexible length of tubing supplies oxygen from a flowmeter and allows the patient some freedom for movement in a cage or stall. Changing the catheter to the opposite nasal passage every 1 to 2 days has been recommended to prevent pressure necrosis, jet lesions, and accumulation of mucus.²⁷

The flow-rate requirements for oxygen during insufflation are quite variable, the patient's ventilation and the desired $F_{I}O_2$ being two important factors. Following anesthesia, adult horses require a minimum of 15 L/min of oxygen flow to improve the PaO_2 in arterial blood, and proportionally lower flows (e.g., 5 L/min) are suitable for smaller horses and foals.²⁶ In small animals, flow rates of 1 to 7 L/min are typically used for the administration of nasal oxygen. Approximate flow rates for dogs and cats to achieve rather specific ranges of $F_{I}O_2$ have been suggested.^{27,28} In dogs, various flow rates of 100% oxygen administered intranasally were studied, and flow rates of 50, 100, 150, and 200 mL $kg^{-1} min^{-1}$ produced inspired-oxygen concentrations measured at the tracheal bifurcation of 28%, 37%, 40%, and 47%, respectively.²⁹ To prevent mucosal drying with prolonged insufflation, oxygen should be flowed through a bubble-type humidifier.

Tracheal Insufflation

An intratracheal catheter placed percutaneously into the trachea through the cricothyroid membrane or between tracheal rings near the larynx can be used to insufflate oxygen to a compromised patient. Intratracheal administration of 100% oxygen has been evaluated in dogs, and flow rates of 10, 25, 50, 100, 150,

Fig. 18.40. A standard stainless-steel cage with a Plexiglas door facilitating administration of humidified oxygen to an English bulldog. Although concentrations of oxygen are unlikely to be very high, patients with respiratory distress often show clinical improvement.

200, and 250 mL $kg^{-1} min^{-1}$ produced inspired-oxygen concentrations at the tracheal bifurcation of 25%, 32%, 47%, 67%, 70%, 78%, and 86%, respectively.³⁰ The technique for tracheal insufflation has been described for small animals.^{27,30} The catheter should be placed aseptically, be of the over-the-needle type, relatively large bore, have several smooth fenestrations to prevent jet lesions, and ultimately positioned with the tip near the bronchial bifurcation. Oxygen should be humidified, and flow rates should approximate those used for nasal insufflation.

Oxygen Cages

Oxygen cages (Figs. 18.40 and 18.41) specifically designed for small animals are commercially available, but expensive. These cages regulate oxygen flow, control humidity and temperature, and eliminate carbon dioxide from exhaled gases. For small animals, flow rates of oxygen, cage temperature, and cage humidity have been recommended to be less than 10 L/min, approximately 22°C, and 40% to 50%, respectively.²⁷ With these flow rates,

Fig. 18.41. Two commercial oxygen cages designed for small veterinary patients. The cages can control environmental temperature, deliver oxygen, and absorb carbon dioxide from expired gases.

most oxygen cages produce an environmental oxygen concentration of about 40% to 50%.²⁷ Oxygen concentrations of 30% to 40% generally are adequate for patients with moderate pulmonary disease.²³ Oxygen cages are not practical for large horses,²⁶ and, even in smaller animals, the effectiveness of an oxygen cage diminishes as body size increases. Because of this, nasal insufflation of oxygen has supplanted oxygen cages in many instances, even for smaller dogs and cats.

Smaller canine patients can be managed easily in oxygen cages, but temperature and humidity are more difficult to control with larger dogs. A major disadvantage of an oxygen cage is that the animal must be removed from the cage for examination and treatment, requiring the patient to breathe room air or oxygen by mask during this period. Clinically, some dogs and cats with serious ventilatory compromise respond very well to an oxygen-enriched environment as initial therapy; the increase in $F_{I}O_2$ is associated with decreased ventilatory effort, and the patient stabilizes and becomes more manageable prior to further examination and treatment.

Oxygen Toxicity

Oxygen toxicity develops with prolonged exposure to high oxygen concentrations.^{31,32} Oxygen toxicity leads to the deterioration of pulmonary function, pulmonary edema, and death. The length of time that a patient's PaO_2 is elevated may be more predictive of oxygen toxicity than the duration of exposure to a high $F_{I}O_2$.³² There is significant species and individual variability in susceptibility to oxygen toxicity.^{27,32} In human patients, the guideline is that 100% oxygen should not be administered for more than 12 h of exposure.²⁷ In general, a patient should not be deprived of a high concentration of oxygen if a high $F_{I}O_2$ is required to maintain an adequate PaO_2 ; it has been stated that the brain softens (due to hypoxemia) before the lungs harden (owing to changes induced by prolonged exposure to high oxygen tensions).³³ As a guideline for prolonged administration of oxygen, 40% to 50% oxygen is generally safe, but higher inspired con-

centrations should be used if necessary to maintain a patient's PaO_2 at approximately 90 to 100 mm Hg and ensure hemoglobin saturation with oxygen.

Mechanical Ventilation

Essentially, all anesthetized patients hypoventilate; they do not maintain arterial carbon dioxide partial pressure ($PaCO_2$) values near 40 mm Hg because of abnormal alveolar ventilation. Although controlled ventilation is not necessary for all anesthetized patients, various circumstances may compel an anesthetist to employ intermittent positive-pressure ventilation (IPPV). The absolute indication for mechanical ventilation is apnea.³⁴ However, IPPV should be instituted if hypoventilation becomes significant, if neuromuscular blocking drugs are employed, or if intrathoracic surgery is performed.³⁵ General anesthesia for longer than 1 1/2 h may constitute a reason for IPPV.³⁶ In addition, IPPV may be needed to facilitate inhalant anesthesia. Hypoventilating animals may not absorb enough anesthetic to maintain surgical anesthesia. IPPV will enhance alveolar ventilation and increase the uptake of the inhalants. This may help in eliminating the oscillations between deep and light anesthesia associated with depression of spontaneous ventilation.

Maintaining relatively normal carbon dioxide tensions in arterial blood is the primary goal of mechanical ventilation in anesthetized patients. Normal values for $PaCO_2$ are generally in the range of 35 to 45 mm Hg for most species. However, controversy exists about the routine use of IPPV in anesthetized patients, particularly anesthetized horses, simply to keep $PaCO_2$ near 40 mm Hg. Because IPPV is associated with reduced cardiovascular function and moderate increases in $PaCO_2$ are associated with improvement in some cardiovascular variables, IPPV for every anesthetized patient is neither universally accepted nor universally practiced. The definition of an acceptable degree of hypercapnia in an anesthetized animal is not without debate. For spontaneously breathing horses, a range of 60 to 70 mm Hg of $PaCO_2$ has been suggested as perhaps safer than controlled ventilation with its potentially adverse effects on cardiovascular function and tissue perfusion.³⁶ Others have recommended IPPV for horses only when $PaCO_2$ values exceed 60 mm Hg³⁷ or even 70 mm Hg.^{26,37} Employing IPPV in large anesthetized animals, including horses and other species, to maintain $PaCO_2$ values between 35 and 50 mm Hg remains common practice. For a more definitive answer to this debate, large-scale clinical trials with various sized horses and anesthetic-surgical conditions need to be completed.

The direct cardiovascular effects of carbon dioxide include dilation of peripheral arterioles and myocardial depression. Indirectly, carbon dioxide evokes sympathoadrenal responses, which cause blood pressure elevation, tachycardia, and increased myocardial contractility.³⁸ Moderate (60 to 70 mm Hg) to high (75 to 85 mm Hg) increases in $PaCO_2$ in spontaneously breathing and mechanically ventilated, lightly anesthetized horses were associated with augmented cardiovascular function compared with horses with normal carbon dioxide tensions; these hemodynamic effects were accompanied by increases in circulating catecholamines.³⁹ If more normal (35 to 45 mm Hg) arterial carbon

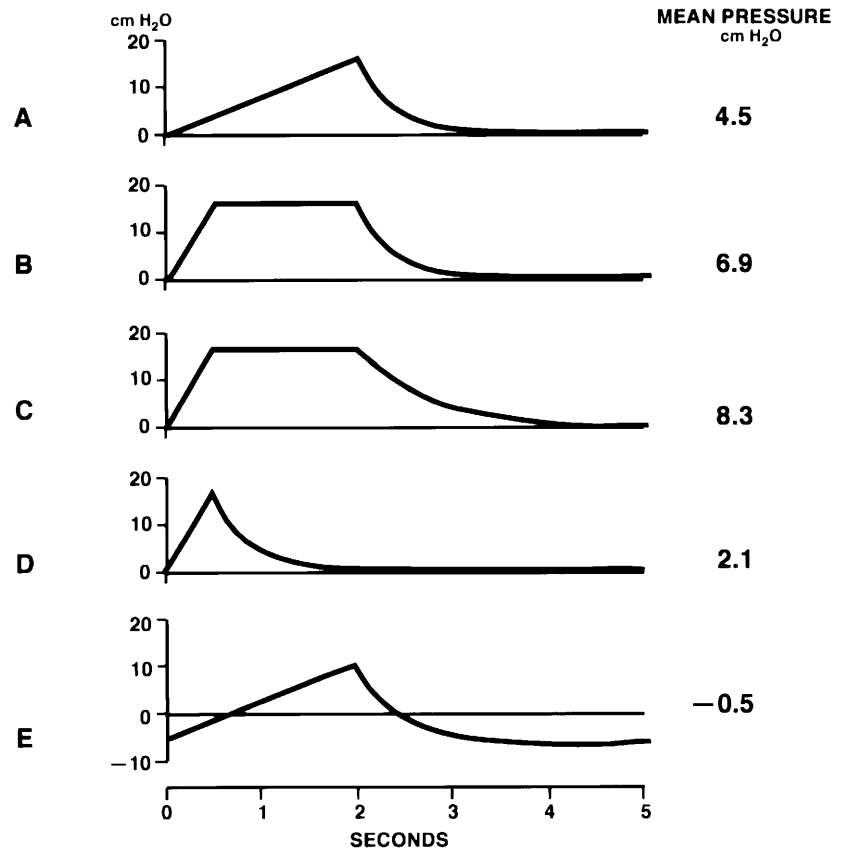

Fig. 18.42. Diagrams illustrating the mean pressure in the lungs in relation to positive-pressure ventilation: the effects of a long inspiratory time (A), an inspiratory plateau or holding pressure at the end of inspiration (B), an inspiratory plateau with retarded expiration (C), a rapid inspiration (D), and a slow inspiration with a negative expiratory phase (E). Lower mean pressure is most desirable from the standpoint of cardiovascular function, and D illustrates the most desirable type of ventilation, although the inspiratory time depicted is shorter than normally used clinically. From Mushin et al.,⁷¹ in Lumb and Jones.⁷²

dioxide tensions correlate with lower values for blood pressure, myocardial contractility, and cardiac output in anesthetized animals, the argument can be made that spontaneously breathing (slightly hypercapnic) anesthetized animals may maintain cardiovascular function better than animals whose ventilation is controlled with IPPV. The use of inotropic drugs may be necessary to maintain cardiovascular function during surgical anesthesia in mechanically ventilated horses. Nevertheless, there are good reasons to maintain PaCO₂ values within reasonable limits in anesthetized animals.

Inhalant anesthetics (e.g., halothane) and epidural or spinal anesthesia reduce the circulatory responses to carbon dioxide.^{38,40} In addition, hypercapnia has been associated with increases in vagal tone and slowing of heart rate.⁴¹ Indeed, hypercapnia has long been related to enhanced vagal responsiveness, bradycardia, and even cardiac arrest. It used to be said that “hypercapnia does not stimulate vagal activity directly, but it ‘sets the stage’ for cardiac arrest if such a stimulus is present.”⁴² It is known that carbon dioxide produces narcosis in dogs, the degree of which depends on the PaCO₂ value; narcosis progressively increases with PaCO₂ values above 95 mm Hg and induces complete anesthesia at 245 mm Hg.⁴³ Hypercapnia and the associated increases in circulating catecholamines have been linked to the development of cardiac arrhythmias, especially when the heart has been sensitized by halogenated inhalant anesthetics.⁴⁴ In human pediatric patients whose airways were managed by masks, hypercapnia was associated with an increased incidence

of arrhythmias.⁴⁵ The authors noted that light anesthesia or a combination of factors such as hypercapnia and halothane might have been as important as hypercapnia alone in the production of arrhythmias in these children. Thus, there is a negative side to uncontrolled hypercapnia that should be considered for anesthetized patients, and the veterinarian or anesthesiologist should weigh the advantages against the disadvantages in the anesthetic management of each patient.

Mechanical ventilation does negatively affect cardiovascular function (Fig. 18.42). The depression of cardiovascular function may be significant. When ventilation is controlled and negative pressures are not generated during inspiration, venous return is not enhanced. Indeed, IPPV may physically impede venous return to the right side of the heart, leading to decreases in stroke volume, cardiac output, and arterial blood pressure. In anesthetized, mechanically ventilated horses, a reduction in blood pressure and damping of the pressure waveform is not uncommon, especially in critically ill patients with a marginal blood volume. The negative effects of mechanical ventilation on cardiovascular function can be exacerbated by prolonging inspiratory time, holding positive pressure in the lungs at the end of inspiration, retarding exhalation, applying positive pressure during the expiratory phase, and employing an excessively rapid respiratory rate. Some of these effects are illustrated in Fig. 18.42. Fortunately, these negative effects can be overcome in many cases by the appropriate expansion of extracellular fluid volume and, if necessary, the administration of inotropic drugs.

Guidelines for mechanical ventilation usually include values for inspiratory time, respiratory rate, inspiratory to expiratory time ratio, and tidal volume. Some variations exist because of differences in body size, species, physical condition of the lungs and thorax, and existing disease processes.

Normal tidal volume is generally considered to range between 10 and 20 mL/kg of body weight.⁴⁶ A good working guideline for tidal volume in the domestic species is approximately 10 mL/kg.⁴⁷ For IPPV, the tidal volume set on a mechanical ventilator is usually increased above the normal spontaneous tidal volume to compensate for pressure-mediated increases in the volume of the breathing system and airway. Increasing the tidal volume (bellows volume) by 2.2 to 4.4 mL/kg has been recommended.³⁵ Settings for tidal volume—15 mL/kg in large animals and 20 mL/kg in small animals—have been suggested.⁴⁷ Use of small tidal volumes may cause atelectasis, which may only be recognized grossly during thoracotomy or with blood-gas analysis, because atelectasis contributes to mismatching of pulmonary ventilation and perfusion leading to decreased PaO₂. The tidal volume should be delivered to the patient over a relatively short period to avoid maintaining positive intrathoracic pressure. Inspiratory time should be approximately 1 to 1.5 s in small animals and 1.5 to 3 s in large animals.

The inspiratory time compared with time during the entire expiratory phase is termed the *I-E ratio*. That fraction should be 1:2 (I-E) or less for mechanical ventilation in all patients. Ratios that approach 1:1 produce a long duration of positive intrathoracic pressure, which interferes more with cardiovascular function. If a patient's respiratory rate is 10 breaths/min and the inspiratory time is 1.5 s, the I-E ratio will be 1:3. In general, the exact value of the I-E ratio is not important as long as the ratio is less than 1:2. With some ventilators that incorporate specific, unchangeable I-E ratios, the options for controlling respiratory rate may be limited.

Tidal volume and inspiratory time affect the development of peak inspiratory pressure. In general, 15 to 30 cm H₂O will expand the lung,⁴⁷ and 15 to 20 cm H₂O and 20 to 30 cm H₂O have been recommended as peak inspiratory pressures for mechanical ventilation of small animal species with normal lungs and large animal species with normal lungs, respectively.³⁵ Excessive or sustained pressure during IPPV can cause excessive expansion and volutrauma, leading to disruption of the alveolar membrane, to the development of interstitial air, and ultimately to the transfer of air into the mediastinum, pleural space, or abdomen.⁴⁸ A good guideline for peak inspiratory pressure is not to exceed 30 cm H₂O. Special attention to peak pressure is important for animals that have experienced lung trauma (e.g., diaphragmatic hernia).⁴⁹

The appropriate respiratory rate for mechanical ventilation varies with the species and the tidal volume selected. The following recommendations have been published: dogs, 8 to 14 breaths/min; cats, 10 to 14 breaths/min; horses and cows, 6 to 10 breaths/min; and small ruminants and pigs, 8 to 12 breaths/min.⁴⁷ In patients requiring smaller than usual tidal volumes, to avoid excessive inspiratory pressures (e.g., lung trauma, diaphragmatic hernia, or gastrointestinal distension, including GDV), respira-

tory rates can be increased to maintain the appropriate minute ventilation.

When controlled ventilation is discontinued at the end of anesthesia, the return of spontaneous ventilation may be impaired. If PaCO₂ is low, spontaneous ventilation may not resume. Part of the management of controlled ventilation should be maintenance of relatively normal carbon dioxide tensions, and hypocarbia should be avoided. The residual effects of opioids, anesthetics, and adjunctive drugs (e.g., neuromuscular blocking drugs) at the end of anesthesia may contribute to a delayed return to spontaneous ventilation. Complicating factors associated with general anesthesia or surgery (e.g., hypothermia or hypovolemia) may slow an animal's return to consciousness and thus spontaneous ventilation. In general, the arterial tension of carbon dioxide must increase to stimulate the animal to breathe spontaneously, or the patient must regain a level of consciousness that promotes spontaneous ventilation. Before attempting to discontinue controlled ventilation, the anesthetist should ascertain that depth of anesthesia is decreasing, that the effects of muscle-relaxing drugs have subsided or have been antagonized, and that cardiovascular function is relatively normal. Then, the animal can be weaned from controlled ventilation.

The patient should continue to receive supplemental oxygen until spontaneous ventilation is relatively normal. Reducing the rate of controlled ventilation usually increases PaCO₂ enough to stimulate spontaneous breathing when an animal is regaining consciousness. Generally, the patient is mechanically or manually ventilated at a rate of one to four breaths per minute until spontaneous ventilation resumes. In many cases, animals begin to breathe spontaneously after the vaporizer has been turned off and most of the inhalant anesthetic has been eliminated, even though controlled ventilation has not been stopped. Some patients require some type of external stimulus to begin breathing (e.g., pinching the skin between a dog's toes). After the animal begins to breathe spontaneously, assisted ventilation and supplemental oxygen should be provided until the respiratory rate and tidal volume begin to normalize.

Anesthesia Ventilators

Anesthesia ventilators provide for mechanical ventilation of patients being maintained with inhalant anesthetics. Simply, an anesthesia ventilator is a reservoir bag (a bellows or concertina bag) in a closed container (bellows housing) that can substitute for the reservoir bag of an anesthesia breathing system. Within limits, the ventilator can drive its bellows to produce a specific tidal volume or a specific inspiratory pressure at a preselected rate. The anesthesia ventilator performs the same job as the anesthetist who periodically squeezes the circle system's reservoir bag to ventilate the patient. Some anesthesia ventilators are stand-alone units that are attached to an anesthesia machine when needed, whereas other ventilators are manufactured as an integral part of the anesthesia machine. Most anesthesia ventilators designed for human patients are appropriate for veterinary patients weighing less than approximately 140 kg. Ventilators specifically designed for large animals are needed for pa-

Fig. 18.43. Diagram of a generic, double-circuit ventilator. Driving gas enters at A, leading to compression of the bellows and forcing gas in the patient circuit toward the breathing system and the patient's respiratory system (C). Overflow gas from the patient circuit exits through the pop-off valve (E) and flows into the scavenger system (B). F, tidal volume adjustment; D, bellows; and H, bellows housing.

tients weighing more than 140 kg. Admittedly, these guidelines for body weight and selection of a ventilator are somewhat arbitrary.

Classification

The power source, drive mechanism, cycling mechanism, and type of bellows have been used to classify anesthesia ventilators.⁵⁰ The power source may be electricity, compressed gas, or both. The drive mechanism is commonly compressed gas, even when electric controls are used. Anesthesia ventilators are usually double-circuit units (Fig. 18.43). *Double circuit* refers to two gas sources: (a) the driving-gas circuit (outside of the bellows), which compresses the bellows, and (b) the patient gas circuit (inside the bellows), which originates at the anesthesia machine and provides oxygen and anesthetic to the breathing system and pa-

tient. Specific ventilators for veterinary applications are classified in Table 18.1.

Anesthesia ventilators are typically, though not always, time cycled.⁵⁰ Fluidic timing devices were common in the late 1970s, and fluid-controlled ventilators remain in use. Newer electronic ventilators incorporate solid-state timing circuitry and are classified as time cycled and electronically controlled. A pressure-cycling mechanism may be present in some ventilators, and some have been described as volume cycled. In most cases, a timing mechanism plays a major role in a ventilator's function, and volume or pressure limits may affect the change in the respiratory cycle from inspiration to expiration.

The direction that the bellows moves during expiration, either ascending or descending, also helps to characterize anesthesia ventilators. Newer anesthesia ventilators usually have ascending

^aBellows is described in reference to the direction of movement during expiration.

bellows. The ascending bellows is considered safer because it will not fill if a disconnection occurs in the breathing circuit.⁵⁰ The ascending bellows falls to the bottom of the bellows housing during a disconnection, giving an immediate visual indication of ventilator failure. Ascending bellows are incorporated into modern electronic ventilators. Ventilators with descending bellows may continue to cycle even with a complete disconnection of the ventilator from the breathing system.

The terms *tidal volume preset*, *volume preset*, and *volume constant* have been used to describe anesthesia ventilators; these terms have been included in operation manuals and other descriptive literature authored both by manufacturers and by medical personnel. The implication is that the ventilator delivers exactly the tidal volume selected despite the total inspiratory time or the amount of inspiratory pressure that develops. However, the tidal volume that actually reaches a patient's lungs may vary from the setting on the ventilator. Variations are related to the compliance of the breathing system, leaks in the system, and the entry of fresh gases into the breathing system. Although the terms *tidal volume preset*, *volume preset*, and *volume constant* may be practical, the user should understand the unknown influences on the quantity of gas actually delivered to the patient.

In addition, ventilators may be called *pressure preset*, indicating that inspiration continues until a selected pressure is reached, no matter what tidal volume is necessary to achieve the pressure. The amount of gas delivered to a patient depends on a number of factors, including the resistance and compliance of the breathing system and the patient's respiratory system. Although inspiratory pressure may not vary over time, the tidal volume may change as compliance of the respiratory system changes.

Even though ventilators have been classified as *volume limited* and *pressure limited*, and *pressure cycled*, *time cycled*, and *volume cycled*, these terms may be somewhat misleading or confusing because the mechanism that actually causes the change from expiration to inspiration is most often a timing mechanism.

Indeed, the change from one phase of ventilation to the other may involve more than one mechanism, including volume, pressure, and/or time. Some ventilators may use different cycling mechanisms depending on the mode of operation.⁵⁰ A pressure-limited ventilator is one that delivers gas to a patient during inspiration until a preset pressure develops in the bellows, at which point the expiratory phase begins. The disadvantage of pressure-limited ventilation is that the tidal volume delivered to a patient may decrease if respiratory compliance decreases during ventilation. A volume-limited ventilator delivers a present tidal volume (within the limits discussed earlier) without regard for the maximum inspiratory pressure (up to the preset maximum pressure for the ventilator). Inspiratory pressure may increase if compliance decreases during mechanical ventilation. Most anesthesia ventilators have a maximum pressure limit during inspiration for the safety of the patient, and that pressure limit varies with the model of the ventilator. Ventilators that are used as volume-limited units may truly be limited by time rather than by volume, and that fact becomes apparent if the inspiratory flow rate is too slow.

Terminology of Mechanical Ventilation

Several abbreviations are used in the medical literature to describe various types of ventilation. Common abbreviations are included and discussed in the following subsections.

IPPV (*Intermittent Positive-Pressure Ventilation*)

With IPPV, airway pressure is maintained above ambient pressure during inspiration, and airway pressure falls to ambient pressure to allow passive expiration.⁴⁸ *Conventional positive-pressure ventilation* (CPPV), also called *control-mode ventilation* (CMV), is a form of IPPV in which a ventilator delivers a preset tidal volume at a preset frequency.⁵¹ *Assist-control-mode ventilation* (AMV) provides a preset tidal volume from the ventilator in response to patient-initiated attempts to inspire; a preset frequency of ventilation is delivered by the ventilator if the pa-

tient fails to initiate breathing.⁵¹ The term *intermittent positive-pressure breathing* (IPPB) is synonymous with IPPV.

PEEP (Positive End-Expiratory Pressure)

With PEEP, airway pressure at end expiration is maintained above ambient pressure. The term *PEEP* is applied when positive pressure is maintained between inspirations that are delivered by a ventilator.⁵¹ The term *ZEEP*, or *zero end-expiratory pressure*, has been used in studies comparing the effects of PEEP with the effects of ZEEP.⁵² In addition, some ventilators can create negative pressure to assist expiration or to speed the egress of gases during the expiratory phase. This has been termed *NEEP* or *negative end-expiratory pressure*.

CPAP (Continuous Positive Airway Pressure)

When airway pressure is maintained above ambient pressure during spontaneous breathing, the term *CPAP* is applied instead of PEEP.⁵¹

IMV (Intermittent Mandatory Ventilation)

This method of ventilation is used for ventilatory support and for weaning of patients from ventilators. The technique allows patients to breathe spontaneously, but it inserts mechanical breaths at a preset tidal volume and frequency.^{51,52} Most veterinary anesthesia ventilators are not designed for delivering this form of ventilation, and IMV is provided by critical care ventilators for human patients. The periodic sigh that anesthetists provide manually during spontaneous ventilation to expand the lung and decrease collapsed alveoli in anesthetized animals may be considered IMV.²⁶

The terms *assisted ventilation* and *controlled ventilation* are common in the veterinary literature. Assisted ventilation can be performed manually by anesthetists, who synchronizes their compression of the breathing bag with a patient's spontaneous breathing to augment the tidal volume.⁵³ With a mechanical ventilator, assisted ventilation is basically patient-initiated ventilation, with the ventilator delivering the preselected tidal volume. Since the patient determines the frequency of ventilation, it also determines minute volume.⁵⁴ Some veterinary ventilators can provide assisted ventilation, delivering a tidal volume from the bellows when a patient creates negative pressure at the initiation of a breath.⁵⁵

During *controlled ventilation* as defined earlier for CMV, inspiration is initiated by the ventilator and a preset respiratory rate is maintained. The ventilator sets frequency, tidal volume, and minute volume. Controlled ventilation is necessary in any situation that renders a patient unable to initiate an adequate number of breaths. Essentially all anesthesia ventilators will operate in this mode, and some operate only in this mode. Controlled ventilation can be provided manually by an anesthetist using the reservoir bag of the breathing system to establish both rate and tidal volume, and thus minute volume, for the patient.⁵³

The term *assisted-controlled ventilation* has been defined as assisted ventilation (patient-controlled rate with ventilator-controlled tidal volume) with a preset minimum acceptable respiratory rate; if the patient-initiated rate falls below the preset

rate, the ventilator will cycle at the minimum preset rate. This mode is similar to AMV as defined earlier. The use of assisted-controlled ventilation has been suggested for the transition period between spontaneous and controlled ventilation.

Guidelines for Use

The controls on most anesthesia ventilators include settings for tidal volume, inspiratory time, inspiratory pressure, respiratory rate, and I-E ratio (either adjustable or preset). Other controls may be present, but the four listed are basic. The following guidelines have already been discussed, but will again be briefly reviewed. The setting for tidal volume is usually between 10 and 20 mL/kg, and the inspiratory pressure is normally between 12 and 30 cm H₂O. In small patients, the respiratory rate should be set between 8 and 12 breaths/min, whereas the respiratory rate for large animals should be set between 6 and 10 breaths/min. In setting the ventilator, inspiratory time should be short in comparison to expiratory time so that positive interpleural pressure will minimally interfere with venous return and cardiac output. Inspiratory time should be 1 to 1.5 s in small animals and preferably less than 3 s in large animals. Therefore, the I-E ratio should be 1:2 or less (e.g., 1:3 or 1:4), depending on the respiratory rate.

Examples of Ventilators for Small Animals

Although not all-inclusive, the following discussion describes ventilators that are appropriate for small animal patients. Some of these ventilators were designed specifically to support anesthetized veterinary patients, whereas others were designed for human use, but are applicable to veterinary patients. The classification, principles of operation, and other points about the general function of each ventilator are included. Before operating a ventilator, the user should consult the operation manuals and follow all preuse evaluation procedures recommended by the manufacturer.

Drager Small Animal Ventilator (SAV)

This ventilator (Fig. 18.44) was marketed as an optional component for the Drager Narkovet 2 Anesthesia Machine, but was available on a mobile stand (universal pole) specifically designed for the ventilator.⁵⁶ Presently, the ventilator is not being manufactured, but these ventilators remain in use for veterinary anesthesia. The SAV is classified as double circuit, tidal volume preset, and time cycled, with an ascending bellows; it is pneumatically powered and has fluidic circuitry. The pressure of the driving gas should be between 40 to 60 pounds per square inch (psi). The controls include a power ("on-off") switch, a tidal volume adjustment rod to set the attached plate within the bellows housing to the selected tidal volume (200 to 1600 mL), a frequency control knob (10 to 30 breaths/min), and an inspiratory flow knob to control the rate of flow into the bellows housing to drive the bellows. The inspiratory flow knob should be set so that the bellows is fully compressed at the end of the inspiratory phase; however, the bellows should not be deformed at the end of inspiration. Deformation of the bellows at the end of inspiration may indicate an increase in tidal volume by as much as 100 mL. The inspiratory flow control setting affects the peak pressure that

Fig. 18.44. Dräger SAV (small animal ventilator; front view). The ascending bellows and the bellows housing with the tidal volume marked in milliliters are shown in the *bottom* of the photograph, and the inspiratory-flow control knob (*left*), the frequency control knob (*center right*), and the power switch (*far right*) are shown in the *top* of the photograph.

is achieved on inspiration and the inspiratory time. Higher inspiratory flows produce shorter inspiratory times and tend to produce higher peak inspiratory pressures. The ratio of inspiratory to expiratory time phase is preset to 1:2. This ventilator provides only controlled ventilation. The ventilator relief valve behind the bellows chamber compensates for the continuous entry of fresh gases into the breathing system. Because the ventilator uses an ascending bellows, the effect of gravity on the bellows maintains a PEEP of approximately 2 cm H₂O.

Before using the ventilator, the proper connections to the gas-supply and scavenger system should be made, and the appropriate preuse checkout procedures should be done for all equipment. Assuming that the anesthesia machine, breathing system, and ventilator are functional, the following is a reasonable step-by-step approach to the operation of this ventilator with a circle breathing system:

Fig. 18.45. Hallowell EMC Model 2000 Small Animal Veterinary Anesthesia Ventilator (front view). The bellows shown is the medium sized for tidal volumes between 300 and 1600 mL, and the basic control knobs and alarm indicator light are on the front panel. Photograph courtesy of W. Stetson Hallowell.

1. The tidal volume adjustment rod is set appropriately for the patient.
2. Corrugated tubing from the ventilator's breathing-hose terminal is connected to the circle system's reservoir-bag mount.
3. The circle system's APL valve (adjustable pressure-limiting or pop-off valve) is closed.
4. The ventilator's power switch is turned on.
5. The frequency of ventilation is adjusted to approximately the desired number of breaths per minute.
6. The inspiratory flow control knob is adjusted to produce the desired inspiratory time to deliver the preset tidal volume.
7. Frequency of ventilation and inspiratory flow may need to be readjusted to achieve the desired rate of breathing and inspiratory time.

Hallowell EMC Model 2000 Small Animal Veterinary Anesthesia Ventilator

This ventilator (Fig. 18.45) is designed for use with standard small animal anesthesia machines and breathing systems, and the connections to the breathing system, scavenger, and driving gas are shown in Fig. 18.46.⁵⁷ This ventilator is classified as double circuit and time cycled with an ascending bellows; it is pneumatically and electrically powered. The ventilator is essentially vol-

Fig. 18.46. Hallowell EMC Model 2000 Small Animal Veterinary Anesthesia Ventilator (rear view). Note the connectors on the bellows housing for the breathing system, scavenger system (exhaust), and driving gas. Photograph courtesy of W. Stetson Hallowell.

ume constant within the practical limits described earlier. The ventilator is pneumatically driven and electronically controlled by an electrically activated solenoid valve that allows gas pressure to be supplied to the volume control during the inspiratory phase of the ventilatory cycle. The ventilator's power switch is incorporated into the respiratory-rate control. Therefore, the ventilator is on when the rate selector is turned from the off position to the desired frequency of respiration (6 to 40 breaths/min). The pressure of the driving-gas supply (either oxygen, nitrogen, or clean dry air) should be regulated between 30 to 60 psi. This high flow is necessary only for larger patients.

The control module of the ventilator has the following adjustable components: the on-off and respiratory-rate control knob, a volume control knob, an inspiratory hold pushbutton, and a maximum working pressure limit (MWPL) selector. The ratio of inspiratory to expiratory time phase is preset at 1:2. However, this ventilator is available with an optional adjustable I-E ratio in the range of 1:1.5 to 1:4, enabling users to minimize the inspiratory time when ventilating at a lower frequency of ventilation. The volume control is a variable orifice-metering valve that regulates the driving-gas flow, which compresses the bellows. Basically, the volume control is used to set minute volume. It regulates the inspiratory flow rate directly, and a higher inspiratory flow rate at any given respiratory rate will produce a greater tidal volume. The inspiratory hold pushbutton interrupts the ventilatory cycle and prevents discharge of gas from the bellows housing until the button is released or the MWPL is reached. The MWPL can be set between 10 and 60 cm H₂O. If the MWPL is reached at any time, the inspiratory phase of ventilation is terminated and exhalation is allowed. Low breathing-system pressure will be detected if pressure at the end of inspiration is less than 5 cm H₂O, and a red warning light will illuminate and an alarm will sound indicating the possibility of a disconnection of the patient circuit from the ventilator. This

Fig. 18.47. Hallowell EMC Model 2000 Small Animal Veterinary Anesthesia Ventilator (front view). The bellows shown is the largest one for tidal volumes between 0 and 3000 mL. The basic control knobs and alarm indicator light are on the front panel. Photograph courtesy of W. Stetson Hallowell.

ventilator provides for controlled ventilation; assisted ventilation is not an option.

Three sizes of interchangeable bellows and bellows housings are available to enable various sizes of patients to be ventilated effectively (Fig. 18.47). With the proper bellows, the manufacturer indicates that tidal volumes as small as 20 mL and as large as 3 L can be delivered and that the patient can effectively

breathe spontaneously from the bellows when the ventilator is not in operation. The ventilator relief valve compensates for the continuous entry of fresh gas into the breathing system, and the resistance of the relief valve creates a PEEP of 2 to 3 cm H₂O.

Before using the ventilator, connections to the gas-supply and scavenger system should be made, and the appropriate preuse checkout procedures should be done. Assuming proper function of the anesthesia machine, breathing system, and ventilator, the following is a reasonable operational approach for this ventilator with a circle breathing system:

1. The MWPL selector (Fig. 18.45) is set to the desired maximum pressure (safety limit), and the pressure transducer (Fig. 18.46) is connected to the breathing system according to the manufacturer's recommendations.
2. Corrugated tubing from the ventilator's breathing system connector is attached to the circle system's reservoir-bag mount, and the ventilator is attached to the scavenger system.
3. The circle system's pop-off (APL) valve is closed.
4. The ventilator's volume control is adjusted to the minimum setting.
5. The ventilator's power-rate switch is turned on, and the desired frequency of ventilation is set.
6. The volume control knob is adjusted to produce a flow of gas during inspiration that produces the desired tidal volume and/or peak inspiratory pressure.
7. During maintenance, the minute volume is adjusted with the volume control, and the rate control can be used to adjust the size of each tidal volume.

Mallard Medical Model 2400V Anesthesia Ventilator

This ventilator⁵⁸ (Fig. 18.48) was originally designed to allow continuous mechanical ventilation of anesthetized pediatric and adult human patients. It is sold to veterinarians as a stand-alone unit for use with breathing system and anesthesia machine. Classified as a double-circuit ventilator, it has electric and pneumatic power sources. The ventilator is controlled by a micro-processor, and the manufacturer describes the ventilator as electronically time cycled and volume limited. The tidal volume is selected by limiting the upward expansion of the bellows. Tidal volume is adjusted by moving a cylinder within the bellows housing to coincide with the desired setting in milliliters, and the cylinder within the bellows housing is secured by a control knob (nut) located on the top center of the housing. This ventilator employs an ascending bellows. The bellows is pneumatically driven, and the ventilator operates at a pressure of 50 ± 10 psi.

The controls are positioned on a console, which is located below the bellows housing. A master on/standby/off switch is present in the right lower corner of the console's front panel; the standby mode allows preselection of respiratory rate and inspiratory time, and the I-E ratio is computed and displayed digitally on light-emitting diode (LED) displays before mechanical ventilation is initiated. Respiratory rate and inspiratory time are controlled by ten-turn potentiometers to allow selection of 2 to 80 breaths/min (respiratory rate) and 0.1 to 3.0 s (inspiratory time), respectively. The I-E ratio display shows the relationship of in-

Fig. 18.48. Mallard 2400V Small Animal Anesthesia Ventilator. The bellows is collapsed on the floor of the bellows housing. The tidal volume control is set at approximately 1600 mL. The control knobs on the console are described in the text.

spiratory time to expiratory time, giving inspiratory time a value of 1. A black control knob located in the lower left portion of the front panel allows adjustment of inspiratory flow rate (10 to 100 L/min), and a display gauge near the control knob indicates whether the flow being used is low, medium, or high. A green pushbutton is located in the front center portion of the control console; this button activates inspiration as long as the button is pushed in. This button can be used to maintain mechanical ventilation in the event of a power failure and can be used to sigh the patient.

Two sizes of bellows are available. The adult bellows provides tidal volumes ranging from 200 to 2200 mL; the pediatric bellows produces volumes ranging from 50 to 300 mL. An exhalation valve assembly is located on the back of the control console. This valve is closed pneumatically during the inspiratory phase of ventilation, and it opens automatically during the expiratory phase. Excess gas from the patient circuit exits through this valve to prevent the buildup of excessive pressure. The post (19 mm) of this valve should be attached to a scavenger system for elimination of waste gases from the working environment. With an ascending bellows, PEEP (usually 2 or 3 cm H₂O) will be present. In addition, PEEP of up to 20 cm H₂O can be added to the system with the control knob of the optional PEEP valve. Also, an adjustable overpressure relief valve within the console is preset to 80 cm H₂O, and this limits the maximum pressure that can be developed in the patient breathing circuit. Externally, this pressure can be adjusted from 20 to 100 cm H₂O. This ventilator has audible alarms if the ventilator fails to cycle or if an electric power failure occurs. In addition, the LED displays will indicate selection of an inverse I-E ratio, failure of the ventilator to cycle, and low supply-gas pressure (<30 psi).

Before using the ventilator, the proper connections to the gas-supply and scavenger system should be made, and the appropriate preuse checkout procedures should be done for all equipment. Assuming proper function of the anesthesia machine, breathing

Fig. 18.49. Metomatic Veterinary Ventilator. The ventilator's bellows is connected by a corrugated breathing tube to the reservoir-bag port of the circle breathing system to enable controlled ventilation. Anesthesia was maintained with halothane in oxygen in this dog.

Fig. 18.50. Control panel of a Metomatic Veterinary Ventilator. The function of the various controls of this ventilator are discussed in the text.

system, and ventilator, the following is a reasonable operational approach for this ventilator with a circle breathing system:

1. Prior to clinical applications, refer to the operation manual for instructions and conduct performance verification procedures.
2. Select the appropriate control settings for the tidal volume by limiting the upward expansion of the bellows.
3. Place the master switch in the *standby* mode and dial the desired settings for the respiratory rate and the inspiratory time, based on the patient's needs.
4. Set the inspiratory flow control to the desired rate of flow—low, medium, or high—depending on the needs of the patient.
5. Connect the corrugated tubing from the ventilator's bellows to the circle system's reservoir-bag mount and attach the ventilator to the scavenger system.
6. Close the circle system's pop-off (APL) valve.
7. Set the master switch to the *on* position.
8. The ventilator should cycle according to the selected settings, and only minor adjustments should be necessary (i.e., slight alterations in inspiratory time).

Metomatic Veterinary Ventilator

This ventilator is shown in Figs. 18.49 and 18.50. This unit was designed to ventilate anesthetized small animals being maintained with circle breathing systems. The ventilator is no longer being manufactured, but many units are still in operation in veterinary hospitals.

This ventilator is classified as double circuit and time cycled, with fluidic circuitry and a descending bellows. Within the limits of the definitions, it can be used as a volume-preset ventilator or as a pressure-limited ventilator. The ventilator is powered pneumatically and will function properly with an oxygen-supply pressure to 45 to 55 psi.

Controls (Fig. 18.50) for this ventilator are as follows:^{59,60} power (on-off) switch, tidal volume control, inspiratory flow-rate

control, expiratory time control, expiratory flow-rate control, inspiratory hold pushbutton, and inspiratory trigger-effort control. The power switch controls a valve that supplies pneumatic power (oxygen at 50 psi) to the ventilator. The tidal volume control adjusts the bellows from 0 to 1400 mL. The inspiratory flow-rate control regulates the rate of delivery of gas from the bellows to the patient during inspiration and is adjustable from 20 to 70 L/min. The inspiratory pressure control sets the maximum pressure that can be delivered to the patient circuit during inspiration, up to 40 cm H₂O; pressure is adjustable from 10 to 40 cm H₂O. The expiratory time control adjusts the time between the end of one inspiratory phase of respiration and the beginning of the next and can be varied from less than 1 to at least 12 s; essentially, it is a setting for respiratory rate although rate is influenced to some degree by other controls. The expiratory flow-rate control allows variation in the rate at which the bellows descends to the fully extended position and is adjustable from 15 to 100 L/min. The inspiratory hold pushbutton allows the initiation of inspiration at any point during the respiratory cycle by depressing and immediately releasing the button. If the pushbutton is depressed and held, inspiration will be initiated, and the bellows will remain at the end-inspiratory position until the button is released. The inspiratory trigger-effort control sets the sensitivity of the ventilator to the negative pressure produced by the patient's inspiratory effort. The setting can be low, which would require only a slight negative pressure to initiate a cycle, or high, which prevents the patient from triggering inspiration; the setting is adjustable from -0.5 to -5.0 cm H₂O. Many of these ventilators were equipped with a patient circuit pressure gauge (manometer) mounted on top of the bellows housing. This ventilator can be set to provide controlled or assisted ventilation.

The ventilator provides a relief valve (pop-off valve) to allow the escape of excess gases that are delivered to the patient circuit. Generally, the pressure in the patient circuit returns to zero at end expiration, since a descending bellows is employed.

Four modes of ventilation can be employed with this ventilator:

1. *Controller, volume controlled and pressure limited.* The rate and pattern of respiration are controlled by the ventilator. The selected tidal volume is delivered as long as inspiratory pressure does not exceed 40 cm H₂O. If the pressure limit is reached before the entire tidal volume is delivered, inspiration will cease.

2. *Controller, pressure controlled and volume limited.* The rate of ventilation is controlled by the ventilator. The ventilator delivers gas to the patient until the preset pressure limit is reached or until the contents of the bellows are fully discharged. Since tidal volume is affected by pressure, changes in airway resistance and compliance of the lungs can alter tidal volume.

3. *Assistor-controller, volume controlled and pressure limited.* The respiratory cycle is initiated by any spontaneous inspiratory effort on the part of the patient. The minimum frequency of ventilation is set by the ventilator, and if the patient fails to initiate the preset number of breaths, the ventilator will cycle at the minimum frequency. The preset tidal volume is delivered unless the inspiratory pressure reaches 40 cm H₂O, at which point inspiration will cease.

4. *Assistor-controller, pressure controlled and volume limited.* The respiratory cycle is initiated by spontaneous inspiratory efforts, and the minimum frequency is set by the ventilator. The patient may initiate a faster rate of respiration. The ventilator delivers gas to the patient until a preset pressure is reached or until the bellows is fully discharged. The tidal volume will be affected significantly by changes in compliance of the lung and airway resistance.

When using the Metomatic ventilator, the first mode (controller, volume controlled and pressure limited) is most frequently used. Before using the ventilator, the proper connections to the gas-supply and scavenger system should be made, and the appropriate preuse checkout procedures should be done. Assuming that the anesthesia machine, breathing system, and ventilator are functional, the following is a step-by-step approach to the operation of the ventilator with a circle breathing system:

1. Select the desired tidal volume.
2. Set the inspiratory trigger-effort control to a high setting, but not to the maximum.
3. Turn the inspiratory pressure control to a high setting (the maximum setting or high enough to assure that the bellows will deliver a complete tidal volume).
4. Set the inspiratory flow-rate control to a midrange setting. After the ventilator is in use, this control will be reset to deliver the tidal volume in approximately 1 to 1.5 s.
5. Set the expiratory flow rate to a midrange setting. This setting can be refined after the ventilator is in use; a setting is usually employed that will not impede ventilation.
6. Set the expiratory time control to a midrange setting. This control should be reset to allow the appropriate frequency of ventilation after the ventilator is in use.
7. Connect the corrugated tube from the ventilator's bellows to the circle system's reservoir-bag port.
8. Close the pop-off (APL) valve of the circle.
9. Turn the power switch on.

Fig. 18.51. Ohmeda 7000 Ventilator. The control module is shown with six controls on the *left* two-thirds of the panel and six warning indicators on the *right* two-thirds of the panel. This ventilator is equipped with a pediatric bellows assembly (0 to 300 mL for tidal volume).

10. Observe the character and rate of ventilation, and refine the adjustments of the various controls. Usually, inspiratory flow rate is adjusted first, followed by frequency or expiratory time, and expiratory flow rate.

Ohmeda 7000 Electronic Anesthesia Ventilator

The Ohmeda 7000 (Fig. 18.51) is a double-circuit ventilator with a pneumatically driven ascending bellows. The ventilator is electronically controlled with a preset minute volume. It is specifically designed as an anesthesia ventilator and can be fitted with either an adult or a pediatric bellows, and its application in human anesthesia has been described.^{50,54,61} This ventilator and upgraded models are available for use in human patients⁵⁴ and are readily applicable to small animal anesthesia. The control module (Fig. 18.51) has six controls, including the minute volume dial (2 to 30 L/min with the adult bellows and 2 to 12 L/min with the pediatric bellows), the respiratory-rate dial (6 to 40 breaths/min), the I-E ratio dial (1:1, 1:2, and 1:3), power (on-off)

switch, the sigh switch (to provide a “sigh” equal to 150% of the tidal volume once every 64 breaths), and a manual cycle button (used to manually initiate a ventilatory cycle only during the expiratory phase). The scale on the bellows housing ranges from 100 to 1600 mL on the adult bellows and from 0 to 300 mL on the pediatric bellows. The bellows assembly exhaust port is 19 mm OD, the connection to the anesthesia machine is 22 mm, and there is a high-pressure (50 psi) diameter index safety system (DISS) fitting for an oxygen line for the driving-gas circuit. The control module of the ventilator computes tidal volume, inspiratory time, expiratory time, and inspiratory flow based on the settings of the various control dials. The bellows should be fully distended (starts at the zero mark on the bellows housing scale) before inspiration begins.

The driving-gas supply is oxygen at 50 psi, which is reduced to 38 psi by a precision regulator within the ventilator; the gas line with the reduced pressure connects to a manifold of five solenoids. Electronic controls regulate the solenoid valves to deliver flows in 2-L/min increments from 4 to 60 L/min. Based on control settings, a precise volume of gas (equal to the tidal volume) is delivered to the bellows chamber to drive the bellows during the inspiratory phase, which forces gas from the bellows into the patient circuit. Flow stops when the full tidal volume has been delivered. A high-pressure relief valve opens at a pressure of 65 cm H₂O if such pressures should occur. During the expiratory phase, gas from the patient circuit (flow from the anesthesia machine) enters the bellows. The ventilator relief opens when the bellows is fully distended and a pressure of 2.5 cm H₂O has been exceeded; excess gas from the patient circuit is vented into the scavenger system.

The manufacturer recommends a bellows assembly-leak test. With the ventilator attached to a circle breathing system with the breathing system’s pop-off valve closed, the Y piece occluded, all fresh gas flow off, and the bellows filled from the anesthesia machine’s oxygen-flush valve, the bellows should drop no more than 100 mL/min. If a significant leak is present, the ventilator should not be used until the leak is sealed. If the anesthesia machine, breathing system, and ventilator are all in proper working order as indicated by preuse checkout procedures, the following guidelines are appropriate for use of the ventilator:

1. Properly connect the electric and pneumatic power sources for the ventilator.
2. Using the control dials, set the desired values for minute volume, respiratory rate (frequency), and I-E ratio.
3. Make the appropriate connections from the ventilator bellows to the circle system’s reservoir-bag port and to the scavenger system.
4. Close the pop-off (APL) valve of the circle system.
5. Be sure that the bellows is completely filled with oxygen-anesthetic mixture.
6. Switch the power control to *on*.
7. Make final adjustments in minute volume and respiratory rate to meet the needs of the patient.

The next generation of ventilators from Ohmeda is the 7800 series of ventilators. The 7800 is available as a stand-alone unit and

potentially could be applied to small animal patients. The ventilator is classified as electronically controlled, pneumatically driven, and tidal volume preset, and can accurately deliver tidal volumes of 50 to 1500 mL. A major difference between the 7000 and 7800 series is that tidal volume, rather than minute ventilation, is selected by the operator, which appears to be a significant advantage.⁶¹

Vet-Tec Small Animal Ventilator (SAV-75)

This ventilator is designed for use in small animal anesthesia.⁶² The bellows is designed to ascend on expiration and is pneumatically driven by a Bird ventilator. Used without a bellows, Bird ventilators are classified as single-circuit ventilators, but the SAV-75 performs as a double-circuit unit. This ventilator can be used for ventilation in assist, control, or assist-control modes. When the system is operating, the Bird ventilator supplies gas to pressurize the space between the bellows and the bellows housing (canister) to force the bellows downward, which delivers gases from the bellows through the interface hose (corrugated breathing tube) to the breathing system. The controls on the Bird ventilator include inspiratory pressure, inspiratory flow rate, expiratory time (apnea control), and inspiratory sensitivity. In addition, a manometer, a hand timer (push-pull mechanism), and a DISS connector for the source of pneumatic power are prominent features of the ventilator. Inspiratory pressure can be varied to a maximum of 60 cm H₂O, inspiratory sensitivity from -0.5 to -5.0 cm H₂O, expiratory time to produce 4 to 60 controlled breaths/min, and inspiratory flow to a maximum of 70 L/min. Safety relief occurs on inspiration if a pressure of 65 cm H₂O develops. The pneumatic power source should be delivered to the ventilator inlet at 50 psi. The bellows can deliver a tidal volume of up to 2000 mL. Inspiration can be started or stopped by use of the hand timer. The Bird ventilator is time cycled unless the push-pull manual cycling rod is pulled out, causing the ventilator to be pressure cycled.⁵⁵ Figure 18.52 shows a Bird ventilator.

Before using the SAV-75 ventilator for controlling ventilation during anesthesia, the power-supply and scavenger system should be connected, and the appropriate preuse checkout procedures should be done for all equipment. Assuming proper function of the anesthesia machine, breathing system, and ventilator, the following is a reasonable operational approach for the ventilator with a circle breathing system in the control mode:

1. Set the inspiratory sensitivity control to a high setting to eliminate the possibility of patient-initiated ventilation.
2. Set the inspiratory pressure control to the range of 15 to 20 cm H₂O and readjust the setting to achieve the desired tidal volume after steps 5 and 6 have been completed.
3. Connect the corrugated hose (interface hose) from the ventilator’s bellows to the reservoir-bag port of the circle system.
4. Close the pop-off (APL) valve of the circle system. At this point, the bellows may need to be filled by increasing the flow of oxygen to the patient circuit (oxygen flowmeter of the anesthesia machine).
5. Turn the inspiratory flow control on to start the ventilator and set the flow control to deliver a tidal volume in approximately 1 to 1.5 s.

Fig. 18.52. A Bird Mark 7 Ventilator. The inspiratory-sensitivity control is on the *left* end of the ventilator, the inspiratory-pressure limit is on the *right* end, the driving gas inlet is on the *top*, and the manometer, inspiratory-flow control, air-mix selector, and expiratory-time control are on the *front* panel of the ventilator. From Lumb and Jones.⁷²

6. Set the expiratory time control to establish a respiratory rate appropriate for the patient, often 8 to 12 breaths/min.
7. For final settings, the operator should understand that there are interactions between the controls on a Bird ventilator (e.g., changing inspiratory flow may affect respiratory rate).

ADS 1000 Veterinary Anesthesia Delivery System and Critical Care Ventilator

This microprocessor-controlled ventilator is marketed either for use with a vaporizer or for patients not requiring an anesthetic (e.g., critical care patients).⁶³ The ventilator-anesthesia system (Fig. 18.53) functions as a nonbreathing circuit, does not incorporate a bellows assembly, and does not include a canister for chemical absorbent to eliminate carbon dioxide. It is not intended for connection to another breathing system. Based on the patient's body weight, the microprocessor determines the values for the various ventilatory parameters to be provided by the ventilator.

This ventilator fits into the single-circuit class and is powered electrically and pneumatically. According to the operation manual, the ventilator must be supplied with oxygen at a pressure of 50 psi for the display to report the minute volume per kilogram of body weight accurately for the patient. Little published information other than testimonials is available about the clinical effectiveness of this ventilator system, but *in vitro* performance with a test lung has been studied.⁶⁴ The performance of the ventilator system *in vitro* changed across the range of body weights (1 to 20 kg) included in the study. Overventilation occurred at

Fig. 18.53. ADS 1000 Veterinary Anesthesia Delivery System and Critical Care Ventilator. The ports for the breathing hoses are located on the *right* side of the ventilator, and the controls for the ventilator are located on the *front* panel of the console.

body weights less than 4 kg, and underventilation was evident at body weights greater than 8 kg. The authors concluded that the ventilator could support ventilation, but the displayed parameters did not always accurately reflect the actual performance of the ventilator.

The front panel of the ventilator has the following controls and components (Fig. 18.53): power switch, mask-mode switch, set-run switch, weight-selection buttons, fill-hold button, breathe button, display for various ventilatory parameters with adjustments for these parameters below the display, and two ports for attachment of corrugated breathing tubes. Before attempting to use the ventilator, the operator should read the manual supplied by the manufacturer. The following is a summary of the manufacturer's guidelines for operating the ventilator, but is not intended to replace or supplant the manual supplied for the ventilator:

1. Connect the green oxygen hose on the back of the ventilator to an oxygen source (50 psi).
2. Attach the breathing tubes to the breathing-circuit ports on the front of the ventilator.
3. Connect the scavenger *out* port on the back of the ventilator to the hospital scavenger system.
4. Connect the electric cord to the 120-VAC–1.5-amp port on the back of the ventilator to an electric outlet.
5. Attach the vaporizer connectors to the appropriate ports on the back of the ventilator.
6. Allow the ventilator to complete the self-diagnostic test described in the operator's manual. The test will help to determine failure of the safety pop-off valve, inadequate oxygen supply, and the presence of leaks.
7. After diagnostics are complete, the mask function should be off and the set-run switch should be in the *set* position. The display will then show settings for a 20-kg patient (minute volume of 24 L/min, 9 breaths/min, peak inspiratory pressure of 15 cm H₂O, and the assist mode in the *off* position).

- Using the weight-up or weight-down button, enter the correct weight of the patient in kilograms into the display, and the ventilator will automatically set the ventilatory parameters based on the patient's weight. Ventilation will be completely controlled (the default setting for *assist* is off).

Once these steps are completed, the patient should be anesthetized and intubated with a cuffed endotracheal tube. The Y piece connecting the breathing tubes should be attached to the endotracheal tube connector, and the vaporizer should be set appropriately. The ventilator's set-run switch should be set to *run*. Controlled ventilation should begin.

Examples of Ventilators for Large Animals

Although not all-inclusive, the following discussion includes descriptions of ventilators that are appropriate for use during anesthesia in large animal patients. Classification, principles of operation, and function are discussed.

Drager Large Animal Anesthesia Ventilator

This ventilator (Fig. 18.54) is included as a part of the Narkovet-E Large Animal Anesthesia Machine; the entire system is called the Narkovet-E Large Animal Anesthesia Control Center. The ventilator was not marketed as a stand-alone unit for large animal anesthesia. Although they are no longer being manufactured, some of these ventilator-anesthesia machine combinations remain in use in veterinary hospitals. The ventilator is powered pneumatically, generally at a pressure of 50 psi.⁶⁵ It is classed as double circuit, tidal volume preset, time cycled, and pneumatically driven with a descending bellows, and it uses fluidic circuitry. The controls include an on-off switch, a tidal volume control with a scale of 4 to 15 L on the bellows housing, a frequency control (6 to 18 breaths/min), and a flow control knob that determines inspiratory flow (a combination of flow and maximum pressure being delivered to the bellows compartment); the manufacturer recommends that the flow setting be adjusted so that the bellows always reaches the upper stop. The inspiratory to expiratory time ratio of 1:2 is preset.

Before using the ventilator, the proper connections to the gas-supply and scavenger system should be made, and the appropriate preuse checkout procedures should be done. The instruction manual for ventilators includes a standard preuse check for the ventilator.⁶⁵ The following is a logical approach to the operation of the ventilator with a circle breathing system:

- Connect the compressed-air-supply hose to the ventilator.
- Adjust the tidal volume control to the appropriate setting for the patient and ensure that the self-locking mechanism is engaged to prevent inadvertent movement of the bellows stop plate during use.
- Attach the corrugated breathing hose from the bellows to the reservoir-bag port of the circle system.
- Close the pop-off (APL) valve on the circle system.
- Turn the power switch on.
- Adjust the frequency control knob to the desired respiratory rate.

Fig. 18.54. Narkovet-E Large Animal Anesthesia Control Center: the ventilator's bellows and the bellows housing with tidal volume marking (4 to 15 L), with the large animal circle system on the *left* and the reservoir bag for the circle breathing system on the *right*. The controls for the ventilator are on the panel above the bellows housing at the *top* of the unit.

- Adjust the flow control knob so that the bellows reaches the upper stop at end inspiration. If the bellows does not return to its original position during expiration (usually indicative of a leak in the patient circuit), the bellows can be filled by using a higher flow from the oxygen flowmeter, and the leak should be corrected.

Narkovet-E Electronic Large Animal Control Center

This is a combination of Drager's Narkovet E-2 Large Animal Anesthesia System (anesthesia machine and circle breathing system) with a Drager AV-E ventilator (Figs. 18.55 through 18.57). The ventilator is not available as a stand-alone unit for large animals and is no longer being manufactured, but machines are still in use. The ventilator is classified as double circuit, tidal volume preset, and time cycled, with a descending bellows. The ventilator is electronically controlled and pneumatically driven. It is powered electrically (120 VAC) and pneumatically (40 to 60 psi with oxygen, but air is an option).⁶⁶ The controls (Figs. 18.55 and 18.57) include an on-off switch, a self-locking knob located below the bellows assembly to control the tidal volume (4 to 15 L), a thumbwheel controller-indicator switch to adjust the respiratory rate (frequency control from 1 to 30 breaths/min), a flow control setting to determine the inspiratory flow rate, and the inspiratory-expiratory phase time ratio control (a thumbwheel indicator-controller to adjust the I-E ratio in increments of 0.5 from 1:1 to 1:4.5). The manufacturer recommends that the flow

Fig. 18.55. Narkovet-E Electronic Large Animal Control Center: the bellows and bellows housing with markings for tidal volume (4 to 15 L), the corrugated breathing hose from the bellows to the circle system (behind the bellows housing), and the self-locking knob or wheel (*bottom center*) for selection of tidal volume. In addition, the controls for the ventilator and anesthesia machine (*top* of the photograph) are included and are shown in detail in Fig. 18.56.

control knob be adjusted so that the bellows always reaches the upper stop of inspiration. The ventilator provides for controlled ventilation; assisted ventilation is not an option.

Before using the ventilator, the proper connections to the gas-supply and scavenger system should be made, and the appropriate preuse checkout procedures should be done. The instruction manual for the ventilator includes a standard preuse checklist. The following is a step-by-step approach to the operation of the ventilator with a circle breathing system:

1. Connect the gas supply (oxygen hose) to the anesthesia machine and ventilator.
2. Adjust the tidal volume control to the appropriate setting for the patient and ensure that the self-locking mechanism is engaged to prevent inadvertent movement of the bellows stop plate.

Fig. 18.56. Narkovet-E Electronic Large Animal Control Center: the control panel for the ventilator is on the *left* of the photograph. The power switch in the off position is directly under the thumbwheel controller-indicator switch for frequency (respiratory rate) selection on the *left* of the panel. The thumbwheel controller-indicator switch for inspiratory-expiratory ratio selection is on the *right* of the panel, with the inspiratory flow control directly above it. Some of the basic parts of the anesthesia machine, including the flowmeters (*center* of the photograph) for oxygen and nitrous oxide, the halothane vaporizer, and the flush valve (*bottom left*), are present.

Fig. 18.57. Narkovet-E Electronic Large Animal Control Center: the top of the bellows and the bellows housing, with an elbow connecting the bellows to the corrugated breathing tube, which attaches to the reservoir port of the circle breathing system. To the *left* of the elbow is the overflow valve from the bellows, which is connected to the scavenger system from the ventilator when the ventilator is in use. The clear, small-diameter tubing attached to the pop-off valve is part of the mechanism for closing the pop-off valve during the inspiratory phase of controlled ventilation.

3. Select the desired frequency of ventilation.
4. Select the desired I-E ratio.
5. Attach the corrugated breathing hose from the bellows to the reservoir-bag port of the circle system.

6. Close the pop-off (APL) valve on the circle system.
7. Turn the power supply switch on.
8. Adjust the flow control knob so that the bellows reaches the upper stop at end inspiration. If the bellows does not return to its original location during expiration, it can be filled by increasing the flow from the oxygen flowmeter.

Mallard Medical Rachel Model 2800 Anesthesia Ventilator

This ventilator (Fig. 18.58) is a microprocessor-based, electronic control system that facilitates controlled ventilation in large animals being maintained on circle breathing systems (R. Pearson, personal communication, Mallard Medical, Irvine, CA).⁵⁸ The ventilator is designed to interface with currently available large animal circle systems. The stand for the ventilator and the bellows is designed for the attachment of a circle breathing system and at least two vaporizers for inhalant anesthetics, and it has shelves to accommodate physiological monitoring devices.

Most of the functional considerations for the Model 2800 are

similar to those for the Model 2400V. The control console for the 2800 is located above the bellows housing instead of below the housing as it is in the 2400V, and LED displays are employed as they are in the 2400V. The ventilator is controlled by a microprocessor, but the pneumatics have been modified for generation of greater inspiratory flows, which are adjustable from 10 to 600 L/min. The bellows is inverted and ascends during expiration, and two sizes of bellows are available (3 and 21 L), allowing the selection of appropriate tidal volumes for patients with a wide range of body weights. Like other ventilators with inverted bellows, the Model 2800 produces PEEP because of the effect of gravity on the bellows. However, the amount of PEEP is controlled by a pneumatic vacuum pump on the 2800: the pump creates negative pressure between the bellows and the bellows housing during the expiratory phase of ventilation and functions to reduce the level of PEEP according to the adjustments made by the operator. An ambient end-expiratory pressure may be achieved.

Before using the ventilator, the proper connections to the gas

Fig. 18.58. Mallard Medical Rachel Model 2800 Large Animal Anesthesia Ventilator: the ventilator with a Matrx circle system attached (*left side*). The corrugated breathing hose that exits the bellows below the bellows housing is attached to the reservoir-bag port of the circle system. The control console for the ventilator is located at the *top* of the photograph. The controls for the 2800 are similar to those shown in Fig. 18.48 for the Model 2400V.

and electric power supplies and the scavenger system should be made, and the appropriate preuse checkout procedures should be done for all equipment. The following is a reasonable operational approach for the Model 2800 ventilator with a circle breathing system:

1. Place the master switch in the standby mode and dial the desired settings for respiratory rate and inspiratory time, according to the patient's needs.
2. Set the inspiratory flow control to the desired rate of flow—low, medium, or high—depending on the patient's needs (typically in the high range for large animals).
3. Connect the corrugated tubing from the ventilator's bellows to the circle system's reservoir-bag mount and the ventilator exhalation port to the scavenger system.
4. Close the circle system's pop-off (APL) valve and release the ventilator's bellows. Ensure that the bellows is fully inflated and positioned at zero.
5. Turn the master switch on, and inspiration should begin.
6. If the bellows does not return to zero during the expiratory phase, the bellows can be filled with flow from the oxygen flowmeter. Alternately, the bellows can be filled with the flush valve, but the anesthetic concentration in the breathing circuit will be reduced any time this is done.
7. The inspiratory time can be adjusted to produce the appropriate tidal volume for the patient.
8. Finally, the PEEP control is adjusted to set the desired end-expiratory pressure.

Vet-Tec Model 3000 Large Animal Anesthesia Ventilator

This is a large animal anesthesia ventilator designed for use in equine and bovine practices.⁶⁷ A similar ventilator in combination with a large animal anesthesia machine (Model 2000 Large Animal Anesthesia Machine and Ventilator) is also available.⁶⁷ The ventilator system has been described as a “bag-in-a-barrel” powered by a Bird ventilator.³⁵ The LAVC-2000 and the LAVC-3000 systems can be converted to a 5-L system for use in foals by adding a 5000-mL bellows and a canister (bellows housing) insert. Numerous variations of these ventilator-anesthesia machine combinations were possible, because the manufacturer would customize the unit upon request. The bellows in this ventilator system is driven by a modified Bird Mark 7 ventilator. Used without a bellows, the Bird Mark 7 is classed as a single-circuit ventilator, but the LAVC ventilator system is double circuit and has been classified as a pressure-preset ventilator.³⁵ The ventilator has been produced with a descending bellows, but literature from the manufacturer indicates the availability of an inverted bellows. The Bird ventilator is pneumatically powered. This ventilator system can be used for ventilation in assist, control, or assist-control modes. When the system is operating, the Bird ventilator supplies gas to pressurize the space between the bellows and the bellows housing (canister) to force the bellows in an upward motion delivering gases from the bellows, through the interface hose, to the breathing system.

The controls on a Bird Mark 7 (Fig. 18.52) include inspiratory pressure, inspiratory flow rate, expiratory time (apnea control),

and inspiratory sensitivity. In addition, a manometer, a hand timer (push-pull mechanism), and a DISS connector for the source of pneumatic power are prominent features of the ventilator. With the modified Bird Mark 7, inspiratory pressure can be varied from 5 to 65 cm H₂O, inspiratory sensitivity from -0.5 to -5 cm H₂O, expiratory time from 5 to 15 s, and inspiratory flow from 0 to over 450 L/min. The pneumatic power source should be delivered to the inlet of the ventilator at 50 psi. The bellows can deliver a tidal volume of up to 20 L. Inspiration can be started or stopped by use of a hand timer. The Bird Mark 7 is a time-cycled ventilator unless the push-pull manual cycling rod is pulled out, which causes the ventilator to be pressure cycled.⁵⁵

Before using the Model LAV-3000 ventilator for controlling ventilation during anesthesia, the power-supply and scavenger system should be connected, and the appropriate preuse checkout procedures should be done for all equipment. The following is a reasonable operational approach for the ventilator with a circle breathing system in the control mode:

1. Set the inspiratory sensitivity control to a high setting to eliminate the possibility of patient-initiated ventilation.
2. Set the inspiratory pressure control to the range of 20 to 30 cm H₂O and readjust the setting to achieve the desired tidal volume after steps 5 and 6 have been completed.
3. Connect the corrugated hose (interface hose) from the bellows to the reservoir-bag port of the circle system.
4. Close the pop-off (APL) valve of the circle system. Then, the bellows may need to be filled by increasing the flow of oxygen to the patient circuit (oxygen flowmeter on the anesthesia machine).
5. Turn the inspiratory flow control on to start the ventilator and set the flow control to deliver a tidal volume in approximately 1.5 to 3.0 s.
6. Set the expiratory time control to establish a respiratory rate appropriate for the patient, often 7 to 10 breaths/min.
7. For final settings, the operator should understand that there are interactions between the controls on a Bird ventilator (e.g., changing inspiratory flow may affect respiratory rate and vice versa).

Hazards Associated with the Use of Ventilators

During anesthesia, the use of a ventilator allows the anesthetist to concentrate on monitoring and supportive procedures. If an anesthetist is preoccupied with manually controlling or assisting ventilation, monitoring and support may be neglected. A good example is the use of a mechanical ventilator in anesthesia for equine colic surgery. There is some loss of contact between the anesthetist and the patient when a ventilator is used, especially in regard to respiratory function. Without a “hand on the reservoir bag,” an anesthetist may miss such developments as disconnections in the patient circuit, variations in respiratory resistance and compliance, and changes in the rate of spontaneous ventilation. In addition, a ventilator, because of its sounds and regularity, may lull an anesthetist into believing that ventilation is adequate

when, in fact, it is not.⁶¹ Ventilators are mechanical and may malfunction, and many veterinary ventilators are not equipped with the alarm systems that are now required for human ventilators. Finally, ventilators add a source of possible contamination to the breathing system.⁶¹

The hazards of mechanical ventilation are usually associated with malfunctions and failure of the equipment or inappropriate or inadvertently altered control settings. The operator should select a ventilator capable of meeting the respiratory requirements for the patient. Ventilators designed specifically for small animals or human patients are not necessarily appropriate for larger animals. A ventilator must be able to generate an adequate inspiratory flow rate and tidal volume if it is to be safe for use in larger animals. General hazards associated with ventilators include hypoventilation, hyperventilation, excessive airway pressure, negative pressure during expiration, and failure of alarms, if the ventilator is so equipped. Hypoventilation can be associated with power failure, dysfunction of the ventilator, cycling failure, inadequate design for the patient, leak of driving gas, loss of breathing-system gas, incorrect settings, and obstruction of flow.⁶¹

Respiratory Assist Devices

Several types and brands of respiratory assist devices are available. Some are completely manual in operation (resuscitation bags with one-way valves), and some use compressed gas (oxygen) to assist ventilation (demand valves). The mechanics of these devices have been reviewed.⁶¹

Manual Resuscitators

A manual resuscitator is appropriate for application of IPPV to small veterinary patients. Several brands of resuscitators are available. The basic components of a manual resuscitator are a compressible self-reexpanding bag, a bag-refill valve, and a non-rebreathing valve.⁶⁸ Some resuscitators can be attached to a source of oxygen to enrich the oxygen content of inspired gases (Fig. 18.59). Manual resuscitators can be fitted with a reservoir to serve as a source of oxygen when the oxygen flow to the resuscitator does not meet the filling demands of the resuscitator. The addition of such a reservoir makes the resuscitator more cumbersome to use.⁶⁸

Demand Valves

A demand valve can be used to deliver intermittent positive pressure ventilation. The demand valve is set to deliver oxygen when the patient begins to inspire (creating a negative inspiratory pressure) until exhalation starts or until a certain preset pressure is reached.⁶⁸ Expiration is passive through the valve outlet. The outlet may be restrictive to expiration in large patients. The device can be disconnected from the endotracheal tube after inspiration to decrease the resistance to exhalation if the demand valve must be used for an extended time.²⁶ A demand valve can be triggered manually to deliver oxygen to the patient as long as the activation button is held down or until the preset pressure limit is reached. Alternately compressing and releasing the control button allows application of IPPV. A demand valve with the capac-

Fig. 18.59. A manual resuscitation bag. Plastic tubing, which may be connected to an oxygen flowmeter, is attached to the bag refill valve to facilitate the addition of oxygen to inspired gases. The components of the resuscitation bag include the clear elbow (*right*), which is a non-rebreathing valve, the black self-inflating bag, and a refill valve (the black apparatus on the *left* end of the bag). The non-rebreathing valve may be connected to a mask or to an endotracheal tube.

Fig. 18.60. The Hudson Demand Valve (*left*) with an adapter for attachment to a large animal endotracheal tube connector.

ity for a high inspiratory flow rate is most desirable for use in large animals; demand valves generating low inspiratory flows will cause an excessively long inspiratory time in patients requiring a large tidal volume.

Demand valves are available from various manufacturers. The Hudson Demand Valve (Fig. 18.60) has been described for use in horses.⁶⁹ It delivers approximately 200 L/min if the oxygen-supply pressure is 50 psi and greater than 275 L/min if the supply pressure is 80 psi. This valve will accept a standard connector for an endotracheal tube (15 mm), and an adapter will allow attachment of the demand valve to a large animal endotracheal tube connector. The equine demand valve sold by J.D. Medical (Phoenix, AZ) functions at an inlet pressure of 50 to 75 psi. This

Fig. 18.61. The Elder CPR/Demand Valve. The oxygen inlet is shown with high-pressure oxygen hose connected. The clear plastic connector at the *bottom* of the photograph will fit endotracheal tube connectors, and the button in the *top center* of the demand valve activates and controls the flow of oxygen.

demand valve is available with various lengths of supply-gas hose and several sizes of adapters for endotracheal tubes. The Elder CPR/Demand Valve (Fig. 18.61) is intended to provide 100% oxygen to breathing or apneic patients.⁷⁰ The unit operates on a regulated inlet supply of oxygen at pressures between 40 and 80 psi. There is a variable pressure limit of 60 cm H₂O. Variable pressure (0 to 60 cm H₂O ± 5 cm H₂O) can be delivered to the patient, depending on the amount of pressure that is placed on the manual control button. Two models of this demand valve allow the choice of two set flow rates: 40 L/min at 40 psi and 160 L/min at 40 psi. The inlet for the valve is a DISS male oxygen fitting, and the outlet is 15 mm ID for attachment to an endotracheal tube connector and 22 mm OD for accepting a standard adult mask. This demand valve is easily adapted to fit both large and small animal endotracheal tubes with an adapter similar to the one shown in Fig. 18.60.

Introduction

The purpose of anesthesia is to provide reversible unconsciousness, amnesia, analgesia, and immobility for invasive procedures. The administration of anesthetic drugs and the unconscious, recumbent, and immobile state, however, compromise patient homeostasis. Anesthetic crises are unpredictable, and tend to be rapid in onset and devastating in nature. The purpose of monitor-

ing is to achieve the goals while maximizing the safety of the anesthetic experience.

The purpose of preoperative monitoring is to determine the existence and magnitude of abnormal processes that might compromise a patient's response to anesthesia and the operative procedure, and to guide the development of the anesthetic plan. The preoperative assessment provides the basis for tailoring drug selection and the intraoperative and postoperative monitoring and support to the specific needs of the patient. Intraoperative monitoring, the subject of this chapter, focuses on insuring an optimum anesthetic depth with minimal physiological impairment. The purpose of postoperative monitoring is to warrant a full and complete recovery from the anesthetic state and to provide adequate analgesia.

Anesthetic Mortality

Anesthetic issues and problems are common, but mortality from them is rare. The difference is in the monitoring, which can lead to the early recognition and correction of the problem. Such events, when they are easily rectified, are seldom even defined as problems. An adverse event that threatens the life or causes the death of a patient is universally defined as a problem. Perioperative cardiac arrest, as opposed to the problem(s) that could potentially cause it, is objective and not likely to be underrecognized. Such mortality analyses may help define when and what should be monitored during anesthesia.

Earlier studies reported a perioperative mortality rate of 20 to 189 per 10,000 patients administered anesthetics.¹⁻⁴ Anesthesia contributed to 2.5 to 9.2 deaths per 10,000 patients administered anesthetics. Mortality rates were higher among patients with poorer preoperative physical status and greater age where biological reserves are limited, and among patients undergoing emergency procedures where preoperative planning and preparation are limited, but were still of notable frequency in young, healthy patients undergoing planned procedures. Of the deaths, 1% occurred at induction, 10% to 30% intraoperatively, 10% early postoperatively, and the remainder over the ensuing days.^{3,4} Intraoperative causes of death included the primary disease process; aspiration; hypovolemia and hypotension; hypoxia secondary to airway or endotracheal tube problems, or pneumothorax; misdosing of drugs; and hypothermia. Postoperative causes of death included the primary disease process, arrest during endotracheal tube suctioning, aspiration, pneumonia, and heart failure.

Perioperative mortality was reported to be 8.8/10,000 patients administered anesthetics in a recent study of human patients.⁵ Deaths attributed entirely to anesthesia were quite uncommon (0.1/10,000), but anesthetic-contributed mortality (anesthesia in combination with surgery and augmented by the underlying disease) was 1.4/10,000. In addition, there was a 0.5/10,000 incidence of postoperative coma 1 day after anesthesia. Of anesthesia-related deaths, 17% occurred in American Society of Anesthesiologist (ASA) classification 1 or 2, 45% in ASA class 3, and 38% in ASA class 4 or 5 patients. Of the deaths, 29% occurred intraoperatively, 6% in recovery, and the remainder postoperatively. No deaths were recorded at the time of induction, which is a notoriously dangerous point in the anesthetic experience. Many problems were noted during induction, but no deaths resulted from them. Of the anesthesia-related deaths, 52% involved cardiovascular problems (hypovolemia and inadequate volume replacement, hypotension and hypertension, ventricular arrhythmias, or heart failure), and 10% involved respiratory problems (inadequate oxygenation, airway problems, aspiration, or ventilatory failure). Metabolic problems were a distant third category.⁶ Inadequate preoperative preparation was thought to occur in 25%, and inadequate monitoring in 10%, of the anesthesia-related deaths.

In a survey study reported in 1990, cardiac arrests, 55% of which were fatal, occurred in 2.6 per 10,000 patients administered anesthetics.⁷ Anesthesia was thought to play a role in 45% of these cardiac arrests. Of anesthesia-related deaths, 23% occurred in ASA classification 1 or 2, 17% in ASA class 3, and 61% in ASA class 4 or 5 patients. Of the cardiac arrests, 47% were thought to be due to preventable causes, the most common of which were errors in drug administration and hypoxia.

A veterinary study in 1998 cited a complication rate of 2.1% in 8087 dogs and 1.3% in 8702 cats, and an overall mortality rate of 0.1% (10/10,000 anesthetics).⁸

Life-threatening perioperative problems, and therefore the thrust of monitoring, seem to focus on the cardiopulmonary system, although other organ systems and metabolic issues cannot be ignored. Certain patient groups appear to represent greater risk, although anesthesia and operation represent great risk to any patient. Critically ill patients are somewhat advantaged because we know in advance to pay special attention. Healthy patients undergoing routine procedures are perhaps disadvantaged if we let our guard down because we are not expecting a problem. Monitoring encompasses (a) assuring an appropriate anesthetic level and (b) guarding against excessive physiological impairment.

Monitoring Anesthetic Level

The purpose of assuring an appropriate level of anesthesia is to minimize the detrimental effects of excessively light levels of anesthesia (awareness, recall, pain, and movement), as well as those of excessively deep levels of anesthesia (hypoventilation and hypoxemia; reduced cardiac output, hypotension, and inadequate tissue perfusion; hypothermia; and prolonged recovery). The term *anesthetic depth* is somewhat of an anachronism because it is based on the concept that anesthetic agents cause pro-

gressive depression of central nervous system (CNS) function. It is clear that anesthetic agents have different mechanisms of action on the CNS, most of which are depressant, but some of which are stimulant.⁹ Consciousness might better be represented as a sphere, as opposed to a line. When cortical function is pushed outside the boundaries of this sphere (in any direction) (as opposed to below a line), unconsciousness occurs. Consciousness might be viewed as a state of organized CNS function, and anesthesia as a state of disorganized CNS function produced by facilitated or impaired neurotransmitter release or receptor receptivity. The terms *level of anesthesia* and *anesthetic depth*, however, are familiar and are used in this chapter, but refer to the relationship between anesthetic-induced CNS function and the center of the *sphere of consciousness*.

The state of *general anesthesia* is defined as the lack of awareness of all aspects of one's environment (including pain). Anesthetic drugs, administered in small dosages, may cause sedation, but not anesthesia. There are, of course, degrees of sedation or obtundation between fully awake and anesthetized, but there is no consensus as to what to call them. An animal that is visibly lethargic, sluggish, and depressed, but is spontaneously aware of its environment, might be described as being mildly sedated or obtunded. An animal that is "sleeping" and does not appear to be aware of (or care about) its environment when unstimulated, but that is readily awakened with verbal or light tactile stimulation, might be described as being moderately sedated or obtunded. An animal that awakens only with strong tactile or noxious stimulation might be described as being more sedate or obtunded, whereas anesthetized or comatose patients cannot be awakened even by strong, painful stimulation. Some sedative drugs (e.g., opioids), even in high dosages, do not induce anesthesia reliably. Some sedative drugs administered in small dosages do not even induce sedation, but can decrease a patient's apprehension or anxiety: This is *tranquilization*. Tranquilizers (phenothiazines and benzodiazepines) can never be anesthetics, but they can potentiate the anesthetic effects of anesthetics. Anesthetic drugs, if dosed judiciously, can act as tranquilizers, sedatives, or true anesthetics. Opioids can induce an anesthesia-like state in high dosages, but, if used alone, spontaneous movement in animals and awareness in people are not uncommon.

Analgesia is the lack of awareness of nociceptive stimuli. Some agents (e.g., opioids and nitrous oxide) are good analgesics, but are not particularly good at inducing loss of awareness (anesthesia). Some anesthetic drugs (barbiturates, propofol, etomidate, halothane, and sevoflurane) are good anesthetics but have no analgesic qualities (in subanesthetic dosages). These agents can be used for surgical procedures, however, because, once anesthetized, animals lose their ability to perceive pain. The eminent problems with these agents are the variation in anesthetic depth associated with nociceptive stimulation during the operative procedure and the lack of postoperative analgesia. Some agents (ketamine and isoflurane) are good anesthetics, as well as good analgesics.

There are also levels of anesthesia. In Guedel's classic description of anesthetic depth,¹⁰ loss of consciousness defines the border between stages I and II, and the cessation of spontaneous mus-

cle movement the border between stages II and III (the surgical stage of anesthesia). In the lighter plane of stage III, a hemodynamic response and muscular movement in response to noxious stimuli might still be present, but stage II provided a comfortable margin between these responses and awareness of the noxious stimulus. A hemodynamic response or reflex muscular movement in response to a noxious stimulus proved a light level of surgical anesthesia and yet the patient was far removed from being aware of the noxious stimulus: the ideal anesthetic level. This is an important concept either to accept or to reject because it bears directly upon the philosophy of much of the recent research that equates a hemodynamic response, an electroencephalographic (EEG) response, or a muscular movement response to a noxious stimulus with the conscious awareness of pain.

One of the major goals of anesthesia is that the patient should lack awareness during the procedure. Amnesia is often listed as one of the goals of anesthesia, but it is somewhat of an oxymoron. If the first goal is met, then there is nothing to forget. It would hardly be philosophically acceptable to allow awareness of pain during the operative procedure, as long as the patient forgot about it afterward. It turns out that the first goal (lack of awareness) is not always met, but that awareness, and discomfort and pain, are also not synonymous. There is also a naturally high incidence of amnesia afterward. Awareness probably occurs considerably more frequently than people remember it.¹¹ In one study, 20 patients were deliberately awoken intraoperatively from propofol anesthesia and asked to perform cognitive tasks, and then were reanesthetized for completion of the surgical procedure.¹² Only 35% of these patients could remember the experience. Awareness, it turns out, is a very difficult thing to study because it can be studied only by asking patients whether they remember anything. There is also the difference between spontaneous, explicit recall of specific events and implicit, nonspecific recall that can be obtained only with extensive questioning or hypnosis. Explicit recall is often better 1 week after surgery than it is after 1 day, so the study results depend on when the question is asked. The incidence of explicit awareness in people is cited to be about 0.2%.¹³ Intraoperative awareness is also not always associated with intraoperative pain nor posttraumatic suffering, but when it is, it is a serious problem.¹³ Many reports of awareness in people are associated with insufficient dosages of anesthetic; for example, in cesarean section when fetal depression is a concern, and in cardiac and trauma patients where anesthetic-induced cardiovascular depression is a concern.¹³ The easiest way to prevent intraoperative awareness is to provide adequate amounts of anesthetic. Preventing movement, hemodynamic, and EEG response to surgical stimulation, although not necessary in most patients, would seem to be the best means of minimizing intraoperative awareness in all patients.

In general, patients lose recall at the lightest levels of anesthesia first, awareness second, movement in response to a nociceptive stimulus third, and a hemodynamic or EEG response to a nociceptive stimulus fourth, with increasing anesthetic depth. For halothane, MAC_{awake} (minimum alveolar concentration [MAC] to prevent response to verbal command in 50% of patients; awareness) is about 0.4%; $MAC_{incision}$ (MAC to prevent muscu-

lar movement in response to a strong surgical stimulus) is about 0.9%; and MAC_{BAR} (MAC to block the autonomic response to skin incision) is about 1.1%.¹⁴ The MAC_{awake} and the $MAC_{incision}$ were reported to be 0.39 and 1.3 for isoflurane and 0.61 and 2.0 for sevoflurane, respectively.¹⁵ Patients maintained at an end-tidal anesthetic concentration that is sufficient to prevent movement in response to surgical stimulation, let alone sufficient to prevent a hemodynamic response, have a 2^{1/2}- to 3-fold anesthetic margin between them and awareness. The *bispectral index* (BIS) is a processed electroencephalogram that quantifies the degree of anesthetic-induced cortical electrical depression. A value below 60 is associated with loss of recall, below 50 with the loss of awareness, below 40 with the loss of muscular movement in response to a noxious stimulus, and below 20 with burst suppression (deep anesthesia). MAC_{BAR} and MAC_{BIS} (the MAC associated with an increase in BIS to 60 in response to nociceptive stimulation) were reported to be about the same in cats.¹⁶ BIS has been used to help ensure that patients are well anesthetized, pain free, and unaware.^{13,17}

A hemodynamic or EEG response or movement in response to a nociceptive stimulus does not mean that an animal is consciously aware of the stimulus; the evidence seems to be quite contrary to this assumption. These reactions might represent the ideal anesthetic level (light, but not too light). However, in the clinical practice of anesthesia, since a 100% lack of awareness is the goal, maintaining a depth of anesthesia that is free of hemodynamic, EEG, and movement response to surgical stimuli, as long as the cardiovascular system can handle it, would seem to maximize the likelihood of achieving the lack-of-awareness goal. Spontaneous movement during anesthesia is, however, a characteristic of some anesthetic agents (opioids, etomidate, and propofol) and is not synonymous with inadequate anesthetic depth.

Anesthetic level represents the balance between the amount of drug(s) administered, the amount of surgical stimulation (which tends to awaken patients), and the severity of illness (which tends to synergize the anesthetic). Anesthetic requirements change over time (with an overall decreasing trend) within a single anesthetic experience, because of variations in the magnitude of surgical stimulation, the gradual filling of redistribution sites, and variations in body temperature. It would not be appropriate to maintain initial vaporizer settings or drug infusion rates for the duration of the operative procedure, because animals would invariably be excessively anesthetized by the end of the procedure. Anesthetists should repeatedly try to decrease the amount of anesthetic administered during the course of an anesthetic. Since the dosage of anesthetic required for a patient cannot be predicted, however, the administration of each anesthetic should be considered a clinical experiment. If the signs of anesthetic depth suggest that an animal's anesthesia level is getting too light, then perhaps the anesthetic dose should be returned to its previous setting; unless, of course, one is at the end of the operative procedure: then light is right. The challenge is to keep the animal in a light to medium level of anesthesia; that is, deep enough to abate conscious perception and to provide adequate muscle relaxation, yet light enough that the signs of anesthesia clearly indicated that the animal is not too deeply anesthetized.

Single, point-in-time measurements are meaningful when they are severely abnormal; an animal that is prematurely leaving the operating table of its own will is a problem at the moment, and it does not matter what depth was assessed 5 min earlier. For the most part, though, measurements and evaluations are interpretable only in the context of previous measurements (the palpebral reflex at the moment, compared with what it was 15 min earlier) and with reference to other related parameters. (If an animal is scrambling to leave the table, who cares whether it has a palpebral reflex?) Given the mechanistic differences between anesthetic drugs and interindividual differences in response to them, monitoring of anesthetic level is, at best, very uncertain. It is nevertheless the explicit responsibility of anesthetists to ensure that these drugs are administered in the safest possible way by monitoring the animal's response to them.

Physical Signs of Anesthetic Depth

These depend, for the most part, on the evaluation of muscular tone and muscular reflexes. The signs of anesthetic depth vary from moment to moment, from individual to individual, and between species and anesthetic drugs. No one sign alone defines anesthetic depth. Assess as many signs as possible. They invariably suggest different levels of anesthesia, one sign suggesting a light level, one medium, and one deep, and the anesthetist is left to sort it all out. Observers should prioritize the signs (some are more reliable than others) and then average their findings (medium in the aforementioned example). The presence of a sign is much more meaningful than the absence of it. For instance, in most species and with most anesthetics, the presence of a palpebral reflex is a reliable sign of a light level of anesthesia. The absence of a palpebral reflex suggests that the level is not light. In some individuals, though, the sign is unreliable, and the level is light despite the absence of the reflex. When the signs of anesthetic depth are unclear or contradictory, anesthetic drug administration should be decreased until the animal is clearly at a light to medium level of anesthesia. Lastly, know that there is no obligatory correlation between level of anesthesia and physiological consequence of anesthesia; a light level does not preclude severe hypotension or hypoxemia. These are some points to remember:

1. The recent history of anesthetic dosing is an important component of the evaluation of the depth of anesthesia: Large dosages should be associated with a deep level of anesthesia and vice versa. The vaporizer setting or the drug infusion rate helps define the amount of anesthetic being delivered to a patient. End-tidal anesthetic concentrations and plasma drug concentrations define the amount of anesthetic in a patient. Usual vaporizer settings, drug administration rates, and end-tidal and plasma concentrations that are appropriate for induction (loading) and then maintenance for the various common anesthetics are discussed elsewhere in this text (Chapters 8 through 16). The issue here is that the anesthetic drug dosing is just the beginning of the evaluation of the depth of anesthesia, not the definition of it. "Usual" dosages may cause excessive anesthesia in animals with serious underlying disease and hypothermia. Normal anesthetic drug dosages do not guarantee that an animal will not be overanes-

thetized. Equally important is that vaporizers and infusion pumps do not always work properly, and normal settings may actually overshoot or undershoot the mark. Knowledge of anesthetic drug dosing and knowledge of the amount of drug "on board a patient" define only what they measure and are not the definition of anesthetic depth in an individual patient. You are going to need more information.

2. Spontaneous movement is a reliable sign of a light level of anesthesia with most anesthetics. Focal muscle twitching has been associated with etomidate and propofol administration and should not be interpreted, per se, to indicate a light level. Spontaneous muscular movement is common with opioid-based anesthetic protocols and also should not be interpreted to indicate a light level. Muscle hypertonus can be a feature of ketamine-based protocols and should not be interpreted to indicate a light level.

3. Reflex movement in response to surgical stimulation is a reliable sign of a light level of anesthesia. It does not, however, mean that an animal is experiencing pain from a nociceptive stimulus.

4. An abrupt increase in heart rate, blood pressure, or breathing rate, specifically in response to surgical stimulation, is generally considered to be a reliable sign of a light level of anesthesia. In general, physiological parameters such as heart rate, arterial blood pressure, breathing rate, and minute ventilation should trend upward as an animal becomes more lightly anesthetized and downward when an animal becomes deeply anesthetized. These are not, however, reliable *premonitory* indicators of anesthetic depth; they are often observed to be quite stable until after an animal abruptly awakes or suffers cardiovascular collapse. There are also many abnormalities that affect these parameters (in either direction) that have nothing to do with anesthetic level. Anesthetic level is only one of the differentials that should be considered when an animal develops a decreased or increased heart or breathing rate.

5. Mandibular muscle tone should be *lots*, *some*, and *none* in light, medium, and deep levels of anesthesia, respectively, in dogs and cats. The descriptors *lots*, *some*, and *none* must be indexed to the species and breed of an animal; one would never expect a cat to have the same muscle tone as a mastiff. Mandibular muscle tone is assessed by the resistance encountered when trying to just open the mandible. Puppies never have any mandibular muscle tone, and this parameter cannot be used to evaluate their depth of anesthesia. Large animals always have much muscle tone and this parameter cannot be used to evaluate their depth of anesthesia. Ruminants and swine exhibit a chewing reflex when they are lightly anesthetized.¹⁸

6. A change to an abdominal (diaphragm)-first breathing pattern signals a deeper level of anesthesia, as does bradypnea and hypoventilation.

7. The presence of a palpebral reflex is a reliable indicator of a light level of anesthesia. The absence of it suggests a medium or deep level. The goal would be an anesthetic depth where the palpebral reflex is either just barely present or just barely absent. Some individuals fail to exhibit a palpebral reflex even though their anesthesia level is actually light. With keta-

mine use, the palpebral reflex is always present and the eyelids remain open as opposed to the effect of most other anesthetics on this parameter.

8. The presence of a *pupillary light reflex* (pupillary constriction in response to a bright light shined upon the retina) and the presence of a *dazzle reflex* (a blink in response to a bright light) are reliable indicators of a light to light to medium level of anesthesia. The pupillary light reflex may be minimized or eliminated by parasympatholytics.

9. In small animals, with traditional anesthetics, eyeball position is central (and the pupil size is medium) when the animal's anesthesia level is light, is rotated ventromedially when the level is medium, and is central again (and the pupil is dilated) when the level is deep. The eyeball does not rotate when ketamine is used. In horses, the eyeball can rotate, though not reliably so, but spontaneous nystagmus does occur. A very slow, "roving" eyeball ("one minute it's here; the next it's over there") might represent a medium level of anesthesia, whereas a fast nystagmus represents a very light level in this species. Nystagmus may occur in light levels of anesthesia in ruminants and swine, but disappears at deeper levels. In these species, the eyeball rotates ventrally with deeper levels of anesthesia. Nystagmus does not normally occur in anesthetized small animals.

10. The lack of tear production as noted by a dry-appearing cornea is a sign of a deep level of anesthesia with traditional anesthetics. Lacrimation or "tearing" is seen in horses and is a sign of a light level.

11. The gag and swallow reflexes are reliable indicators of a light level of anesthesia in nearly all species.

EEG: Monitoring of Anesthetic Depth

Typically, the EEG pattern changes from a low-wave, high-frequency pattern during the awake state to high-wave, low-frequency with anesthesia to burst suppression (intermittent periods of electrical silence) and finally persistent electrical silence with deep levels of anesthesia. The raw EEG signals, however, require a considerable volume of recording and considerable specialized training and expertise to interpret subtle changes. Computerized analysis of raw EEG signals facilitates interpretation of those signals. EEG voltage changes (power) as a function of time (time domain) generate such indices as total EEG power, median power frequency, or burst suppression. Interpretational algorithms (by fast Fourier transformation) might also examine signal activity as a function of frequency (frequency domain) and generate such indices as spectral edge frequency (SEF₉₅) (the frequency below which 95% of the total EEG power resides), median frequency (the median EEG power frequency), and the relative power of the delta (0.5 to 3.5 Hz), theta (3.5 to 7.0 Hz), alpha (7 to 13 Hz), and beta (13 to 30 Hz) frequency ranges compared with total EEG power.¹⁹ Such indices have been used to characterize anesthetic depth in people^{6,20-22} and animals.²³⁻²⁶ Other indices²⁷ and combinations of indices,²⁸ BIS and Narcotrend (Monitor Technik, Bad Bramstedt, Germany), may represent a more integrated approach to EEG analysis compared with the classic indices^{19,22} and may be more user-friendly.

BIS analysis (Aspect Medical Systems, Newton, MA) repre-

sents a variably weighted value derived from four subparameters: (a) burst suppression ratio (time domain); (b) a quasi value (time domain); (c) β_2 power ratio in the 30- to 47-Hz range compared with that in the 11- to 20-Hz range (frequency domain); and (d) the bispectral biocoherence ratio of peaks in the 0.5- to 47-Hz range compared with the 40- to 47-Hz range (frequency domain).¹⁷ BIS has been extensively studied in humans primarily as an index of sedation^{29,30} or depth of anesthesia.^{16,22,26,31-34} It has also been used as an index of brain function in neurological patients.^{35,36} The BIS monitor does not require calibration and displays a bar graph denoting signal quality and amount of electromyographic interference. Excessive muscle movement can be a problem.³⁷ The monitor displays a number between 0 and 100: Values above 90 are compatible with awake and alert, 80 to 90 with anxiolysis, 60 to 80 with hypnotic or moderate obtundation, below 60 with loss of recall, below 50 with unresponsiveness to verbal stimuli, below 20 with burst suppression, and 0 with isoelectric stimuli (Aspect Medical Systems). Not all anesthetics affect BIS in the same way: Propofol, midazolam, and thiopental strongly depress it, inhalational anesthetics have an intermediate effect, opioids have little effect, and nitrous oxide and ketamine tend to increase the BIS value.¹⁷

Narcotrend analyzes the raw EEG data and then categorizes the levels of sedation as awake (A0), subvigilant (A1 and A2), sedation (B0, B1, and B2), anesthesia (C0, C1, and C2), moderate anesthesia (D0, D1, and D2), deep anesthesia or burst suppression (E), and coma/electrical silence (F).³⁸

Auditory evoked EEG responses have been used primarily to assess neurological function in CNS disease, but have also been used to assess anesthetic depth and awareness or recall.³⁹ Many studies have used sensory (to a noxious stimulus)-evoked EEG or BIS, hemodynamic responses, and movement responses to evaluate nociception.

All EEG indices are subject to large individual and anesthetic drug variation. Depending on the magnitude of the stimulation and the depth of anesthesia, stimulus-induced EEG changes could represent either an arousal pattern or a pattern that suggests a deeper level of anesthesia (the *paradoxical* response).^{23,40} The EEG changes do not reflect analgesic properties of an anesthetic drug, per se, but only its hypnotic properties. No EEG index has yet replaced physical evaluation of patients and common sense, although several indices clearly aide the evaluation of anesthetic depth, reduction of anesthetic drug dosages, and shortened recovery times.³⁸

Monitoring Perioperative Pain and Analgesia

Nociception is the neural response to a noxious stimulus. *Pain* is the conscious interpretation that the nociceptive stimulus is sufficiently unpleasant to motivate its owner to do something about it. The evaluation of pain is more simple in communicative people (you ask them) than in neonates and animals. The existence of pain in an animal and the need for analgesic therapy depend on the observation of behavioral changes or abnormalities that can reasonably be attributed to pain. Unfortunately, none of the

“pain signs” are specific to pain; many nonpainful situations cause them, as well.

Physical Signs of Pain

It might be helpful to divide pain into levels of magnitude: mild, moderate, and severe. *Severe pain* might be defined as that which is intolerable; the kind of pain where the animal throws itself about its cage in a mindless frenzy because the pain is so severe that it simply cannot deal with it in any other way. Unprovoked vocalizing (crying or whimpering) by an animal that does not have CNS disease and is not recovering from anesthesia, but does have a disease that might be painful, is taken as evidence of severe pain. *Mild pain* might be equated with that amount which one would consider to be a nuisance and not necessarily of such magnitude that its owner would seek out pain-relief medications. Such an animal can tolerate it well and can usually go about its normal daily activity. Since the pain does not interfere with behavior in any fashion, it defies recognition by an outside observer.

Moderate pain may be described as that which starts to interfere with normal behavior, appetite, or activity of an animal that has a disease or that has undergone a surgical procedure or experienced a trauma that is reported to be painful in people. The animal may exhibit an anxious expression and may not rest comfortably, and may be unable to sleep. The animal is less concerned with happenings in its environment. Appetite may be decreased or absent and the animal may lose weight, energy, or productivity. The animal's activity may be decreased (if the animal is trying to minimize pain associated with movement). It may just lie in one spot for extended periods with its eyes open, staring into space without focusing on anything in particular. The animal's activity may become increased (if the animal is trying to find a position wherein the pain is diminished), and the animal may assume abnormal positions. The animal may move, but infrequently, and stiffly, as though to guard and protect the painful area. The attitude may also change to that of an animal that is less tolerant to being handled than normal. The attitude may become more fearful or more aggressive.

The pain may be classified as moderate if an animal develops an anxious expression or tenses when the area in question is about to be touched, or if it cries out or responds aggressively when the area is touched (assuming that these represent inappropriate responses for this particular individual or species to an otherwise innocuous stimulus). Secondary physiological changes that may result from pain are tachycardia, tachypnea, hypertension, arrhythmias, dilated pupils, salivation, and/or hyperglycemia.

EEG: Monitoring of Analgesia

The EEG indices measure brain electrical activity that changes in an approximately consistent pattern with anesthetic depth in such a way that one can predict with some accuracy when a patient loses awareness, recall, and response to a noxious stimulus. EEG changes observed in response to nociceptive stimulation generally reflect a lighter level of anesthesia, although a “paradoxical arousal” response, reflective of a deeper level, is common.^{23,40}

These EEG indices are not a measure of pain, per se, but of a cortical response to the nociceptive stimulus, in the same way that movement or a change in heart rate may occur in response to a nociceptive stimulus. These responses do not prove that an animal is experiencing pain, but only suggest a cortical electrical response to the nociceptive stimulus; the animal may or may not be experiencing pain.

Most studies use the EEG indices to measure the ability of various drugs to diminish a response to a specifically timed, induced surgical stimulus (such as an incision).^{40–43} Although the administration of nitrous oxide did not affect 95% spectral edge frequency or BIS in the absence of surgical stimulation,⁴⁴ it was associated with a dose-dependent decrease in these parameters when administered during major lumbar surgery.⁴⁵ Although the administration of fentanyl did not affect 95% spectral edge frequency or BIS, per se, it prevented the decrease in these indices (paradoxical response) associated with skin incision.⁴³ Both results were attributed to the analgesic properties of the drugs. In a novel approach to studying preemptive analgesia, when the spectral edge frequency was maintained within the target range of 8 to 12 Hz, postoperative pain scores and morphine requirements were reduced.⁴⁶ There are no analgesia monitors per se, but only monitors of the cortical electrical response to nociceptive stimuli. When a drug diminishes the EEG response to a nociceptive stimulus, it is often presumed to be because of its analgesic qualities (unless, of course, it is because of its hypnotic qualities).

Analgesia assessment in the postoperative period is a different challenge from that of a specific, timed, nociceptive stimulus in the intraoperative period. Postoperatively, pain is pretty much ongoing. The objective might be to return the EEG index and the patient to a state that is relaxed, sedate, and pain free (that is clearly not an arousal nor a paradoxical arousal state) and to maintain them in that state. In EEG terms, this might be an SEF₉₅ of 8 to 12 Hz or a BIS value below 60. In physical examination terms, this is represented by behavior which suggests that the animal is comfortable and reasonably pain free. The EEG indices are not likely to be particularly helpful in weaning an animal off of analgesic drugs; that is, in determining when it is okay to withdraw them and allow an animal to return to a normal, aroused, drug-free, pain-free state.

Important Concepts in the Provision of Analgesia

The administration of analgesic drugs prior to the nociceptive stimulus (preemptive analgesia) is thought to reduce the *ramping up* process (amplification of the nociceptive signal) by the modulatory interneurons within the spinal cord. Preemptive analgesia reduces the magnitude of postoperative pain as well as the dosages of analgesics administered.

Animals cannot truly be evaluated for pain during the recovery phase (the reflex phase) of anesthesia. Nevertheless, excessive vocalizing and activity during this time should be subdued with a sedative; they can cause the animal's owner considerable angst. Ensure that the source of the discomfort is not a full urinary bladder (animals typically receive a large volume of fluids during surgery and often do not urinate).

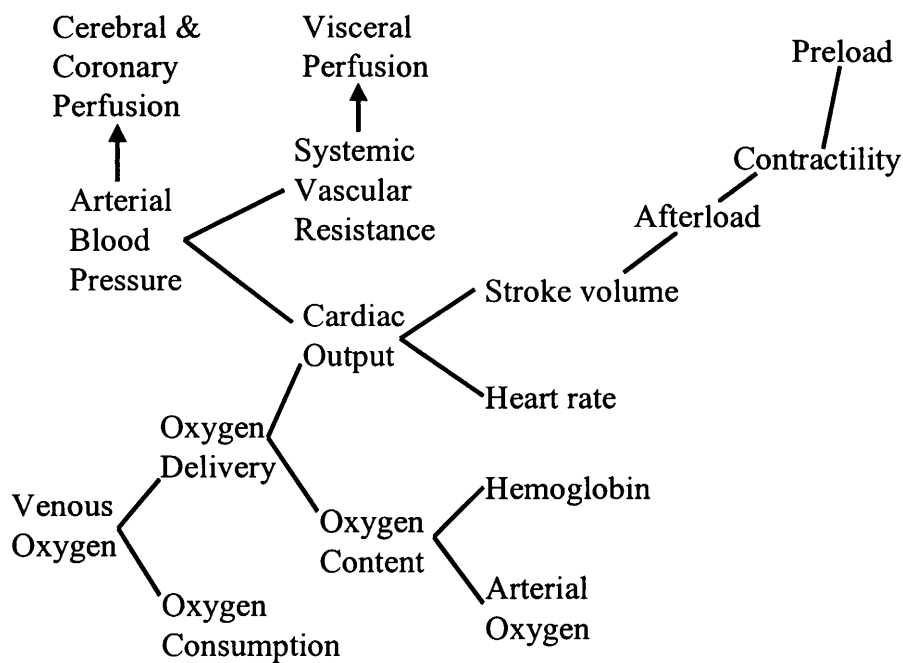

Fig. 19.1. Integration of cardiopulmonary performance.

In the postoperative period, after the evaluation of pain signs, because they are not specific, one is invariably left with doubt as to whether an animal is experiencing pain. In the end, the decision is subjective. Animals should subjectively appear to be comfortable, respond to human interaction normally, sleep, eat and drink, and move about with ease. If they do not present a comfortable picture, something should be done. Analgesic drugs are not without potential adverse effects, and there is sometimes great hesitancy to administer them to treat a problem that one is not sure exists. The relative risks, however, are low and by far outweighed by the potential harm associated with unremitting pain. When it is unclear whether an animal is experiencing undue pain and when it is unclear whether analgesics should be administered, it is appropriate to administer a full dose of an analgesic.

Free nerve endings transduce pressure, heat, or chemical nociceptive stimuli into an electrical signal (transduction) that is then transmitted to the spinal cord, brain stem, and thalamus (transmission). In the dorsal horn of the spinal cord, nociceptive signals can be diminished or augmented by ascending or descending interneuronal pathways (modulation). The somatosensory cortex then integrates, interprets, and quantifies the nociceptive stimulus (perception). Different analgesic drugs affect nociception at different levels of the process, and this justifies the use of drugs with multilevel effects and the use of multiple drugs to take advantage of their differential foci of effect. Transduction can be inhibited by local anesthetics, opioids, and antiprostaglandins; transmission by local anesthetics and α_2 -agonists; spinal modulation by local anesthetics, opioids, α_2 -agonists, *N*-methyl-D-aspartate antagonists (ketamine), antiprostaglandins, and anti-convulsants; and perception by general anesthetics, opioids, α_2 -agonists, and tranquilizers (phenothiazines).⁴⁷

When one or two dosages of an analgesic fail to alleviate the “pain signs,” chances are that pain was not the problem in the

first case. The use of anxiolytics may be indicated. Acepromazine (0.01 mg/kg) has been remarkably effective; diazepam (0.2 mg/kg) may or may not be effective.

Physiological Consequences of the Anesthetic State

Although the pharmacodynamic effects of the various anesthetic drugs vary, the mechanisms by which they cause morbidity and mortality are the same: excessive bradycardia, arrhythmias, myocardial depression, vasodilation, hypotension, hypoventilation, hypoxemia, or hypothermia. These common problems should be the focus of intraoperative monitoring of organ function. Ongoing, automatic, audible monitors of organ function are the mainstays of intraoperative monitoring and crisis prevention. Single, point-in-time measurements are meaningful when their results are severely abnormal: A heart rate of zero is a problem at the moment, and it does not matter what it was 15 min earlier. For the most part, though, measurements and evaluations are only interpretable in the context of previous measurements (trends) and with reference to related parameters (Fig. 19.1). A dog’s heart rate of 50 beats/min may not be a problem if blood pressure and cardiac output are adequate to meet the tissue perfusion needs of the patient, or may even be an appropriate compensation if the arterial blood pressure is high. Some expected cardiopulmonary changes associated with the administration of various anesthetic agents are listed in Tables 19.1 (dogs) and 19.2 (horses).

Cardiovascular Monitoring

Heart Rate and Rhythm

Heart rate and stroke volume are important to cardiac output. Slower heart rates are usually associated with larger end-diastolic

ventricular volumes and larger stroke volumes; up to a point, cardiac output is preserved by the larger stroke volumes.⁴⁸ Heart rate is too slow when it is associated with low cardiac output, hypotension, or poor tissue perfusion. In lieu of this kind of evi-

dence or a reasonable cause for the bradycardia, values of 60 beats/min for dogs, 90 for cats, and low 20s for horses are common triggers for treatment. Common causes and treatment for bradycardia are listed in Table 19.3. Verify that the problem is truly bradycardia as opposed to a slow pulse rate, which could be caused by ventricular arrhythmias. Excessive vagal tone can be caused by pharyngeal, laryngeal, or tracheal stimulation; by pressure on the eyeball or rectus muscles; or by visceral inflammation, distension, or traction.

Sinus tachycardia is primarily a sign of an underlying problem (Table 19.4). It becomes a problem for patients only when there is not enough time for diastolic filling: Cardiac output decreases. In people, because of coronary artery disease, sinus tachycardia is feared because the increased myocardial oxygen consumption may exceed oxygen-delivery capabilities. In lieu of cardiac output information, the trigger level for specific treatment of sinus tachycardia may be somewhere in the low 200s for dogs, the high 200s for cats, and 80 for horses.

Ventricular arrhythmias, in an animal that did not have them prior to anesthesia, are primarily a sign of an anesthetic-induced complication (Table 19.5). Make sure that the electrocardiographic abnormality is truly of ventricular origin as opposed to a right bundle branch block, which appears similar to a ventricular rhythm except that it is preceded by a P wave. Ventricular arrhythmias may also be caused by intrinsic myocardial disease or arrhythmogenic factors released from various debilitated abdom-

Table 19.3. Causes of perioperative bradycardia.

Cause	Treatment
Anesthetic overdosage	Lighten the level of anesthesia
Opioids	Administer a parasympatholytic
α_2 -Agonists	No treatment
Excessive vagal tone caused by visceral stimulation	Less stimulation; parasympatholytic
Hypothermia	Rewarm
Hyperkalemia	Calcium or insulin-glucose therapy
Sick sinus syndrome	Administer a parasympatholytic or sympathomimetic
Atrioventricular conduction block	Administer a parasympatholytic or sympathomimetic
End-stage metabolic failure	Administer a parasympatholytic or sympathomimetic
Hypoxia	Administer oxygen
Parasympathomimetics (e.g., acetylcholinesterase inhibitors)	Administer a parasympatholytic
Organophosphates	Administer a parasympatholytic
Digitalis	Administer a sympathomimetic

Table 19.4. Causes and treatment of tachycardia.

Cause	Treatment
Too light a level of anesthesia	Deepen the level of anesthesia
Ketamine	No treatment
Parasympatholytics (e.g., atropine)	Give less or by the subcutaneous or intramuscular route the next time; glycopyrrolate
Sympathomimetics	Decrease the infusion rate
Hypovolemia	Restore blood volume
Hyperthermia	Cool
Hypoxemia	Administer oxygen
Hypercapnia	Improve ventilation or eliminate rebreathing
Individual variation	No treatment
Paroxysmal supraventricular rhythm	Administer verapamil or diltiazem
Recovery phase	No treatment
Postoperative pain	Administer analgesics
Pheochromocytoma	Sympatholytic

inal organs. Ventricular arrhythmias become a problem for a patient when they interfere with cardiac output, arterial blood pressure, and tissue perfusion, or when they threaten to convert to ventricular fibrillation. Ventricular arrhythmias should be treated when (a) the minute-rate equivalent approaches the trigger point for treating sinus tachycardia, (b) they are multifocal, or (c) the ectopic beat overrides the T wave of the preceding depolarization. Total elimination of the ventricular arrhythmia is not necessarily the goal of therapy, because large dosages of antiarrhythmic

Table 19.5. Causes of ventricular ectopic pacemaker activity.

Endogenous release of catecholamines or sympathomimetic therapy
Hypoxia or hypercapnia
Hypovolemia or hypotension
Myocardial inflammation, disease, or stimulation (intracardiac catheters or pleural tubes)
Thoracic and nonthoracic trauma
Certain anesthetics lower the threshold to endogenous or exogenous catecholamines (halothane, xylazine, thiamylal, or thiopental)
Hypokalemia (potentiated by respiratory or metabolic alkalosis, or glucose-insulin therapy)
Hyperkalemia (potentiated by acidosis, hypocalcemia, succinylcholine, or may be iatrogenic)
Visceral organ disease (gastric volvulus and/or torsion)
Intracranial disorders (increased pressure or hypoxia)
Digitalis toxicity (potentiated by hypokalemia and hypercalcemia)

mic drugs have deleterious cardiovascular and neurological effects. A simple decrease in the rate or severity of the arrhythmia may be a suitable end point to the titration of antiarrhythmic drugs (Table 19.6).

Ventricular arrhythmias can be caused by several mechanisms that are not readily apparent from the electrocardiographic appearance of the arrhythmia: (a) abnormal automaticity characterized by rapid, spontaneous, phase 4 depolarization; (b) reentry of depolarization wave fronts because of unidirectional conduction blocks; (c) early after-depolarizations caused by diminished repolarizing potassium currents prolonging action potentials; and (d) delayed after-depolarizations caused by abnormal oscillations of cytosolic calcium concentrations after myocardial or Purkinje cell repolarization. A given antiarrhythmic may be effective in one mechanism and be ineffective, or even worsen the arrhythmia, in another. Antiarrhythmic therapy is always a bit of a clinical trial. Lidocaine is a first-choice antiarrhythmic because it selectively affects abnormal cells without affecting automaticity or conduction in normal cells.

Vasomotor Tone

Peripheral and visceral perfusion is primarily regulated by vasomotor tone. Vasodilation improves peripheral perfusion, whereas vasoconstriction impairs it. Vasodilation is a potent cause of hypotension, whereas vasoconstriction increases blood pressure. Vasomotor tone is assessed by mucous membrane color (pale = vasoconstriction, whereas red = vasodilation), capillary refill time (<1 s = vasoconstriction, whereas >2 s = vasodilation), toeweb to core temperature gradient ($>4^\circ\text{C}$ = vasoconstriction, whereas $<2^\circ\text{C}$ = vasodilation). Vasoconstriction may be caused by hypovolemia, heart failure, hypothermia, or the administration of vasoconstrictor drugs. Vasodilation may be caused by the systemic inflammatory response, hyperthermia or the administration of vasodilator drugs. Treatment should be directed to the underlying cause; vasocorrective therapy is only utilized as a last resort (Table 19.7).

Table 19.6. Antiarrhythmic drugs.

Drug	Mechanism	Indication	Intravenous Dosage
Lidocaine	Sodium-channel blocker	VPCs	1–4 mg/kg; 2–6 mg/kg/h
Procainamide	Sodium-channel blocker	VPCs; APCs	1–4 mg/kg; 2–6 mg/kg/h
Quinidine	Sodium-channel blocker	VPCs; APCs	5–15 mg/kg
Amiodarone	Sodium-channel blocker and other effects	VPCs	5 mg/kg over 20 min
Atenolol	β Blocker	APCs; VPCs	0.2–1 mg/kg
Esmolol	β Blocker	APCs; VPCs	0.2–0.5 mg/kg; 0.5–10 mg/kg/h
Propranolol	β Blocker	APCs; VPCs	0.01–0.3 mg/kg
Diltiazem	Calcium-channel blocker	APCs	0.05–0.25 mg/kg; 0.05–0.3 mg/kg/h
Verapamil	Calcium-channel blocker	APCs	0.05–0.25 mg/kg

APCs (atrial premature contractions), supraventricular arrhythmia; VPCs (ventricular premature contractions), ventricular arrhythmia.

Central Venous Pressure

Central venous pressure (CVP) is the luminal pressure of the intrathoracic vena cava. Peripheral venous pressure is variably higher than CVP, is subject to unpredictable extraneous influences, and is not a reliable indicator of CVP. CVP is the relationship between central blood volume and central blood volume capacity. Central blood volume is determined by venous return and cardiac output. Verification of a well-placed, unobstructed catheter can be ascertained by observing small fluctuations in the fluid meniscus within the manometer synchronous with the heartbeat, and larger excursions synchronous with ventilation. Large fluctuations synchronous with each heartbeat may indicate that the end of the catheter is positioned within the right ventricle. Direct observation of the CVP waveform may help identify the proper location of the catheter tip (Fig. 19.2). Measurements should be made during the expiratory pause phase (during either spontaneous or positive-pressure ventilation) because changes in pleural pressure affect the luminal pressure within the anterior vena cava.

The normal CVP in small animals is 0 to 10 cm H₂O. It is 15 to 30 cm H₂O in laterally recumbent horses, and 5 to 10 cm H₂O in dorsally recumbent horses.⁴⁹ Low-range or below-range values indicate hypovolemia and suggest that a rapid bolus of fluids should be administered. Above-range values indicate relative hypervolemia and that fluid therapy should be stopped. CVP is a measure of the relative ability of the heart to pump the venous return and should be measured whenever heart failure is a concern. CVP is also a measure of the relationship between blood volume and blood volume capacity and could be measured to help determine the end point for large fluid volume resuscitation. CVP measurements are used to determine whether there is “room” for additional fluid therapy in the management of hypotension.

CVP is not a measure of preload (only of preload pressure) and is a poor predictor of stroke volume or cardiac output.⁵⁰ Preload is end-diastolic muscle stretch that, in vivo, is mostly related to end-diastolic volume, which, clinically, is reflected in the measure of end-diastolic diameter. CVP is a filling pressure, not a vol-

Fig. 19.2. Central venous and ventricular pressure waveforms. CVP, central venous pressure; and ECG, electrocardiogram.

ume, and will not be representative of preload in diseases associated with decreased ventricular compliance (i.e., hypertrophy, tamponade, and fibrosis). Diastolic performance (relaxation) is also adversely affected by some anesthetics.⁵¹

Arterial Blood Pressure

Arterial blood pressure is a consequence of the relationship between blood volume and blood volume capacity. Arterial blood volume is determined by cardiac output and systemic vascular resistance. Arterial blood pressure is a primary determinant of cerebral and coronary perfusion. Systolic blood pressure is primarily determined by stroke volume and arterial compliance. Diastolic blood pressure is primarily determined by systemic vascular resistance and heart rate. Mean blood pressure is the average pressure: one-half of the area of the pulse-pressure waveform. If the pulse-pressure waveform were a perfect triangle, mean pressure would be one-third of the difference between diastolic pressure and systolic pressure. To the extent that the pulse-pressure contour is not a perfect triangle—a tall, narrow pulse-pressure waveform is common—the mean pressure will be closer to diastolic. The mean arterial blood pressure is physiologically the most important because it represents the mean driving pressure for organ perfusion. Many clinical instruments, however, measure only

systolic blood pressure. The relationship between systolic blood pressure and mean arterial blood pressure is variable, depending on the shape of the pulse-pressure waveform; systolic blood pressure should always be assessed with this in mind.

Assessment of pulse quality by digital palpation is an evaluation of both the height and width of the pulse-pressure waveform compared with normal. Tall, wide pulse-pressure waveforms are seen in sepsis, whereas tall, narrow waveforms occur with a patent ductus and during cardiopulmonary resuscitation. Small, narrow pulse-pressure waveforms are seen with small stroke volumes and vasoconstriction. A small stroke volume can be seen with hypovolemia, poor heart function from any cause, tachycardia, and ventricular arrhythmias. The pulse-pressure waveform is largely a reflection of stroke volume and vessel size. It is not a measure of arterial blood pressure per se, although, in a species-dependent and very general way, vessels with low pressure are easier to collapse and vice versa. The weak, thready pulse that occurs with hypovolemia is caused by small stroke volumes and vessel constriction; patients with this symptom may be normotensive. Peripheral pulse quality (such as the dorsal metatarsal in dogs) decreases and disappears earlier than it does in larger, more central arteries (such as the femoral) with progressive hypovolemia. The relative pulse quality of more peripheral versus

more central arteries may provide a rough index to the magnitude of the problem.

Arterial blood pressure can be measured indirectly by sphygmomanometry or directly via an arterial catheter attached to a transducer system. *Sphygmomanometry* involves the application of an occlusion cuff over an artery in a cylindrical appendage. The width of the occlusion cuff should be about 40% of the circumference of the leg to which it is applied. The occlusion cuff should be placed snugly around the leg. If it is applied too tightly, the pressure measurements will be erroneously low because the cuff itself, acting as a tourniquet, will partially occlude the underlying artery. If the cuff is too loose, the pressure measurements will be erroneously high because excessive cuff pressure will be required to occlude the underlying artery. Inflation of the cuff applies pressure to the underlying tissues and will totally occlude blood flow when the cuff pressure exceeds systolic blood pressure. As the cuff pressure is gradually decreased, blood will begin to flow intermittently when the cuff pressure falls below systolic pressure. When this occurs, (a) the manometer pressure at which needle oscillations begin to occur on the manometer during cuff deflation (caused by the pulse wave hitting the cuff) corresponds approximately to systolic blood pressure, and (b) the manometer pressure at which one can digitally palpate a pulse distal to the cuff corresponds approximately to diastolic blood pressure. *Doppler ultrasound* involves the application of a small piezoelectric ultrasound crystal over an artery. Some Doppler instruments measure blood flow and are used to measure systolic blood pressure, whereas other instruments generate signals from the movement of the arterial wall and can be used to measure

both systolic and diastolic blood pressures. *Oscillometry* analyzes the fluctuation of pressure in the cuff as it is slowly deflated and provides a digital display of systolic, diastolic, and mean blood pressures, and heart rate. Most of these instruments can be set to recycle at discrete time intervals. Small vessel size and motion can interfere with measurements.

All external techniques are least accurate when vessels are small, when the blood pressure is low, and when the vessels are constricted. Direct measurement of arterial blood pressure is more accurate and continuous compared with indirect methods, but requires the introduction of a catheter into an artery by a percutaneous or cut-down procedure. The dorsal metatarsal and ear arteries in dogs and cats, and the facial and metatarsal arteries in horses and cows, are commonly used. The subcutaneous tissues around these arteries are relatively tight, and hematoma formation at the time of catheter removal is rarely a problem. Once the catheter is placed, it is connected to a monitoring device. The catheter must be flushed with heparinized saline at frequent intervals (hourly) or continuously to prevent blood clot occlusion. The measuring device could be a long fluid administration set suspended from the ceiling. Fluid is instilled into the tubing via a three-way stopcock to a very high level and then allowed to gravitate into the artery until the hydrostatic pressure of the column of water is equalized with the mean arterial blood pressure of the patient. Since blood pressure oscillates, leaving the system open between measurements is not advised because that will let blood enter the catheter and clot and occlude it. Alternatively, the measuring device could be an aneroid manometer (Fig. 19.3). Water or blood must not be allowed to enter the manometer.

Fig. 19.3. Aneroid manometer system for measuring arterial blood pressure. The intra-arterial catheter is attached to a sterile length of extension tubing (since the system measures only mean pressure, the tubing does not have to be high-pressure, low-compliant tubing); a three-way stopcock; another extension tubing; another stopcock; and a third extension tubing, which is attached to the aneroid manometer. A saline-filled syringe is attached to the first stopcock, which is closed to the patient. Saline is injected into the tubing toward the manometer until the pressure registers at least 150 mm Hg (it needs to be only slightly higher than mean arterial blood pressure). The first stopcock is then closed to the syringe (opened between the pressurized manometer system and the arterial catheter), and the equilibrated pressure equals mean arterial blood pressure. Since blood pressure varies, do not leave the system open between measurements; blood will flow into the catheter and clot. This is an intermittent pressure-measuring device. The second stopcock enables the removal of excess saline from the tubing so that fluid does not get into the aneroid manometer.

Sterile saline is injected into the tubing toward the manometer via a three-way stopcock until the compressed air increases the registered pressure to a level above that of mean blood pressure. The pressurized manometer system is then allowed to equilibrate with the mean blood pressure of the patient. Arterial catheters can also be attached to a commercial transducer and recording system. The extension tubing between the catheter and the transducer should not be excessively long and should be constructed of nonexpansible plastic to avoid damped signals. The transducer should be “zeroed” periodically and calibrated with a mercury manometer to verify accurate blood pressure measurements. The stopcock that is opened to room air for the zeroing process must be at the level of the heart. With modern patient monitors, the transducer can be placed anywhere with reference to the patient (the monitor will compensate internally with an *offset pressure* for any vertical differences between the patient and the transducer). If the relative vertical position between the patient and the transducer changes, the transducer must be rezeroed. With older patient monitors without this offset feature, the transducer and the zeroing stopcock must be placed at the level of the heart.

The fidelity of the reproduction of the pulse-pressure waveform by a fluid-filled measurement system is the result of a rather complex interaction between the frequency response of the measurement system (resonant frequency and damping) and patient factors such as heart rate and systolic vigor. Generally, the intra-arterial catheter should be large; the transducer should be placed close to the patient, with high-pressure tubing connecting the catheter to the transducer; and the measuring system should be free of blood clots or air bubbles (Table 19.8). *Underdamping* occurs when the frequency response of the measuring system is identical to one of the harmonics of the pulse-pressure waveform. The recorded waveform will be exaggerated—the systolic pressure will be erroneously high and the diastolic pressure will be erroneously low; pressure oscillations may override the recorded waveform (Fig. 19.4). *Overdamping* occurs also when the frequency response is less than all of the harmonics of the pulse-pressure waveform. The recorded waveform will be blunted—the systolic pressure will be erroneously low and the diastolic pressure will be erroneously high; the dicrotic notch is diminished or absent (Fig. 19.4).

The frequency response of the measurement system can be assessed by the dynamic pressure response test (Fig. 19.5). This involves the sudden release of pressure on the measurement system, such as is done by flushing the catheter with the continuous-flush device. During the flush procedure, the regis-

Table 19.8. Key features of a high-frequency response measuring system.

Large-inside-diameter catheter
Short (as opposed to long) catheter
Large, more central artery (as opposed to a small, peripheral artery)
Short-catheter-transducer connecting tubing
Noncompliant tubing
No loose, leaky connections
As few stopcocks as possible
No kinks in the tubing
Hyperflexed appendages avoided when the catheter is in a peripheral artery
No air bubbles in the measuring system
No blood clots in the catheter or measuring system (use a continuous-flush device)

tered pressure equals that of the pressure bag (>300 mm Hg). When the flushing procedure is abruptly terminated, the pressure should return to baseline after about one to two negative and one to two positive oscillations.⁵² Ideally, the measuring system would have a high resonant frequency and low damping. The resonant frequency is calculated as 1 s divided by the length of time of one complete oscillation (peak to peak) (Fig. 19.5). Typical values are 10 to 50 Hz.⁵² Damping is calculated as the amplitude reduction ratio: the height of one-half of a complete cycle (peak to trough or vice versa) divided by the height of the previous one-half cycle (Fig. 19.5). Typical values are 0.35 to 0.7.⁵² The appropriateness of the frequency response of the measuring system for a particular patient is determined by a combination of the resonant frequency and the damping. Underdamping is caused by the combination of a low resonant frequency and minimal damping. Overdamping is caused by the combination of a low resonant frequency and excessive damping.

If overdamping or underdamping is noted, check for (and remove) blood clots or air bubbles from the measurement system, exchange low-compliant tubes with rigid tubes, shorten the length of tubing between the catheter and transducer, make sure there are no leaks, and eliminate kinks in the tubing or appendage (if a peripheral artery has been catheterized). If the underdamping problem continues, add a damping device (longer tubing, less rigid tubing, and a small air bubble at the transducer).

Normal systolic, diastolic, and mean blood pressures are ap-

Fig. 19.4. Underdamping and overdamping caused by a frequency response of the measuring system that is the same as one of the harmonics of the original pressure waveform or too low, respectively. **a:** Ideal pressure waveform. **b:** Underdamped pressure waveform. **c:** Overdamped pressure waveform.

Fig. 19.5. Dynamic pressure response test to determine natural frequency response of a measuring system. The pressure is suddenly released and the fluctuations in pressure recorded. **a:** Optimal: The waveform should oscillate 1 to 1.5 full cycles before returning to baseline. The resonant frequency is calculated as 1 s divided by the duration of one complete cycle (peak to peak or trough to trough). The damping is calculated as the amplitude reduction ratio of the height of one-half cycle (peak to trough or trough to peak) divided by the previous one-half cycle. **b:** Underdamped: The waveform oscillates more than two full cycles. **c:** Overdamped: The waveform oscillates less than 0.5 full cycle.

proximately 100 to 140, 60 to 100, and 80 to 120 mm Hg, respectively. In general, one should be concerned when the systolic arterial blood pressure (ABPs) falls below 100 or when the mean arterial blood pressure (ABPm) falls below 80 mm Hg. In general, one should be very concerned when the ABPs falls below 80 or the ABPm falls below 60 mm Hg. Hypotension may be caused by hypovolemia, poor cardiac output, or vasodilation (Table 19.9). Hypertension (high ABPm) is generally attributed to vasoconstriction. High ABPs, not associated with a high ABPm, is generally attributed to an inappropriate frequency response of the measuring system (for that patient and that time). Hypertension can cause increased hemorrhage, retinal detachment, increased intracranial pressure, and high afterload to the heart, and should be treated when ABPm exceeds 140 mm Hg (Table 19.7). High ABPm may be produced by a light level of anesthesia, hyperthermia, sympathomimetic drugs, hyperthyroidism (thyroxine-catecholamine synergy), renal failure (renin-angiotensin), pheochromocytoma (epinephrine), or increased intracranial pressure. In the latter case, the hypertension is most likely caused by the Cushing's response, to maintain an adequate cerebral perfusion pressure, and should not be treated.

Cardiac Output

Poor cardiac output is implied when preload parameters (CVP, pulmonary artery occlusion pressure, jugular vein distension, postcava distension on chest radiograph, and end-diastolic diameter on cardiac ultrasound image) are high and the afterload parameters (cardiac output, arterial blood pressure, and physical and laboratory measures of tissue perfusion) are low or abnormal. Pulse-quality assessment provides an indirect measure of stroke volume. Cardiac output is a flow parameter and can be low even when arterial blood pressure is normal. Cardiac output in humans is most often measured by thermodilution techniques via the balloon-tipped pulmonary artery catheter. Lithium administration is another indicator-dilution technique that has been used.⁵³⁻⁵⁶ It requires its own detector and computer; cardiac output can be measured only a finite number of times (because of lithium accumulation); the detector probes are fairly expensive; and, of course, pulmonary artery pressure and pulmonary artery occlusion pressure are not measured. Cardiac output can also be measured by esophageal Doppler ultrasonography, thoracic electrical bioimpedance, and pulse analysis.^{53,56,57} Cardiac output in normal, awake dogs is 4.42 ± 1.24 L/min/m² (165 ± 43

Table 19.9. Causes of hypotension.

mL/min/kg) and is generally decreased by general anesthetics, except ketamine (Table 19.1). Cardiac output in awake horses is 70 to 90 mL/min/kg and is decreased to 35 to 60 mL/min/kg with general anesthesia.^{58–60}

Cardiac output may be reduced by poor venous return and end-diastolic ventricular filling (hypovolemia, positive-pressure ventilation, or inflow occlusion); by ventricular restrictive disease (hypertrophic or restrictive cardiomyopathy, pericardial tamponade, or pericardial fibrosis); by decreased contractility; by excessive bradycardia, tachycardia, or arrhythmias; by regurgitant atrioventricular valves; or by outflow-tract obstruction. Poor cardiac output should be improved by correcting the underlying problem when possible. Preload should be optimized. When poor contractility is thought to be the problem, anesthetic dosage levels should be decreased to the least amount that will enable the completion of the surgical procedure. Sympathomimetic therapy (Table 19.7) is indicated when poor contractility is thought to be the problem, and fluid therapy and anesthetic drug reduction have failed to restore acceptable forward-flow parameters.

Oxygen Delivery

Oxygen delivery (DO_2) is the product of cardiac output and blood oxygen content (Fig. 19.1). Some myocardial depression is expected with general anesthesia, and this could be associated with a decrease in cardiac output and DO_2 . In fact, DO_2 may be increased or decreased by anesthetic drugs (Table 19.1). A decrease in DO_2 during general anesthesia may not be a problem if oxygen consumption (VO_2) is also reduced by muscular inactivity

and hypothermia.^{61,62} Oxygen consumption, however, like DO_2 , is variably affected by anesthetic drugs^{61,62} (Table 19.1). Critical DO_2 , the DO_2 below which VO_2 decreases linearly, has been reported to be between 160 and 280 mL/min/m² (6 to 11 mL/min/kg) in dogs.^{63–66} In critically ill human patients, a minimum oxygen delivery of 550 to 600 mL/min/m² has been recommended.^{67,68} From our own experiments ($n = 97$), DO_2 in normal dogs is 790 ± 259 mL/min/m² (29.5 ± 8.8 mL/min/kg). Optimal DO_2 was thought to be associated with a minimum DO_2 of 600 mL/min/kg because, when DO_2 decreased below this level, oxygen extraction, arteriovenous oxygen content gradient and arteriovenous partial pressure of carbon dioxide (PCO_2) gradient increased, and central venous partial pressure of oxygen (PO_2) decreased. Alternatively, when cardiac output measurements are unavailable, oxygen extraction above 30%, arteriovenous oxygen content gradient above 5 mL/dL, arteriovenous PCO_2 gradient above 5 mm Hg, or central venous PO_2 (PvO_2) below 40 mm Hg may indicate a less than optimal DO_2 . Most anesthetics (inhalationals, opioids, and barbiturates, but not ketamine) impair oxygen extraction and increase the critical DO_2 compared with baseline.⁶⁹

Pulmonary Monitoring

Breathing Rate, Rhythm, Nature, and Effort

The breathing rate can vary widely, and except for extreme values is of limited value as a respiratory monitor. A change in breathing rate, however, is a sensitive indicator of an underlying change in the status of a patient. Bradypnea may be a sign of deep anesthesia or hypothermia. There are many causes of tachypnea, and it is important not to default to the conclusion that its occurrence represents too light a level of anesthesia (Table 19.10). Arrhythmic breathing patterns are indicative of a problem with the central pattern generator in the medulla. A *Cheyne-Stokes breathing pattern* (cycling between hyperventilation and hypoventilation) may be seen in otherwise healthy anesthetized horses and an apneustic breathing pattern (inspiratory hold) may be seen in otherwise healthy dogs and cats anesthetized with ketamine.

Ventilometry

Ventilation volume can be estimated by visual observation of the chest or rebreathing bag or measured by ventilometry. Normal tidal volume ranges between about 8 and 20 mL/kg. A small tidal volume may be acceptable if the breathing rate is fast enough to accomplish normal alveolar minute ventilation. Normal total minute ventilation ranges between 150 and 250 mL/kg/min for dogs. Dead-space ventilation is about 30% to 40% of tidal volume and minute ventilation in a normal patient breathing a normal tidal volume, but may be much higher with shallow breathing, upper-airway dead space, or pulmonary thromboembolism. Arterial PCO₂ (PaCO₂) is usually considered to be the definition of alveolar minute ventilation, and the measured minute ventilation should be appropriate. A large minute ventilation in combination with a normal (or high) PaCO₂ is indicative of a large dead-space ventilation.

Compliance is calculated as expired tidal volume divided by the change in pressure that it took to generate the tidal volume. A change in airway pressure is easy to measure during positive-pressure ventilation, but to measure the change in transpulmonary pressure during spontaneous ventilation requires the measurement of pleural pressure (which is usually done via the lower esophagus). If, for instance, 10 cm H₂O of pressure was required in order to generate a tidal volume of 10 mL/kg, the compliance would be calculated to be 1 mL/kg/cm H₂O. If the measurements are made during the cyclic breathing process, the value is termed *dynamic compliance*. If the measurements are made after an inspiratory pause, the value is termed *static compliance*. The manner in which these measurements would usually be obtained during general anesthesia would include a component of anesthetic-circuit gas compression and breathing-circuit expansion. Since anesthetic circuits and technique vary, you will need to establish expected values by using your particular equipment and technique. Compliance is decreased by restrictive pulmonary, pleural, or thoracic wall disease.

Partial Pressure of Carbon Dioxide

The PaCO₂ is a measure of the ventilatory status of a patient and normally ranges between 35 and 45 mm Hg. PaCO₂ values may be slightly higher in anesthetized small animals and is considerably higher (60 to 80 mm Hg) in anesthetized horses⁴⁹ (Table 19.2) and cattle.¹⁸ A PaCO₂ in excess of 60 mm Hg may be associated with excessive respiratory acidosis and is usually considered to represent sufficient hypoventilation to warrant positive-pressure ventilation in small animals. PaCO₂ values below 20 mm Hg are associated with respiratory alkalosis and a decreased cerebral blood flow that may impair cerebral oxygenation.

Venous PCO₂ (PvCO₂) is usually 3 to 6 mm Hg higher than PaCO₂ in stable states and can generally be used as an approximation of PaCO₂. The venous partial pressure of carbon dioxide is variably higher in transition states and during hypovolemia or anemia. PaCO₂ may also be estimated by measuring the carbon dioxide in a sample of gas taken at the end of an exhalation (Fig. 19.6). End-tidal PCO₂ is usually 2 to 4 mm Hg lower than PaCO₂ in dogs and 10 to 15 mm Hg lower in horses.⁷⁰ Capnography en-

Table 19.11. Information derived from the capnogram^{71–73}.

Observed Problem	Possible Cause(s)
No waveform	Apnea; obstructed aspirating tubing
Increased baseline	Rebreathing malfunction or contaminated sample cell
Increased plateau	Hypoventilation or increased rate of carbon dioxide production
Decreased plateau To a new, stable level	Hyperventilation, hypothermia, airway leaks, tachypnea, pulmonary thromboembolism, or capnograph calibration error
Abruptly to zero	Airway obstruction, airway disconnect, apnea, or cardiac arrest
Flattened upsweep (line A in Fig. 19.6)	Small airway narrowing and increase in disparity of alveolar time constants
Flattened downsweep (line C in Fig. 19.6)	Rebreathing
Unstable, fluctuating plateau	Spontaneous breathing during mechanical ventilation

ables anesthetists to evaluate adequacy of ventilation, and many other problems, as well (Table 19.11).^{71–73}

An increased arteriovenous PCO₂ gradient suggests decreased tissue perfusion. A note of caution: Do not contaminate the blood sample with sodium bicarbonate, because that will increase PCO₂ dramatically. The causes of hypercapnia and hypocapnia are listed in Table 19.12.

Partial Pressure of Oxygen

The PaO₂ measures the tension of oxygen dissolved in the plasma, irrespective of the hemoglobin concentration. The PaO₂ is a measure of the oxygenating efficiency of the lungs. The normal PaO₂ is considered to range between 80 and 110 mm Hg when an animal is breathing room air at sea level. When room air is being breathed, the PaO₂ would normally decrease during general anesthesia, because of anesthetic-induced hypoventilation, increased ventilation-perfusion mismatching, and atelectasis. Usually, however, anesthetized animals are attached to an anesthetic machine and breath 100% oxygen. The PaO₂ is usually above 500 mm Hg in small animals and above 200 mm Hg in horses.^{49,58,60} Hypoxemia is usually defined as a PaO₂ below 80 mm Hg. Hypoxemia could be caused by low inspired oxygen, hypoventilation while breathing 21% oxygen, and venous admixture (Table 19.13). A PaO₂ below 60 mm Hg is a commonly selected trigger for symptomatic therapy.

PvO₂ reflects tissue PO₂ and bears no correlation to PaO₂. Mixed or central PvO₂ ranges between 40 and 50 mm Hg. Values below 30 mm Hg may be caused by anything that decreases the delivery of oxygen to the tissues (hypoxemia, anemia, low cardiac output, or vasoconstriction) (Fig. 19.1); values above 60 mm Hg suggest reduced tissue uptake of oxygen (shunting, septic shock, or metabolic poisons). Venous blood for such evaluations must be taken from a central vein such as the jugular, anterior

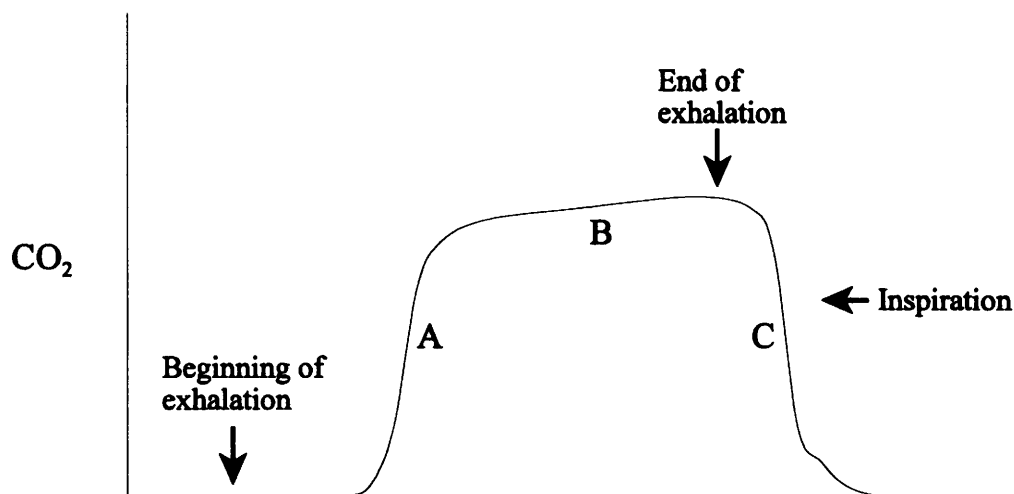

Fig. 19.6. Capnogram. The end-tidal carbon dioxide (CO_2) at the end of exhalation should be only a few mm Hg below arterial CO_2 partial pressure. *Line A* reflects the transition between CO_2 -free anatomical and alveolar dead-space gases and functional alveolar gases. The slope of line A reflects variable emptying of fast and slow alveoli (airway disease flattens the slope of line A). *Line B*, the plateau of the capnogram, reflects alveolar gas; the slight upward slope to line B represents an increasing alveolar CO_2 during exhalation. *Line C* represents inspiration; the slope of line C is less steep with rebreathing.

Table 19.12. Causes of hypercapnia and hypocapnia.

Hypercapnia	Hypocapnia
Hypoventilation	Hyperventilation
Neuromuscular: excessive anesthetic depth; intracranial, cervical, neuromuscular	Light level of anesthesia
Airway obstruction: endotracheal tube; large or small airways	Hypoxemia
Thoracic or abdominal restrictive disease	Hyperthermia
Pleural space-filling disorder: air, fluid, or abdominal viscera	Hypotension
Pulmonary parenchymal disease	Sepsis
Inappropriate ventilator settings	Postoperative recovery phase
Malfunctioning/exhausted soda lime	Postoperative pain
Malfunctioning anesthetic machine: dead-space rebreathing	Inappropriate ventilator settings

vena cava, or pulmonary artery; peripheral PvO_2 values are highly variable and difficult to interpret.

Blood gases are measured at the temperature of the blood-gas analyzer water bath (usually 37°C). Ideally, the animal's body temperature would be identical to that of the water bath, but this seldom occurs. When the animal's body temperature differs from that of the water bath, there will be changes in the measured pH and blood gases associated with the in vitro change in temperature. There is some debate about whether to correct for these temperature changes. If one wants to know what is actually happening in a patient and wants to compare the current measurement with previous measurements, even though there has been a sub-

Table 19.13. Causes of hypoxemia.

Low inspired oxygen
Depleted oxygen supply
Maladjusted flowmeter
Insufficient flow in a Bain's circuit
Anesthetic machine malfunction: dead-space rebreathing
Hypoventilation (when breathing room air)

Low ventilation/perfusion regions: mild to moderate pulmonary parenchymal disease
Small airway and alveolar collapse (no ventilation but perfused regions): moderated to severe pulmonary parenchymal disease
Diffusion impairment: inhalation injury, oxygen toxicity, or inflammatory lung disease
Anatomic right-to-left shunts

stantial change in body temperature, the temperature-corrected values should be used. If a clinician is contemplating therapy to "fix" an abnormality by using normothermic reference points, then the uncorrected values should be used.⁷⁴ "Normal values" for hypothermic or hyperthermic patients are different than those for normothermic patients, but these reference values have not been established for each level of hypothermia or hyperthermia that occurs.

Hemoglobin Saturation with Oxygen

When red to infrared light is transmitted through a blood sample, a certain proportion of it will be absorbed by the various hemoglobins present in the blood sample: oxyhemoglobin, methemoglobin, carboxyhemoglobin, and reduced hemoglobin. A bench-

Fig. 19.7. Oxyhemoglobin dissociation curves for dogs,¹¹⁰ cats,¹¹¹ and horses.¹¹²

top co-oximeter measures and displays values for the first three. The displayed oxyhemoglobin is functional; that is, it is expressed as a percentage of the amount of hemoglobin available for oxygen binding (total hemoglobin minus methemoglobin and carboxyhemoglobin) as opposed to fractional oxyhemoglobin, which is expressed as a percentage of total hemoglobin irrespective of methemoglobin or carboxyhemoglobin. Normal methemoglobin and carboxyhemoglobin levels are normally less than 1% each, and so, usually, functional and fractional oxyhemoglobin levels are quite similar. To the extent that either methemoglobin or carboxyhemoglobin are present in large concentrations, fractional oxyhemoglobin levels will be variably lower than functional oxyhemoglobin levels.

Hemoglobin-oxygen saturation (SO_2) measures the percent oxygen saturation of the hemoglobin and is related to PO_2 by a sigmoid curve. The clinical information derived from the measurement of arterial SO_2 (SO_2) is similar to that obtained from a PaO_2 measurement in that they both are a measure of the ability of the lung to deliver oxygen to the blood. In this matter, functional oxyhemoglobin is the more meaningful number. The “numbers of concern” are, however, different. In general, a PO_2 of 100 mm Hg is equivalent to an SO_2 of 98%; a PO_2 of 80 mm Hg to an SO_2 of 95%; a PO_2 of 60 mm Hg to an SO_2 of 90%; and a PO_2 of 40 mm Hg to an SO_2 of 75%. Exact quantitative correlation depends on the hemoglobin affinity for oxygen. The P_{50} is the PO_2 at which the hemoglobin is 50% saturated and is commonly used to define hemoglobin affinity. The P_{50} for human hemoglobin is 26 to 28 mm Hg; it is slightly higher for dogs and goats; much higher for sheep, cats, and cattle; and lower for

horses. Figure 19.7 and Table 19.14 illustrate representative oxyhemoglobin dissociation curves for horses, dogs, and cats.

Pulse oximeters attach to a patient externally (e.g., tongue, lips, tail, or toenail). For most clinical purposes, most pulse oximeter readings are sufficiently accurate approximations of oxyhemoglobin saturation, though accuracy should be verified by an *in vitro* standard if possible. There are substantial bias and precision variations and response times between different commercial products at different levels of saturation.⁷⁵ Tissue, venous and capillary blood, nonpulsatile arterial blood, and skin pigment also absorb infrared light. There is a fairly narrow spectrum of wavelengths that passes through skin and yet is absorbed by hemoglobin. A pulse oximeter must differentiate this background absorption from that of pulsatile arterial blood. It does this by measuring light absorbance during a pulse and subtracting from that the light absorbance occurring between the pulses. If the pulse oximeter cannot detect a pulse, it will not measure the oxyhemoglobin level.

The accuracy of a pulse oximeter is greatest within the range of 80% and 95%, and is determined by the accuracy of the empirical formula that is programmed into the instrument.⁷⁶ Differences in tissue absorption or scatter of light, different thicknesses of tissue, smaller pulsatile flow patterns and small signal-to-noise ratios, and incompletely compensated light-emitting diodes may account for some inaccuracies. Inaccuracies may also generate from baseline-read errors (motion), differences in sensor location, and electrical or optical interference. When a measurement is obtained, it may either be accurate or inaccurate. When inaccurate, it is usually inaccurately low. When a

PO₂, partial pressure of oxygen.

low measurement is obtained, particularly when it seems incongruous for the patient's condition at the time, it might be wise to retry the measurement in several different locations and then either take the average or the highest reading. If methemoglobin or carboxyhemoglobin were present in high concentrations, they would absorb light and would impact the measurement made by

a two-wavelength pulse oximeter designed to measure only oxyhemoglobin. Because of the biphasic absorption of methemoglobin at both the 660- and 940-nm wavelengths, abnormal accumulations tend to push the oximeter reading toward 85% (underestimating measurements when SaO₂ is above 85%, and overestimating it when SaO₂ is below 85%).⁷⁷ Carboxyhemoglobin absorbs light like oxyhemoglobin at 660 nm, but hardly at all at 940 nm, and this would increase the apparent oxyhemoglobin measurement.⁷⁸ Fetal hemoglobin produces very little effect on measured hemoglobin saturation.⁷⁶ Indocyanine green dye and methylene blue dye absorb light and will generate falsely low saturation measurements.⁷⁶

A pulse oximeter is an ideal perioperative monitor in that it is an automatic, continuous, audible monitor of mechanical cardiopulmonary function. It specifically measures pulse rate and hemoglobin saturation, and it requires a reasonable peripheral pulse quality in order to achieve a measurement. One of the common reasons for poor instrument performance is peripheral vasoconstriction. Its value as an ongoing monitor in detecting hypoxemia has been established.^{75,76} The pulse oximeter is not discriminating for high PaO₂ values where the oxyhemoglobin curve is flat. The difference between a PaO₂ of 500 and 100 mm Hg in an animal breathing 100% oxygen is very important as an index of lung function; the corresponding decrease in SaO₂, from 99% to 98%, would hardly be noticed.

Venous Admixture

Pulmonary dysfunction interferes with the ability of the lungs to transfer oxygen efficiently from the alveoli to the blood, resulting in a lower-than-expected PaO₂. *Venous admixture* is the collective term for all of the ways in which blood can pass from the right side of the circulation to the left side of the circulation without being properly oxygenated (Table 19.13). Several methods are used to quantitate lung-oxygenating efficiency (Table 19.15).

Oxygen Content

This parameter can be measured, but is usually calculated: (hemoglobin concentration × 1.34 [oxygen content of fully saturated hemoglobin] × percent saturation) + (0.003 × PO₂).

Table 19.15. Formulas for quantifying lung-oxygenating efficiency (venous admixture).

Parameter	Formula
Alveolar PO ₂ (P _A O ₂)	([Barometric pressure – 50] × fractional inspired oxygen) – (PaCO ₂ × 1.1), where 50 = saturated water-vapor pressure at 38.5°C, and 1.1 = 1/RQ when RQ = 0.9
Alveolar-arterial PO ₂ gradient (for any F _I O ₂)	Calculated P _A O ₂ × measured PaO ₂
PaO ₂ + PaCO ₂ (for F _I O ₂ = 0.21 at sea level)	Measured PaO ₂ + measured PaCO ₂
PaO ₂ /F _I O ₂ (PF) ratio (for F _I O ₂ > 0.4)	PaO ₂ /F _I O ₂ , where F _I O ₂ is expressed as a decimal fraction between 0.21 and 1.0
Arterial, mixed-venous, and pulmonary capillary oxygen content	(1.34 × Hb × SO ₂) + (0.003 × PO ₂), where 1.34 is 100% saturated hemoglobin (Hb) oxygen content, SO ₂ is hemoglobin saturation, and PO ₂ is partial pressure of oxygen in arterial, mixed-venous, or capillary blood
Venous admixture (for any F _I O ₂)	(Capillary O ₂ content × arterial O ₂ content)/(capillary O ₂ content × venous O ₂ content)

F_IO₂, fraction of inspired oxygen; PaCO₂, arterial carbon dioxide partial pressure; PaO₂, arterial oxygen partial pressure; PO₂, partial pressure of oxygen; RQ, respiratory quotient.

Table 19.16. The relationship between partial pressure of oxygen (PO₂), hemoglobin saturation (SO₂), and oxygen content under different clinical circumstances.

	PO ₂ (mm Hg)	SO ₂ (%)	Hb (g/dL)	O ₂ content (mL/dL)
Normal	100	96.4	15	19.7
Anemia	100	96.4	5	6.8
Methemoglobinemia (50%)	100	96.4	15	10.0
Hypoxemia	40	65.6	15	13.3
Hyperoxemia	500	100	15	21.6

The canine oxyhemoglobin relationship was used for determining SO₂, Hb, hemoglobin concentration. Oxygen content was calculated as $(1.34 \times \text{Hb} \times \text{SO}_2) + (0.003 \times \text{PO}_2)$.

Hemoglobin is by far the most important contributor to oxygen content. The PO₂, SO₂, and oxygen content are related, but each measure provides a distinctly different perspective of blood oxygenation, and the difference can be important (Table 19.16). An increased arteriovenous oxygen-content difference (>5 g/dL) suggests increased oxygen extraction, which is usually attributable to decreased oxygen delivery.

Renal Monitoring

Urine flow is used as an indirect measure of renal blood flow, and renal blood flow is used as an indirect measure of visceral blood flow. Urine output can be assessed by serial palpation of the urinary bladder or by actual measurement after the aseptic placement of a urinary catheter. Normal urine output should be about 1 to 2 mL/kg/h. Maintaining visceral blood flow is, of course, an important aspect of any anesthetic plan and is generally achieved by optimizing the circulating blood volume (sufficient, but not excessive, fluid therapy), monitoring and maintaining forward-flow cardiovascular parameters, and monitoring of laboratory indices of tissue perfusion (standard base excess, lactate concentration, and central PvO₂). Oliguria or anuria, per se, can be treated, after ensuring that renal perfusion is adequate, with furosemide (0.5- to 5-mg/kg bolus ± 0.1 to 0.5 mg/kg/h) or mannitol (0.5-g/kg bolus ± 0.1 g/kg/h). Statistically, diuretic therapy does not prevent acute renal failure, but it does facilitate the medical management of the case.

Temperature Monitoring

Hypothermia

Hypothermia during anesthesia may be associated with anesthetic drug depression of muscular activity, metabolism, and hypothalamic thermostatic mechanisms. Heat loss may be augmented by evaporation of surgical scrub solutions from the skin surface, by the infusion of room-temperature fluids, by contact with cold, noninsulated surfaces, and by evaporation of surface fluid from an exposed body cavity. Core temperature can be

measured with either esophageal or rectal thermistors attached to a continuously displayed thermometer.

Core body temperatures down to 36°C (96°F) are not detrimental to patients.^{79,80} Nonshivering thermogenesis will increase, and there may be some shivering thermogenesis during recovery. Recovery should not be prolonged in any noticeable way. Body temperatures of 32° to 34°C (90° to 94°F) are associated with reduced anesthetic requirements; recovery should be noticeably prolonged. Animals will shiver if they can, but some will not shiver and will have to be artificially rewarmed. Body temperatures of 28° to 30°C (82° to 86°F) have a marked CNS-depressant effect, and usually no anesthetic agent is required. Shivering thermogenesis will not occur, and the animal will have to be rewarmed artificially, at least initially. Atrial arrhythmias may occur. Oxygen consumption is reduced to about 50% of normal, heart rate and cardiac output to about 35% to 40% of normal, and arterial blood pressure to about 60% of normal.⁷⁹ Cerebral metabolism is about 25% of normal. These decreases in hemodynamic parameters are secondary to cold-induced hypometabolism. Measurements must be interpreted in this context rather than in comparison with normothermic values. Body temperatures of 25° to 26°C (77° to 80°F) are associated with prolongation of the PR interval and widened QRS complexes, increased myocardial automaticity, and decreased tissue oxygen delivery out of proportion to decreases in oxygen requirement, resulting in anaerobic metabolism, lactic acidosis, and rearming acidemia. Blood viscosity is about 200% of normal. Body temperatures of 22° to 23°C (72° to 74°F) are usually associated with ventricular fibrillation and death.

Intraoperative hypothermia is usually mild to moderate and, as long as appropriate safeguards are exercised, is seldom detrimental to patients. The largest problem with intraoperative hypothermia is the nonrecognition of it. The continued administration of normothermic amounts of anesthetic to a hypothermic patient can produce a relative anesthetic overdose.

Passive rearming (minimizing further heat loss and enabling patients to warm themselves metabolically) is usually effective in treating mild hypothermia (temperature above 34°C [94°F]) when a patient is capable of metabolic or shivering thermogenesis. Intraoperative heat loss can be minimized by warm room temperatures, insulating barriers between the patient and table surfaces, and administering warmed fluids. Active rearming can be achieved by using circulating warm water or warm-air blankets, infrared heat lamps (optimal distance, 75 cm⁸¹) or radiant-heat warmers; by placing hot-water bottles under the drapes (avoid contact with skin if the water temperature exceeds 42°C); by flushing the abdominal cavity or colon with warm, sterile, isotonic, polyionic fluids; or by extracorporeal techniques.

Aggressive surface rearming should be avoided in very cold patients⁸²⁻⁸⁴ because peripheral vasodilation may induce excessive hypotension in the face of a cold-depressed heart. Ischemic peripheral tissues may have accumulated various metabolites, which may have deleterious cardiovascular effects when large quantities are washed into the central circulation. The rearming rate should be limited to about 1°C/h.⁸⁰

Hyperthermia

Fever is a reset thermostat and is caused by the release of endogenous pyrogens (interleukin 1) from monocytes⁸⁵ in response to infections, tissue damage, or antigen-antibody reactions. Interleukin 1 stimulates prostaglandin synthesis in the hypothalamic thermoregulatory center. Hyperthermia, without a reset thermostat, is pathological. It not uncommonly occurs in large dogs that are cocooned within many layers of drapes on an operating table. Hyperthermia may be potentiated by surface vasoconstriction, light levels of anesthesia, and ketamine administration.

Mild degrees of hyperthermia are not, per se, harmful to patients and may represent an appropriate response to an underlying disease (fever or infection). Mild hyperthermia (below 40°C [104°F]) does not normally require treatment, per se. Cell damage starts at body temperatures above 42°C (108°F), when oxygen delivery can no longer keep pace with the racing metabolic activity and increased oxygen consumption. Severe hyperthermia causes multiple organ dysfunction and failure: renal, hepatic, and gastrointestinal failure; myocardial and skeletal muscle damage; cerebral edema; disseminated intravascular coagulation; hypoxemia; metabolic acidosis; and hyperkalemia.⁸⁶

Malignant hyperthermia—a rapidly, relentlessly, progressive increase in body temperature—is associated with the metabolic heat production of disturbed intracellular calcium recycling at the sarcoplasmic reticulum.^{87,88} Muscle hypertonicity may or may not occur, depending on the calcium concentration in the sarcoplasm. The defect has been identified in families of people and pigs, and a malignant hyperthermia-like syndrome has been reported in dogs,^{89,90} cats,^{91,92} and horses.^{93,94} Aggressive cooling of the animal, by any and all means possible, is indicated. Dantrolene administration (2.5 to 10.0 mg/kg intravenously) is the specific and often effective treatment for this syndrome.

Surface-cooling techniques are most effective with room-temperature fluids. The evaporation of the water from the skin surface causes the cooling. Ice water causes vasoconstriction that impedes heat loss from the core until skin temperature is below 10°C, at which time vessel paralysis and vasodilation occur, and core temperatures decrease precipitously.⁹⁵ Convective heat loss can be enhanced with fans. Conductive heat loss can be enhanced with ice packs. The administration of large volumes of cold crystalloid fluids intravenously into the colon or stomach or into a body cavity is an effective internal cooling technique. The administration of antipyretic drugs (antiprostaglandins, dipyrone, or aminopyrine) is generally an effective treatment for fever, but is ineffective for pathological hyperthermia.

Laboratory Monitoring

Hemoglobin

Whether or not animals are anemic prior to the operative procedure, hemoglobin concentrations will be decreased intraoperatively by anesthetic-induced vasodilation and splenic dilation, non-hemoglobin-containing fluid administration, and blood loss. Historically, in humans, the trigger for a hemoglobin transfusion has been a hemoglobin concentration of 10 g/dL (a packed cell volume [PCV] of 30%).⁹⁶ Recent studies in humans have sug-

gested that a more relaxed trigger of 7 g/dL (PCV = 21%) is associated with at least as good, and perhaps better, morbidity and mortality statistics.⁹⁶ In veterinary medicine, in animals with immune-mediated hemolytic anemia, it is well accepted to withhold blood transfusions until the hemoglobin concentration is below 5 g/dL (PCV = 15%). In human medicine, in Jehovah Witness patients, mortality rate does not increase significantly until the hemoglobin concentration is 5 g/dL (PCV = 15%).⁹⁶ There are many examples of human and veterinary patients surviving much greater levels of anemia.

It may not actually be possible to define a minimum hemoglobin concentration, given the complexities of cardiac output and oxygen-extraction compensatory mechanisms. An animal can tolerate greater degrees of anemia if it has the wherewithal to increase cardiac output. If cardiac output were routinely measured, DO₂ could be calculated, which would eliminate some of the guesswork, but cardiac output is seldom measured. Anesthetic agents commonly decrease myocardial contractility and cardiac output (Tables 19.1 and 19.2), and oxygen extraction is often impaired during general anesthesia,⁶⁹ so it would be predicted that anesthetized patients require a hemoglobin concentration higher than the bare minimum. Metabolic markers of poor tissue oxygenation, such as a low PvO₂, a high arteriovenous oxygen-content gradient, or a high arteriovenous PCO₂ gradient, may help guide the need for hemoglobin transfusions. Lactic acidosis is a late, after-the-fact (but usually before-the-death) index of inadequate tissue perfusion.

Blood may need to be administered in volumes of 10 to 30 mL/kg, depending on the magnitude of anemia. Cats have a small blood volume (50 to 55 mL/kg) compared with most other species, and bolus dosages of all fluids should be approximately 50% of canine recommendations. The amount of blood to administer can also be calculated: (desired PCV – current PCV) × body weight (kg) × 2 mL whole blood (or 1 mL packed red blood cells).

Oncotic Pressure

Plasma oncotic pressure is an important vascular fluid-retention force. When depleted, there is an increased risk of interstitial edema, but, because of an offsetting decrease in perimicrovascular oncotic pressure, it is not as edemagenic as might be expected. An increased capillary hydrostatic pressure or vascular permeability are, in contrast, potent causes of edema. Colloidal osmotic pressure (COP) can be measured: Values in normal animals are 20 to 25 mm Hg. Values of 15 to 20 mm Hg are common in anesthetized and critically ill patients, but are not thought to be of important concern. Values in the low teens should trigger therapy, and values in the single digits should cause great concern. COP can be qualitatively approximated from an albumin measurement (albumin normally accounts for about 70% of the COP). Albumin values in normal dogs, cats, and horses are 2.9 to 4.2, 1.9 to 3.9, and 2.3 to 3.6, respectively. A 50% decrease in albumin is associated with about a 50% reduction in COP and so on. COP can also be approximated by calculation from albumin and globulin measurements:⁹⁷ dogs, $-7.748 + (5.201 \times \text{albumin}) + (4.857 \times \text{globulin})$; cats, $-4.857 + (5.903 \times \text{albumin}) +$

($3.378 \times \text{globulin}$); and horses, $-4.3845 + (5.501 \times \text{albumin}) + (2.475 \times \text{globulin})$.

The cheapest way to augment COP is to administer an artificial colloid such as dextran 70 or hetastarch in bolus dosages (if volume augmentation is also desirable) of 10 to 30 mL/kg or in continuous infusions of 1 to 2 mL/kg/h. Plasma may be indicated if there are concurrent coagulation issues, and whole blood may be indicated if there are concurrent hemoglobin issues.

Bear in mind a note of caution regarding patients with portocaval shunts, which are often presented with single-digit colloid osmotic pressures. Aggressive colloid administration to “get the COP out of the basement” should be avoided because it upsets the COP–capillary hydrostatic pressure balance and causes edema.

Coagulation

Animals bleed perioperatively either because of a cut large vessel or coagulopathy. The latter can be caused by coagulation or platelet problems. Coagulation is assessed by *in vitro* tests such as partial thromboplastin time (PTT; normal values are laboratory dependent: 9 to 18 s), activated clotting time (ACT; <120 s at 37°C), and whole blood clotting time (<4 min at 37°C ; 8 min at room temperature). The PIVKA test assesses for proteins induced by vitamin K antagonists (normal, 15 to 18 s). Elevated fibrin degradation products represent activation of the clotting and fibrinolytic cascades, and an elevated d-dimer level represents fibrinolysis. The results of these tests are usually normal to slightly abnormal in normal animals.^{98–100} Decreased antithrombin (normal: dogs, 80% to 140%; and horses, 130% to 220%¹⁰⁰) may be indicative of a protein-losing “-opathy” and a prothrombotic state or may represent consumption and disseminated intravascular coagulation (DIC). Platelet numbers can be assessed with a platelet count or a platelet screen on a blood smear (normal, 12 to 25 platelets per oil-emersion field, in a good blood smear without platelet clumping; the platelet count is estimated as $15,000 \times$ the number of platelets per oil-emersion field). Platelet function can be assessed by examining for petechia or a buccal mucosal bleeding time (normal, <4 min). Thromboelastography, which provides an integrated assessment of clot formation, can be used to assess for hyper- or hypocoagulopathy.^{101,102}

Coagulopathies may or may not need to be treated. If bleeding is minor and not into a vital organ, and blood can easily be replaced by transfusion, specific therapy may not be necessary. Specific treatment with fresh plasma is necessary if platelets are required; fresh-frozen plasma is used if platelets are not required, but labile factors such as von Willebrand’s factor, factor 8, or antithrombin are required. For vitamin K antagonist poisoning, any kind of plasma will suffice. The goal of plasma therapy is to stop the bleeding, not to return the abnormal laboratory test to normal. The latter would be very expensive and would probably not even be possible because of concerns about hypervolemia.

Glucose

An adequate level of blood glucose is important for cerebral metabolism. Hypoglycemia might occur during general anesthesia, but is most common as a nonspecific hormonal response to the

stress of anesthesia and operation. A blood glucose concentration below 60 mg/dL should be treated with a 2.5% to 5.0% glucose infusion. Severe hypoglycemia should be treated, in addition, with a bolus of glucose (0.1 to 0.25 g/kg). There is growing evidence that persistent moderate hyperglycemia (>200 mg/dL; >11 mM/L) in the intensive care setting is associated with significantly poorer outcomes.^{103–105} In this setting, it has been recommended to enforce glycemic control with insulin in quantities sufficient to maintain the blood glucose concentration below 150 to 200 mg/dL (8 to 11 mM/L).^{104,105} Whether short-term hyperglycemia, as would occur with a typical anesthetic-surgical experience, is detrimental has not been investigated.

Metabolic Acid-Base Status

Metabolic and lactic acidosis result from inadequate tissue oxygenation. The marker for metabolic acidosis is a decreased bicarbonate concentration (normal: 20 to 24 mEq/L in dogs, 18 to 22 mEq/L in cats, and 24 to 28 mEq/L in horses), a decrease in total carbon dioxide concentration (a value 1 to 2 mEq/L higher than bicarbonate), or an increase in the base deficit (normal: 0 to -4 mEq/L in dogs, -3 to -7 in cats, and 4 to 0 in horses). Lactate is the marker for lactic acidosis (normal, <2 mM/L), which is usually presumed to represent inadequate tissue oxygenation.^{106,107} However, the lactate level can also be elevated as a result of catecholamine-stimulated Na-K-ATPase activity.¹⁰⁸ A word of caution: Do not contaminate the blood sample with lactated Ringer’s solution because that will cause a proportionate increase in the measured lactate concentration.

Mild to moderate metabolic acidosis does not need to be treated specifically; correction of the underlying problem should suffice. Severe metabolic acidosis ($\text{pH} < 7.20$) may benefit from therapy with sodium bicarbonate: desired base deficit – measured base deficit \times body weight (kg) \times 0.3. These dosages of bicarbonate should be administered over a period of at least 20 min, and preferably longer.

Sodium

Sodium concentration is important to transcellular fluid flux, and it is important in fluid therapy not to change it too much, too rapidly. Abrupt changes of sodium concentrations of more than about 15 to 17 mEq/L (in either direction) should be avoided because they may be associated with untoward transcellular water shifts and irreversible brain damage.¹⁰⁹ Baseline sodium concentrations below 130 or above 165 mEq/L in dogs must especially be changed slowly (1 mEq/L/h when treating hypernatremia and 0.5 mEq/h when treating hyponatremia). Decreasing the sodium concentration too fast causes immediate intracellular edema (within hours), whereas increasing it too fast causes hemorrhage and central myelinolysis in 3 to 5 days.

Potassium

Hypokalemia is by far the most common electrolyte problem in critically ill animals, but hyperkalemia can also occur. Both are usually preexisting problems. Severe hypokalemia causes hyperpolarization of electrically excitable cells and, eventually, paralysis. Hypokalemia is potentiated by sodium bicarbonate therapy,

respiratory alkalosis, and β_2 -agonist therapy. Severe hypokalemia should be treated with a potassium infusion (up to 0.5 mEq/kg/h). Severe hyperkalemia causes hypopolarization of electrically excitable cells and myocardial arrhythmias and fibrillation, decreased conduction and contractility, and asystole. Severe hyperkalemia can be treated with either calcium gluconate (0.5 mL of 10% solution per kilogram) or 0.1 to 0.25 units of regular insulin per kilogram, followed by the infusion of 0.5 to 1.5 g/kg of glucose over the next 2 h.

Calcium

Hypocalcemia (ionized) could be a preexisting problem or could result from the administration of citrated blood products. Hypocalcemia can be potentiated by sodium bicarbonate therapy and, for unknown reasons, is commonly observed with hypothermia. Hypocalcemia can decrease myocardial contractility and cause vasodilation. There is no broad agreement as to when hypocalcemia should be treated, but, as a general guideline, ionized concentrations below 0.75 mM/L should perhaps be treated. Calcium gluconate can be administered as a bolus (0.5 mL of the 10% solution [9.3 mg/mL or 0.47 mEq/mL] per kilogram) or as an infusion of 0.5 to 1.5 mL of the 10% solution/kg/h.

Magnesium

Hypomagnesemia is usually a preexisting problem associated with malnutrition or refeeding, diuretic therapy, or diabetic ketoacidosis. It can also result from the administration of citrated blood products. Hypomagnesemia is generally associated with widespread cellular dysfunction manifested by neuromuscular excitability (muscle twitching, fasciculations, and tetany) and eventually paralysis. Hypomagnesemia may also be associated with ventricular arrhythmias and refractory hypokalemia, hypophosphatemia, hyponatremia, and hypocalcemia.

Hypomagnesemia should be treated if the ionized portion is less than 0.2 mM/L (0.45 mg/dL). A dose of magnesium sulfate (0.1 to 0.2 mEq/kg) can be administered slowly intravenously. Magnesium sulfate can then be administered at a daily dosage of 0.25 to 1.0 mEq/kg/day (3 to 12 mg/kg/day) as a continuous-rate infusion.

Introduction

The popularity of local anesthetic-induced neural blockade in dogs has increased over the past several years. A major driving force behind this increased usage is acceptance of the concept of

blocking multimodal pathways to control animals' pain and suffering. Unlike most general anesthetics, which block the perception of pain by inducing anesthesia in an unconscious patient, local anesthesia and regional anesthesia completely block transmission of noxious impulses in a region of the body of a conscious patient. General anesthesia may be advantageous in dogs that are considered difficult to sedate and restrain for surgery and where complete immobilization and relaxation of the patient are required. Local and regional anesthesia also decreases the quantity of opioid and inhalation anesthetic required to obtain the desired plane of anesthesia intraoperatively.¹ Topical anesthesia, infiltration anesthesia, field blocks, selected nerve blocks of the head (anesthesia of the maxilla, upper teeth, eye and orbit, mandible, and lower teeth), anesthesia of the foot and leg (ring block, brachial plexus block, and intravenous regional anesthesia), multiple intercostal nerve blocks, lumbosacral epidural anesthesia, and continuous epidural anesthesia are all logical techniques for providing surgical analgesia and anesthesia in dogs that are considered at risk for inhalant or intravenous anesthesia (Table 20.1). Continuous interpleural analgesia and epidural opioid analgesia can be used to relieve postoperative pain following general anesthesia.

This chapter provides a general overview of the most commonly used local and regional anesthetic techniques for surgical and postoperative pain relief in dogs, emphasizing methodology, advantages, and disadvantages. The pharmacology of local anesthetic drugs, highlighting the mechanisms of action, relevant pharmacology and pharmacokinetics, toxicity, and potential drug interactions, are discussed in Chapter 14.

Topical Anesthesia

Many local anesthetics are effective when placed topically on mucous membranes and may be used in the mouth, tracheo-bronchial tree, esophagus, and genitourinary tract. Local anesthetics used topically include lidocaine (2% to 5%), proparacaine (0.5%), tetracaine (0.5% to 2.0%), butacaine (2%), and cocaine (4% to 10%). Preparations include injectables that are applied topically, cream, ointment, jelly, powder, and aerosol. Injectable preparations of lidocaine (0.5% to 5.0%), available in ampules and vials, with and without epinephrine (1:50,000 to 1:200,000), can be used for infiltration (0.5% to 1.0%) and nerve block (1% to 2%), and applied topically to mucous membranes (1% to 5%). Topical local anesthetic agents can relieve pain during cleaning or dressing of wounds, although their effect is highly variable.

Table 20.1. Classification and degree of required dexterity for producing local and regional anesthetic techniques in dogs.

Classification	Techniques	Required Manual Dexterity and Experience
Terminal anesthesia	Topical	+
	Intravenous regional anesthesia	++
Infiltration anesthesia	Subcutaneous, intramuscular injection	+
	Subpleural injection	++
	Ring block	+
Perineural anesthesia	Nerve blocks on the head	++
	Nerve blocks on the legs	+++
	Brachial plexus block	++
	Intercostal nerve block	+
Spinal anesthesia	Lumbosacral epidural anesthesia	++
	Continuous epidural anesthesia (catheter technique)	+++
	Lumbar subarachnoid anesthesia	+++
Postoperative analgesia	Epidural opioid analgesia	++
	Continuous epidural opioid analgesia (catheter technique)	+++
	Interpleural regional analgesia (catheter technique)	+++
Therapeutic analgesia	Anesthesia of the cervicothoracic ganglion	+++
	Anesthesia of the lumbar sympathetic ganglia	+++

+, little; ++, some; +++, considerable.

The lowest effective dose of topical anesthetic should always be used in order to prevent toxicity from excessive drug plasma concentrations.² Time between application of topical anesthetics and onset of anesthesia is generally longer, and pain relief less, than that achieved with infiltration anesthesia. A 2% to 4% solution of lidocaine used for topical anesthesia on mucous membranes produces effects in approximately 5 min and lasts for 30 min.

Local instillation of proparacaine (0.5%), tetracaine (0.5% to 1.0%), butacaine (2%), piperocaine (2%), oxybuprocaine (0.4%), or cocaine (1% to 4%) into the conjunctival sac anesthetizes the cornea and conjunctiva for short procedures (e.g., removal of hypertrophied gland of the third eyelid). Proparacaine (0.5%) has been advocated as an excellent topical anesthetic for examination of a painful eye, removal of foreign bodies, sutures, obtaining conjunctival scrapings, and subconjunctival injections.³ Anesthesia occurs rapidly (1 to 6 min), lasts for 10 to 15 min after single instillation, and may last for up to 2 h after repeated instillation without untoward effects (e.g., irritation or epithelial damage).⁴ A series of three to five instillations of 1 or 2 drops of proparacaine at approximately 1-min intervals may be necessary to produce satisfactory anesthesia of the cornea and conjunctiva. Topical anesthesia is very safe, is simple to apply, and can be repeated, although dogs may resent the application of cold solutions. Data on vascular uptake and maximum blood concentration are not available, large interpatient variability should be expected, and potential for bacterial contamination exists.⁵

Local anesthetic sprays (10% lidocaine or 14% to 20% benzocaine) anesthetize the mucosa up to a depth of 2 mm within 1 to 2 min after application. Anesthesia lasts for approximately 15 to 20 min. The movable nozzle (Jetco nozzle) of the spray can enable easy access to the site of application. Pressure on the nozzle with the forefinger delivers a specific quantity of the anesthetic each second (10 mg of lidocaine from a 10% lidocaine

spray can). The average expulsion rate from a benzocaine (Cetacaine) spray can is 200 mg/s.

Endotracheal tubes are frequently coated with local anesthetic jells but should not be lubricated with jelly containing 20% benzocaine hydrochloride. Topical sprays and ointments containing 14% to 20% benzocaine reproducibly cause dose-dependent methemoglobinemia. Preparations with over 8% benzocaine include Hurricane Spray (20%), Hurricane Topical Anesthetic Gel (20%) and Liquid (20%), Camphophenique Sting Relief Formula (20%), Dermoplast Anesthetic Pain Relief (20%), and Cetacaine Spray (14%).⁶ Exposure of the tracheal mucosa to topical benzocaine oxidizes blood hemoglobin in dogs in proportion to the absorbed dose within 10 min. Methemoglobin cannot bind oxygen or carbon dioxide.⁷ Dogs are usually asymptomatic when concentrations of methemoglobin are less than 20%, but show fatigue, weakness, dyspnea, and tachycardia at concentrations between 20% and 50%.⁸ Laryngeal sprays containing benzocaine should be used with caution, and if signs of cyanosis and respiratory distress develop, methemoglobinemia should be considered. In general, benzocaine should be used sparingly and cautiously while continuously monitoring for cyanosis. Patients at risk of hypoxia after using benzocaine topical anesthesia should receive oxygen⁶ and intravenous methylene blue (1.5 mg/kg) therapy.⁸

One of the oldest forms of topical anesthesia is superficial cooling. Ethyl chloride can be used to freeze a small local area of skin for punctures, skin biopsy, or incision of small abscesses. Ethyl chloride is sprayed on the skin for 3 to 7 s from an inverted bottle and a distance of 10 to 20 cm, with the jet stream aimed so that it meets the skin at an acute angle to lessen the shock of impact (Fig. 20.1). Surface anesthesia results from cooling (<4°C), which occurs during the evaporation process. Attempts to freeze large skin areas by using ethyl chloride are contraindicated be-

Fig. 20.1. Ethyl chloride is sprayed on the skin to produce surface anesthesia.

cause of the potential for frostbite. Ethyl chloride's brief action (<2 min), ability to produce a freezing sensation, and flammability when exposed to open flames and electric sparks (electrocauterization) limit its use. Inhalation of ethyl chloride should be avoided because it may produce narcotic and general anesthetic effects, or fatal coma with respiratory and cardiac arrest.

Pontocaine cream and a liposomal tetracaine preparation (0.5% tetracaine encapsulated into phospholipid vehicles) effectively penetrate human skin within 30 to 60 min of application, producing long-lasting (>4 h) analgesia.⁹ The most clinically usable cream contains a 5% eutectic mixture of 2.5% lidocaine and 2.5% prilocaine (EMLA cream), which overcomes the human stratum corneum barrier within 1 h of topical application without adverse effects.¹⁰ The usefulness of EMLA cream in dogs has been reported.¹¹

Infiltration Anesthesia

Local infiltration of local anesthetics requires their extravascular placement by direct injection and may be the most reliable and safest of all the local anesthetic techniques (Table 20.1). Lido-

caine (0.5% to 2.0%) is the local anesthetic most often used for infiltration. Only sharp and sterile needles should be used. Local anesthesia can be produced by multiple intradermal or subcutaneous injections of 0.3 to 0.5 mL of local anesthetic solution by using a 2.5-cm, 22- to 25-gauge needle or by using a longer needle (3.75 to 5.0 cm) and slowly injecting local anesthetic while advancing the needle along the line of proposed incision (linear infiltration). Pain is minimal if the needle is advanced slowly into the first desensitized wheal and successive injections are made at the periphery of the advancing wheal. This technique assures that the dog senses only the initial needle insertion. Intradermal deposition of local anesthetic over a superficial abscess, cyst, or hematoma is a routine procedure. Infection along the filtration site will not occur if the needle has not entered the abscess. The amount of local anesthetic used for infiltration anesthesia depends on the size of the area to be anesthetized. Approximately 2 to 5 mg/kg of lidocaine or mepivacaine and 4 to 6 mg/kg of procaine without epinephrine may be used to diffuse into surrounding tissue from the site of injection and anesthetize the nerve fibers and endings. Large amounts of relatively dilute solutions are often infiltrated into operative sites. The lowest possible concentration of local anesthetic that will produce the desired effect should be administered. For example, an average dog (20 kg) will tolerate approximately 50 mL of 0.5% lidocaine without demonstrating signs of toxicity, whereas only 20 to 30 mL of 1% lidocaine or 10 to 15 mL of 2% lidocaine can be injected. The local anesthetic may be diluted in 0.9% sodium chloride solution (not with sterile water) to a 0.25% solution if a large volume of local anesthetic is needed for infiltration of a large operative area. The total dose of drug administered should be reduced by 30% to 40% in old dogs (>8 years) and sick or cachectic dogs in poor condition.¹²

Alternatively, approximately 5 to 8 mg/kg of local anesthetic with epinephrine (1:200,000) may be used for infiltration to produce local vasoconstriction, which reduces absorption rates (30%) and helps to maintain a high drug concentration at the nerve fiber, thus increasing the local anesthetic effect and duration (50%). Local anesthetics containing epinephrine should not be injected into tissues supplied by end arteries (e.g., ears and tail) or in thin and dark-skinned dogs (e.g., poodles) because of the risk of severe vasoconstriction, local ischemia, and necrosis. Epinephrine increases the potential risk of cardiac arrhythmias (e.g., sinus tachycardia, ventricular tachycardia, and ventricular fibrillation in a halothane-sensitized heart), although this has not been a problem when administered in conjunction with lidocaine in dogs. Hearts sensitized to ventricular arrhythmias with halothane do not develop serious ventricular arrhythmias when given lidocaine (1.3 to 7.9 mg/kg) containing epinephrine (0.3 to 1.9 mg/kg) in doses found in lidocaine-epinephrine mixtures used commonly for local anesthesia.¹³ Subfascial and intra-arterial injections must be avoided.

Continuous-Infiltration Anesthesia

This can be accomplished by the use of a continuous catheter-insertion system and a disposable infusion pump (Fig. 20.2).¹⁴ A sterile multipore catheter is placed within the surgical incision

Fig. 20.2. Pain management system for continuous local anesthetic infiltration. The Pain Buster Soaker/ON-Q (I-Flow, Lake Forest, CA) provides continuous administration of local anesthetic into the surgery site for 1 to 5 days: (1) 100 mL of 2% lidocaine hydrochloride solution; (2) 60-mL syringe; (3) fill port with protection cap; (4) E-clip to secure the pump; (5) Pain Buster pump; (6) clamp; (7) pump tubing; (8) filter; (9) flow restrictor, 2-mL/h flow rate if placed in direct contact with the skin (31 °C); (10) luer lock on the catheter connector; (11) radiopaque, fenestrated soaker catheter, with a 20-gauge, 59-cm long, 6.5-cm infusion segment; and (12) split-introducer sheath with the needle partially withdrawn from the needle guard.

(e.g., total ear-canal ablation with lateral bulla osteotomy [Fig. 20.3A], forelimb amputation [Fig. 20.3B], or median and lateral thoracotomies) at the end of the surgical procedure. The catheter is connected to an elastomeric reservoir infusion pump (Pain Buster Soaker system; Orthopedics, Vista, CA), which is filled with local anesthetic (i.e., lidocaine, mepivacaine, or ropivacaine) to its full capacity (65, 100, 270, or 335 mL) to deliver the local anesthetic at a constant rate (0.5, 2.0, 4.0, or 5.0 mL/h) for several days. The Pain Buster Soaker technique is generally well tolerated, producing good postoperative analgesia for up to 50 h, with no acute local anesthetic toxicity, hemodynamic instability, or breakthrough pain.¹⁵ Side effects, such as nystagmus, restlessness, apprehension, and vomiting, are readily treated by removing the pump.

Field Block

This technique can be used for anesthetizing large areas. First, intradermal or subcutaneous linear infiltration is produced around the lesion as previously described. Local anesthetic is then deposited in the deeper tissues by passing the needle through the

desensitized skin far enough to infiltrate the deep nerves supplying the area (Fig. 20.4).¹⁶

Intraperitoneal Infusion

The efficacy of intraperitoneal administration of either lidocaine (2%, 8.8 mg/kg with epinephrine 5 µg/mL), bupivacaine (0.75%, 2.2 mg/kg), or 0.9% sodium chloride solution, and additional subcutaneous injection of 2 mL of the assigned solution prior to incisional closure, has been evaluated for analgesia in 10 dogs upon completion of ovariohysterectomy.¹⁷ Surgery was performed with the patient under general anesthesia (acepromazine-butorphanol-thiopental-isoflurane). No adverse side effects were observed. Pain scores, using the visual analogue scale (VAS), peaked for all groups at 0.5 h and returned to baseline by 18 h. Dogs in the bupivacaine group had significantly lower pain scores at 0.5 h than did the dogs in the 0.9% saline group. Butorphanol and/or acepromazine (0.22 mg/kg intramuscularly [IM] or intravenously [IV]) was given to provide supplemental analgesia to 7 of 10 dogs in the saline group, 4 of 10 dogs in the

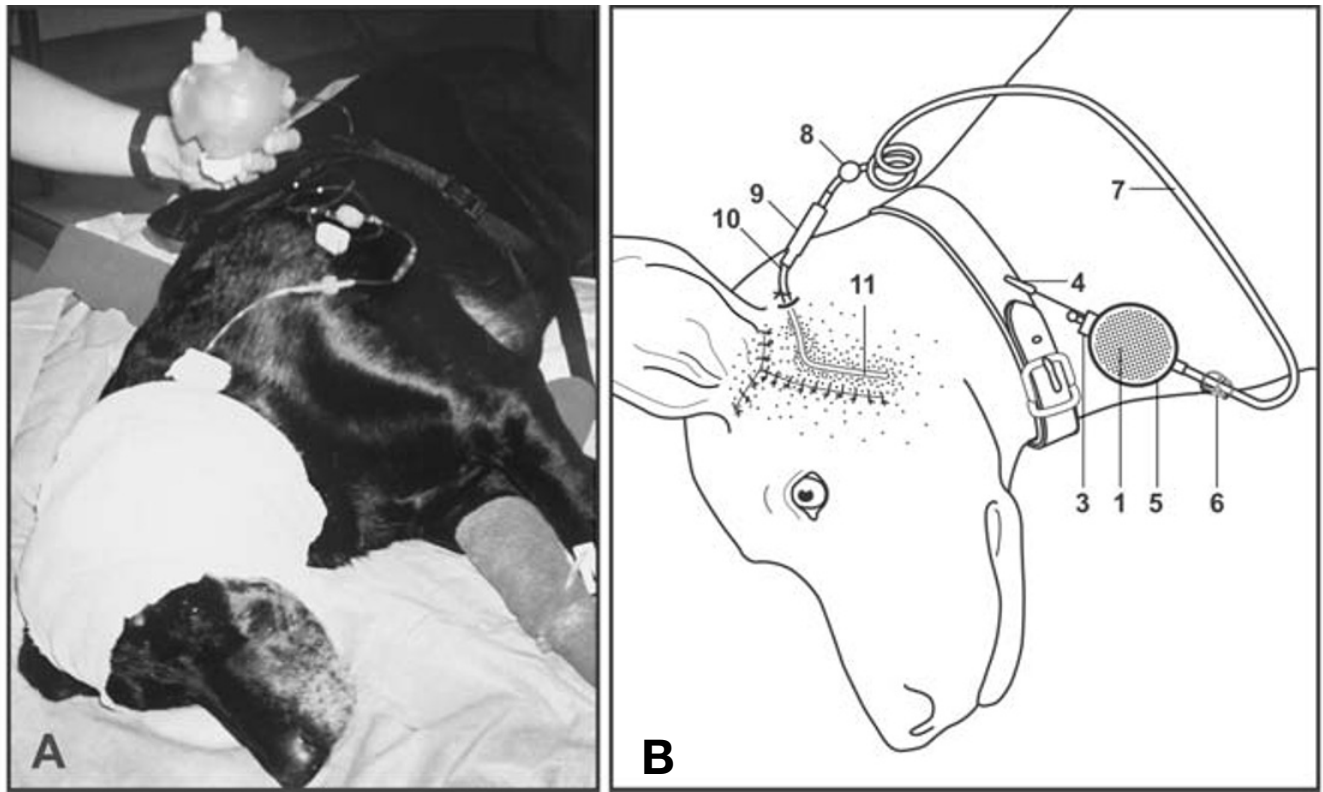

Fig. 20.3. Pain therapy by using the Pain Buster Soaker: black Labrador (39 kg) after total ear-canal ablation **(A)**. The Pain Buster pump is placed into a protective bag hanging beneath the neck. Lidocaine (2%) continuously infiltrates the wounds at a constant rate (2 mL/h) for several days. The numbers refer to the same system components as described in Fig. 20.2 **(B)**.

Fig. 20.4. Field block producing walls of anesthesia enclosing the surgical field.

Fig. 20.5. Needle placement for producing nerve blocks on the head: infraorbital (A), maxillary (B), zygomatic, lacrimal, and ophthalmic (C), mandibular (E), and mental (D) nerves.

lidocaine group, and 2 of 10 dogs in the bupivacaine group. These findings can be interpreted as support for the use of intraperitoneal and subcutaneous bupivacaine for postoperative analgesia following ovariohysterectomy in dogs.^{17,18}

Nerve Blocks

Injection of local anesthetic solution into the connective tissue surrounding a particular nerve produces loss of sensation (sensory nerve block) and/or paralysis (motor nerve block) in the region supplied by the nerves (regional anesthesia). Smaller volumes (1 to 2 mL) of local anesthetic are needed to produce nerve blocks when compared with a field block, thereby reducing the danger of toxicity.

Three supplemental methods of pain relief in 31 anesthetized dogs undergoing total ear-canal ablation with lateral bulla osteotomy have been compared.¹⁹ The use of systemic opioids alone (e.g., oxymorphone, 0.05 mg/kg IV), intraoperative splash block, using bupivacaine (0.5% solution, 1.0 mg/kg per ear), and preoperative nerve block of the great auricular nerve (cervical nerve II) and the auriculotemporal nerve (cranial nerve V), using bupivacaine (0.5% solution, 0.5 mL per site), provided similar pain relief, although 33% of the dogs required additional analgesia or tranquilization after surgery. Rectal temperature, pulse rate, respiratory rate, and postoperative serum cortisol concentrations in dogs were not significantly different among groups ($P < 0.05$).

Regional Anesthesia of the Head

The administration of local anesthetic around the infraorbital, maxillary, ophthalmic, mental, and alveolar mandibular nerves

provides valuable and practical advantages over general anesthesia when combined with effective sedation (Fig. 20.5). Each nerve may be desensitized by injecting 1 to 2 mL of a 2% lidocaine hydrochloride solution by using a 2.5- to 5-cm, 20- to 25-gauge needle.

The infraorbital nerve is desensitized at its point of emergence from the infraorbital canal. The needle is inserted either intraorally²⁰ or extraorally approximately 1 cm cranial to the bony lip of the infraorbital foramen.^{21,22} The needle is advanced to the infraorbital foramen, which can be found between the dorsal border of the zygomatic process and the gum of the upper canine tooth (Fig. 20.5A). Successful injections desensitize the upper lip and nose, the roof of nasal cavity, and the surrounding skin up to the infraorbital foramen.

The maxillary nerve must be desensitized to completely desensitize the maxilla, upper teeth, nose, and upper lip. The needle is placed percutaneously along the ventral border of the zygomatic process approximately 0.5 cm caudal to the lateral canthus of the eye and is advanced into close proximity of the pterygopalatine fossa (Figs. 20.5B and 20.6). Local anesthetic is administered at the point where the maxillary nerve courses perpendicular to the palatine bone between the maxillary foramen and foramen rotundum.^{20,21}

Eye and Orbit

Anesthesia of the eye and orbit is produced by desensitizing the ophthalmic division of the trigeminal nerve. General anesthesia for ophthalmic procedures has increased in popularity; however, retention of ocular reflexes during light and medium planes of general anesthesia in dogs can disturb the surgical field. Regional anesthesia, by anesthesia of ophthalmic nerves, produces immo-

Fig. 20.6. Anesthesia of the maxillary nerve in a poodle (32 kg) after partial maxillectomy: site and direction of the inserted needle.

bility of the eye in addition to sensory anesthesia, and prevents the oculocardiac reflex, which can cause bradycardia, arrhythmias, and cardiac arrest as result of traction on the extrinsic muscles of the eye. A 2.5-cm, 22-gauge needle is inserted ventral to the zygomatic process at the level of the lateral canthus. The point of the needle should be approximately 0.5 cm cranial to the anterior border of the vertical portion of the ramus of the mandible. The needle is advanced medial to the ramus of the mandible in a mediodorsal and somewhat caudal direction until it reaches the lacrimal, zygomatic, and ophthalmic nerves at the orbital fissure (Fig. 20.5C). Deposition of 2 mL of local anesthetic at this site produces akinesia of the globe because of the proximity of the abducens, oculomotor, and trochlear nerves to

the ophthalmic nerve. Motor block is assessed by cessation of the following eye movements: laterally, caused by the lateral rectus muscle (abducens nerve); and upward, downward, medially, and laterally, caused by the superior, inferior, medial, and lateral rectus muscles, respectively (oculomotor nerve). The superior oblique muscle rotates the eye downward and laterally (oculomotor nerve), whereas the inferior oblique muscle rotates the globe upward and laterally (trochlear nerve).²³

Retrobulbar or peribulbar anesthesia for local anesthesia of the eye runs the risk of direct subarachnoid injection, peribulbar hemorrhage, globe perforation, and intravascular injection.^{5,23,24} When performing retrobulbar anesthesia, the risk of puncturing the globe is minimal if a 7.5-cm, 20-gauge needle is inserted at the lateral canthus through the anesthetized conjunctiva and is advanced past the globe toward the opposite mandibular joint until the base of the orbit is encountered.²⁰ When performing peribulbar anesthesia, the potential for puncturing ciliary and scleral blood vessels is minimal if a 5-cm curved needle (0.5-mm internal diameter) conformed to the roof of the orbit is inserted through the anesthetized conjunctival sac at the vertical meridian (Fig. 20.7).²⁵ Directing the needle away from the globe and toward the orbit also minimizes the risk of perforating the globe.

Injection of local anesthetic into the optic sheath can cause respiratory arrest attributable to the infiltration of local anesthetic into the subarachnoid space of the central nervous system (CNS).²⁴ The pressure generated by injection into the optic nerve sheath or intrascleral injection is three or four times that produced by injection into the retrobulbar adipose tissue (135 vs. 35 mm Hg).²⁴ Increased resistance encountered during retrobulbar block should serve as a warning, mandating redirection of the needle in order to prevent subarachnoid injection.

Fig. 20.7. Needle placement for producing retrobulbar anesthesia.

Fig. 20.8. Needle placement for inducing intercostal nerve blocks. **Inset:** (a) skin, (b) subcutaneous tissue, (c) intercostal muscles, (d) rib, (e) subcostal space, (f) pleura costalis and fascia, (g) interpleural space, (h) pleura pulmonalis, (i) intercostal artery, vein, and nerve, and (j) lung.

Lower Lip

This can be desensitized by percutaneously inserting a 2.5-cm, 22- to 25-gauge needle rostral to the mental foramen at the level of the second premolar tooth. Approximately 1 to 2 mL of local anesthetic is deposited in close proximity to the mental nerve (Fig. 20.5D).

Mandible and Lower Teeth

The mandible (including molars, premolars, canine, incisors, skin) and the mucosa of the chin and lower lip can be desensitized by injecting 1 to 2 mL of the local anesthetic in close proximity to the inferior alveolar branch of the mandibular nerve as it enters the mandibular canal at the mandibular foramen (Fig. 20.5E). A 2.5-cm, 22-gauge needle is inserted at the lower angle of the jaw approximately 0.5 cm rostral to the angular process and is advanced 1 to 2 cm dorsally along the medial surface of the ramus of the mandible to the palpable lip of the mandibular foramen.^{20,22}

Intercostal Nerve Block

Intercostal nerve blocks may be used for relieving pain during and after thoracotomy, pleural drainage, and rib fractures, thereby minimizing the need for systemic analgesics that may depress respiration. They are not recommended for dogs with pulmonary diseases, which impair blood-gas exchange, or for dogs that cannot be observed for several hours after injection because of the potential for clinically delayed pneumothorax.

A minimum of two adjacent intercostal spaces both cranial and

caudal to the incision or injury site are selectively blocked because of overlap of nerve supply.²⁶ The site for needle placement is the caudal border of the rib (R3-6) near the intervertebral foramen (Fig. 20.8). Approximately 0.25 to 1.0 mL of 0.25% or 0.5% bupivacaine hydrochloride per site, with or without epinephrine 1:200,000, is deposited. Small volumes and/or diluted local anesthetic solutions should be used as initial pain therapy so that the total dose does not exceed 3 mg/kg. Small dogs receive 0.25 mL/site, medium dogs 0.5 mL/site, and large dogs 1.0 mL/site. Postthoracotomy pain is generally controlled for 3 to 6 h after successful block.²⁶ Heart rate, respiratory rate, hematocrit, plasma protein, blood pH, arterial oxygen partial pressure (PaO₂), and arterial carbon dioxide partial pressure (PaCO₂) do not change significantly in halothane-anesthetized dogs after intercostal nerve block.^{26,27} Prolonged analgesia may be achieved by repeated administrations of local anesthetics, although a patient may not tolerate multiple percutaneous injections. Intercostal nerve block produces relatively high blood concentrations of local anesthetic for a given dose;^{28,29} therefore, the risk of toxic blood concentrations is greater.

Selective intercostal nerve block is easily performed because of the proximity of each nerve to its adjacent rib.³⁰ The intercostal nerves can be visualized beneath the parietal pleura during thoracotomy. This technique provides consistent analgesia and does not produce respiratory depression, with subsequent hypercarbia and hypoxemia, which is a more frequent problem in dogs administered intramuscular or intravenous opioids.^{26,31} Because intercostal bupivacaine (0.5%, 0.5 to 1.0 mL) abolishes nociceptive input only from tissues supplied by the intercostal nerves,

Fig. 20.9. Interpleural catheter placement. **Inset:** (a) skin, (b) subcutaneous tissue, (c) intercostal muscles, (d) rib, (e) subcostal space, (f) pleura costalis and fascia, (g) interpleural space, (h) pleura pulmonalis, (i) catheter, (j) Tuohy needle, (k) lung, and (l) intercostal artery, vein and nerve.

but not from the whole surgical site, additional analgesia with preoperatively administered epidural morphine (0.1 mg/kg) has been suggested to improve both intraoperative and immediate postoperative analgesia in dogs after thoracotomy.³²

Interpleural Regional Analgesia

Interpleural injection of local anesthetics is a relatively new option for managing certain types of acute and chronic pain originating from thoracic and upper abdominal structures in humans.³³ Pain from rib fractures, metastasis to the chest wall, pleura, and mediastinum, mastectomy, chronic pancreatitis, cholecystectomy, renal surgery, abdominal cancer, and posthepatic neuralgia can be relieved by intermittent or continuous administration of local anesthetic into the pleural space through a catheter, without the systemic effects commonly observed after the use of parenterally administered (IM or IV) opioids.³⁴ Most clinical studies have been performed in patients recovering from gallbladder surgery. Less frequently, this technique has been used for pain relief in patients with multiple fractured ribs; other indications are uncommon.³⁵ Reports in the current literature provide evidence both supporting^{36,37} and opposing^{38–40} the effectiveness of postoperative pain management via interpleural analgesia after thoracotomy for pulmonary surgery in humans. The mechanisms of pain relief produced by interpleural analgesia are not fully understood, but at least three different sites of actions have been hypothesized: (a) retrograde diffusion of local anesthetic through the parietal pleura, causing intercostal nerve block;^{41,42} (b) unilateral block of the thoracic sympathetic chain and splanchnic nerves;⁴³ and (c) diffusion of the anesthetic into the ipsilateral brachial plexus, resulting in a parietal block.³³

The technique requires the insertion of a catheter into the pleural space of sedated or anesthetized dogs.^{26,44–51} The catheter is placed into the pleural space either percutaneously or prior to closure of a thoracotomy (Fig. 20.9). Percutaneous placement of a catheter into the pleural space is difficult to perform on dogs with pleural fibrosis, because thickening of the pleura makes identification of the pleural space guesswork. The dog should be sedated, and the skin, subcutaneous tissues, periosteum, and parietal pleura over the caudal border of the rib should first be desensitized with 1 to 2 mL of 2% lidocaine solution, using a 2.5- to 5-cm, 20- to 22-gauge needle. A 5.0-cm × 1.4-mm outer diameter, 17-gauge Huber point (Tuohy) needle is then used for catheter placement. The stylet is removed and the needle filled with sterile saline until a meniscus is seen at the needle's hub. The needle is then advanced until a clicking sensation is perceived as the needle tip perforates the parietal pleura or until the meniscus disappears when the needle tip enters the pleural space (hanging-drop technique).

The hanging-drop technique for the identification of the subatmospheric pleural pressure is not always reliable because the meniscus may also disappear when the needle passes through the intercostal muscles. Alternatively, a freely moving 10-mL glass syringe is attached to the needle. The syringe and needle are then advanced as a unit. On entering the pleural space, the plunger of the syringe is drawn inward by the negative pressure of the interpleural space.³⁴ Some veterinarians place the catheter in the tissue plane superficial to the parietal pleura, close to or in the subcostal space (e in Fig. 20.9), in order to produce a more effective block attributable to a decreased loss of local anesthetic through thoracic drainage tubes.³⁵ A catheter (6- to 10-cm length of fenestrated medical grade silastic tubing, 2-mm inside diameter) can

Fig. 20.10. Interpleural tray for continuous interpleural analgesia. The basic Pleurocert procedure set contains (1) Tuohy needle (1.7 × 80 mm, 16 gauge × 31/4 inches), (2) Y piece with control balloon, (3) radiopaque polyamide catheter (0.65 × 1.05 × 1000 mm), (4) screw connector, (5) luer lock antibacteria injection filter (0.2 μm), and (6) 5-mL glass syringe.

be introduced and advanced 3 to 5 cm beyond the needle tip with minimal resistance after the needle tip is placed subpleurally.

A technique has been developed to insert the catheter without disconnection to minimize the risk of pneumothorax.⁵² The technique involves the use of a Tuohy needle to which a Y piece with a latex balloon and catheter is attached (Fig. 20.10). The needle is inserted until the balloon collapses under the negative pressure of the pleural cavity; the catheter is then advanced as required. The needle is then carefully withdrawn over the catheter, and the catheter is left in place.

Approximately 1 to 2 mg of bupivacaine/kg (0.5%, with or without 5 μg of epinephrine/mL) is injected over 1 to 2 min following negative aspiration of air or blood through the catheter. The catheter is then cleared with 2 mL of physiological saline solution. Bolus interpleural bupivacaine is effective in relieving postthoracotomy pain for 3 to 12 h.²⁶ The addition of epinephrine (5 μg/mL) to the local anesthetic solution may or may not increase the duration of analgesia and decrease the plasma concentration of the local anesthetic.

Complications, such as lung trauma, bleeding, and pneumothorax, are occasionally reported with the blind percutaneous insertion technique in humans.⁵³ The balloon technique is superior to other methods (i.e., loss-of-resistance technique, low-friction syringe-piston movement, and infusion technique). Sterile sets for single continuous interpleural analgesia are available that contain a Tuohy needle, catheter, control balloon, flat antibacterial injection filter, screw connector, screwdriver, and drape (Fig. 20.10).

A catheter can be placed in the open chest by inserting the Tuohy needle through the skin over the rib at a site that is at least two intercostal spaces caudal to the incision while care is taken to retract the lung. The catheter is then passed through the needle and placed 3 to 5 cm subpleurally under direct vision. Local anesthetic is injected in the usual manner. The ventral tip of the catheter is best anchored by using one encircling suture of surgical gut (3.0) in the intercostal space at the site of puncture.

Positioning of the catheter will affect the site of intercostal nerve blockade and is attributable to gravity-induced pooling of the local anesthetic within the interpleural space.^{44,45,54} Dogs that recover from lateral thoracotomy should be placed with the incision side down. Dogs that have had a sternotomy should be placed in sternal recumbency for approximately 10 min to allow the local anesthetic to pool near the incision and adjacent intercostal nerves. The external portion of the catheter should be anchored with tape, sutured to the skin, and covered with a non-occlusive-type dressing that allows air circulation. Reportedly, analgesia produced by interpleural infusion in dogs is similar to analgesia produced by morphine (0.5 mg/kg subcutaneously) or selective intercostal nerve block with bupivacaine (0.5 mL of 0.5% bupivacaine per site), but lasts longer (3 to 12 h).²⁶ Dogs treated with 1.5 mg of interpleural bupivacaine/kg through an interpleural catheter do not demonstrate significant changes in heart rate, respiratory rate, hematocrit, plasma protein, blood pH, or PaCO₂.^{26,49,50,51}

Studies have been performed to evaluate cardiovascular effects of low-dose interpleural bupivacaine (0.5%, 1.5 mg/kg), high-dose interpleural bupivacaine (0.5%, 3 mg/kg), and high-dose interpleural bupivacaine (0.5%, 3 mg/kg) with epinephrine 1:200,000 (5 μg/mL) in four dogs recovering from diazepam-ketamine-1.2% halothane and oxygen anesthesia.^{47,49} The local anesthetic drugs were administered via an interpleural catheter (25 cm long) that was advanced through a 17-gauge needle at the left or right eighth intercostal space. Pneumothorax or any other pulmonary complication was not observed in any of the dogs evaluated radiographically. The low dosage rate (1.5 mg/kg) of 0.5% bupivacaine produced no significant ($P < 0.05$) alterations in heart rate, systolic, diastolic, and mean arterial blood pressure, cardiac output, and pulmonary arterial blood pressure, respiratory rate, and end-tidal carbon dioxide. Cardiac output, expressed as a percentage of change from baseline, was significantly higher in dogs receiving the low dosage (1.5 mg/kg) than dogs receiving

the high dosage (3 mg/kg) of interpleural bupivacaine ($126\% \pm 6\%$ vs. $94\% \pm 6\%$ change). Mean plasma concentrations of bupivacaine peaked 5 to 15 min after interpleural injection. Mean plasma concentrations of bupivacaine in individual dogs were variable and did not significantly ($P < 0.05$) differ among dogs treated with the low dose (1.5 mg/kg), high dose (3 mg/kg), and high dose (3 mg/kg) with epinephrine (1:200,000) of interpleural bupivacaine (0.5%).⁴⁹ Mean arterial blood pressure was decreased to 28 mm Hg in one dog 15 min after interpleural administration of 3 mg of bupivacaine/kg and was decreased to 37 mm Hg in one dog receiving 3 mg of bupivacaine/kg with epinephrine. This dog also demonstrated apnea for approximately 6 min and required positive-pressure ventilation. The maximum plasma concentration of bupivacaine in these hypotensive dogs was 3.4 and 3.6 $\mu\text{g/mL}$, respectively.⁴⁹ The high dosage rate (3 mg/kg) for interpleural administration is not recommended because it may cause hypotension in some individual animals. Careful patient monitoring is advised if dosages approach 3 mg/kg. The addition of epinephrine 5 $\mu\text{g/mL}$ may not be of any advantage because it does not attenuate peak plasma concentrations.⁴⁹

The effects of interpleural bupivacaine (0.5%, 1.5 mg/kg), intramuscular morphine (1.0 mg/kg), or interpleural morphine (0.1 mg/kg) have also been compared. Interpleural bupivacaine produced longer analgesia, less work of breathing, fewer blood-gas alterations, and earlier return to normal pulmonary function in the first 5 to 8 h after thoracotomy.⁵⁰ Interpleural administration of morphine (0.1 mg/kg) did not appear to provide any advantages in terms of analgesia or pulmonary function when compared with the intramuscular administration of morphine (1.0 mg/kg). These results differ from other experimental trials in dogs receiving either 0.5% bupivacaine (1.5 mg/kg) interpleurally, morphine (1.0 mg/kg) IM, or morphine (1.0 mg/kg) interpleurally.⁵¹ Medium sternotomy significantly decreased pH, PaO_2 , mean oxygen saturation of hemoglobin, and dynamic compliance; and significantly increased PaCO_2 , alveolar-arterial difference in the partial pressure of oxygen, pulmonary resistance, and work of breathing. The effects of interpleural administration of bupivacaine and morphine were similar to effects of intramuscular administration of morphine and provided little or no additional benefit. It is not known what the effects of dilution by pleural fluid, such as blood and serum, and loss of local anesthetic through the thoracotomy tube are on overall efficacy. The dose of interpleural bupivacaine may have been inadequate in this study, considering that sternotomy may be more painful than intercostal thoracotomy.

The optimum total dose, concentration, or volume of interpleural bupivacaine in sick dogs have not been reported. Theoretically, one or two of the three branches of the phrenic nerve can be blocked, leaving the remaining branch(es) intact. Isolated contraction of the costal portion of the diaphragm without contraction of the crural portion may result in paradoxical respiration with negative intra-abdominal pressure.⁴⁶ The catheter is usually removed 24 h after thoracotomy when postoperative pain has normally decreased. Long-term use (over several weeks) of an interpleural catheter is possible if the catheter is subcutaneously tunneled.⁵⁵

The administration of interpleural bupivacaine is greatly facil-

Fig. 20.11. Pain therapy in a Chihuahua (2 kg) recovering from left lateral thoracotomy and correction of a patent ductus arteriosus Botalli: 0.5% bupivacaine (1.5 mg/kg) was administered into a chest tube, which was placed interpleurally (total dose = 3 mg = 0.6 mL), and then the chest tube was cleared from the anesthetic with 0.6 mL of 0.9% sterile sodium chloride.

itated in dogs in which a chest tube has been placed for evacuation of air (Fig. 20.11). Interpleural regional analgesia has limitations but also several distinct advantages over the more traditional intercostal nerve block or the administration of parenteral opioids. The procedure is technically simple to perform. Only one needle stick is needed, in contrast to multiple sites of injection when performing an intercostal nerve block. Pain relief lasts longer and is less likely to produce CNS and respiratory depression than after the use of parenteral opioids. Interpleural administration of the local anesthetic (lidocaine or bupivacaine) approximately 30 min prior to removal of the chest tube helps to prevent pain associated with the tube removal.

Infection, tachyphylaxis to local anesthetic, high anesthetic blood concentration, systemic toxicity from local anesthesia, unilateral sympathetic block (evidenced as a Horner's syndrome) and increased subcutaneous skin temperature of the affected side, pleural effusion, phrenic nerve paralysis or paresis, and catheter-related complications (e.g., intrapulmonary placement of catheter) do not occur if the procedure is performed properly. Pain relief is minimal in people and dogs with a misplaced catheter, loss of local anesthetic in the chest tube, excessive bleeding into the pleural space, or altered diffusion within the parietal pleura after mechanical irritation by the surgical procedure.⁵⁶ A dilution of local anesthetic by pleural exudation appears to play a subordinate role in humans because a relationship between a loss of chest tube fluid and interpleural analgesic requirement or pain scores could not be demonstrated.⁴⁰ Care must be taken to avoid the serious potential complication of pneumothorax, particularly when this method is used bilaterally.⁵⁷

Anesthesia of the Foot and Leg

Several techniques may be used to induce anesthesia of the foot and leg successfully: (a) infiltration of tissues around the limb by

Fig. 20.12. Needle placement for brachial plexus block. **Inset:** ventral branches of (a) sixth, (b) seventh, (c) eighth cervical, and (d) first thoracic spinal nerves; (e) tuberosity of humerus; and (f) first rib.

using local anesthetic solution (ring block), (b) intra-articular injection of local anesthetic, (c) infiltration of the brachial plexus with local anesthetic solution (brachial plexus block), (d) injection of local anesthetic into an accessible superficial vein in an extremity that is isolated from the general circulation by placing a tourniquet proximal to the injection site (intravenous regional anesthesia), (e) perineural infiltration of sensory nerves in the limbs (nerve block), and (f) injection of local anesthetic solution into the lumbosacral epidural space to induce anesthesia of the hind legs,

Ring Block

Local infiltration and field block around the distal extremity may be performed with a 2- to 5-cm, 22- to 23-gauge standard needle. Intradermal wheals around a superficial lesion and subcutaneous infiltration around the limb are performed by using a short (<3 cm) and fine (23- to 25-gauge) needle.

Intra-articular Analgesia

A prospective study has compared the analgesic effect of the intra-articular administration of bupivacaine (0.5%, 0.5 mL/kg), preservative-free morphine (morphine sulfate [Duramorph] injection, USP; Elkins-Sinn, Cherry Hill, NJ) at a dose of 0.1 mg/kg diluted with 0.9% sodium chloride to a volume of 0.5 mL/kg or with 0.9% sodium chloride (0.5 mL/kg).⁵⁸ Dogs in the bupivacaine and morphine groups required less supplemental analgesia when morphine (0.5 mg/kg IM) at 6 and 24 h was used after cranial cruciate ligament repair than did the dogs in the 0.9% sodium chloride group. Intra-articular morphine provided some analgesia, as indicated by cumulative pain scores and measurement of pain threshold in both stifles by using a spring-

action load-measuring device (Pain Diagnostics and Thermography, Great Neck, NY), but not to the same level as intra-articular bupivacaine. Intra-articular morphine (0.1 mg/kg) did not produce the bradycardia, respiratory depression, or hypotension that might be observed after systemic administration of morphine. Ongoing inflammation is apparently needed for intra-articular opioids to produce noticeable antinociceptive effects.⁵⁹

Brachial Plexus Block

Brachial plexus block is suitable for operations on the front limb within or distal to the elbow.⁶⁰⁻⁶² The technique should be done in well-sedated standing or laterally recumbent dogs. A 7.5-cm, 20- to 22-gauge needle is inserted medial to the shoulder joint and directed parallel to the vertebral column toward the costochondral junction (Fig. 20.12). In larger dogs, approximately 10 to 15 mL of 2% lidocaine hydrochloride solution with 1:200,000 epinephrine is injected slowly as the needle is withdrawn, if no blood is aspirated into the syringe, thereby placing local anesthetic in close proximity to the radial, median, ulnar, musculocutaneous, and axillary nerves. Gradual loss of sensation and motor function occurs within 10 to 15 min. Anesthesia lasts for approximately 2 h, and total recovery requires approximately 6 h.

A peripheral nerve stimulator can be used to accurately locate the radial, median, ulnar, musculocutaneous, and axillary nerves, thereby reducing the dose of local anesthetic for successful brachial plexus blockade in dogs.⁶² One electrode (the alligator clip on the positively charged lead wire [red plug]) from the nerve locator is attached to the skin, while the other electrode (the alligator clip on the negatively charged lead wire [black plug]) is attached to the proximal portion of the insulated needle (0.72 × 10.8 mm, 22 gauge × 4.25 inches). A 20-mL syringe

Fig. 20.13. (1) Peripheral nerve-stimulator used as an aid in accurately locating nerves when performing nerve-block procedures: The nerve locator is set at 2 Hz and low output (0.5 mA); the 0.5-mA current delivered to the patient is displayed; (2) the lead wire with red plug (+) and alligator clip for the patient's electrode; (3) the lead wire with black plug (–) and alligator clip for the needle; (4) Stimex insulated needle (22 gauge, 4.25 inches, 0.72 × 10.79 mm); (5) extension set; (6) 20-mL syringe with three-way stopcock, filled with (7) 0.2% ropivacaine hydrochloride.

containing the local anesthetic agent (2% lidocaine, 0.5% ropivacaine, or 0.5% bupivacaine, diluted with 0.9% sodium chloride solution to make a 0.375% concentration) is attached to a three-way stopcock, a fluid extension set, and the needle (Fig. 20.13). As the needle is inserted medial to the scapulothoracic joint toward the costochondral junction of the first rib, medial to the scapula but outside the thorax, the nerve stimulator is turned on to 2 Hz and 1.0 mA. As the paw begins to twitch, the needle is precisely placed to obtain maximal twitch with as little current (<0.5 mA) as possible. At this point, the syringe is aspirated to ensure that it is not in a blood vessel, and 0.1 to 0.2 mL of the anesthetic is injected until the twitch disappears. The technique is repeated three or more times, by fanning the needle dorsal and ventral from the initial placement. Direct deposition of the local anesthetic on the nerves at a maximum dose of 1.5 mg/kg of lidocaine, ropivacaine, or bupivacaine will produce good brachial plexus blockade. By using a nerve stimulator, a total dose of 4 mg of bupivacaine with 5 µg/mL of epinephrine was effective in providing anesthesia for middiaphyseal osteotomies of the humerus followed by intramedullary pin fixation in 11 of 12 dogs sedated with acepromazine and anesthetized with propofol.⁶² Analgesia lasted for 11.1 ± 0.5 h.⁶²

Brachial plexus block is relatively simple and safe to perform and produces selective anesthesia and relaxation of the limb distal to the elbow joint (Fig. 20.14). The relatively long waiting period (15 to 30 min) required to attain maximal anesthesia and some occasional failures to obtain complete anesthesia, particularly in fat dogs, are disadvantages of the technique.

Intravenous Regional Anesthesia

Intravenous regional anesthesia (IVRA) is a rapid and reliable method for producing short-term (<2 h) anesthesia of the extremities. The clinical value of IVRA in humans is well established. The IVRA technique is also known as *Bier block*.⁶³ Little information on clinical experiences with IVRA in dogs exists, even

Fig. 20.14. Anesthesia of the brachial plexus of the left thoracic limb in a conscious dog.

Fig. 20.15. Intravenous regional anesthesia in a sedated bullmastiff (80 kg) in right lateral recumbency for skin biopsies at the palmar paws of both front legs. A rubber tourniquet is placed distal to the carpus (right foot) and proximal to the carpus (left foot). The tourniquets are secured with hemostatic forceps, which are taped to the skin. Injection of 12 mL of 1% lidocaine hydrochloride solution (1.5 mg/kg per leg) into the cephalic vein is shown.

though it appears to be a simple, safe, and practical method for providing 60 to 90 min of regional anesthesia in an extremity distal to a tourniquet (Fig. 20.15).^{64,65} The technique is best accomplished in dogs by placing an intravenous catheter in an appropriate and accessible vein (e.g., the cephalic or lateral saphenous vein) distal to the tourniquet. The limb is first desanguinated by wrapping it with an Esmarch bandage. A rubber tourniquet is placed around the limb proximal to the Esmarch bandage. The tourniquet must be tight enough to overcome arterial blood pressure.⁶⁶ Once the tourniquet is secured, the Esmarch bandage is unwrapped, and 2.5 to 5 mg/kg lidocaine is injected IV with light pressure. A period of 5 to 10 min is required to achieve maximum anesthesia before beginning the surgical procedure. Diluted concentrations (0.25% and 0.5%) of lidocaine produce adequate sensory blockade as long as the tourniquet is applied. By avoiding leakage and keeping the local anesthetic isolated in the limb, the incidence and severity of toxic symptoms are decreased and the percentage of successful blocks increased.⁶⁶ Complications resulting from blood-flow deprivation to the limb or from the dose of anesthetic used do not occur if the procedure is limited to 90 min.

Once the tourniquet is removed, sensation returns within 5 to 15 min and residual analgesia remains for up to 30 min. Minimal effects on heart rate, respiratory rate, or the electrocardiogram have been noted in dogs after removal of the tourniquet.⁶⁴ The site and mechanism of local anesthetic action in IVRA are unclear but may involve desensitization of major nerve trunks and/or sensory nerve endings.⁶⁷ Unlike the desensitization described in other nerve blocks, the onset of anesthesia and muscle paralysis begins distally and progresses proximally; thus, the local anesthetic should be injected as distally as possible in the limb to be anesthetized (Fig. 20.16). The blood-free surgery site

Fig. 20.16. Radiographs of the left forelimb of a German shepherd (35 kg). **A:** A mixture of 3 mL of 2% lidocaine hydrochloride solution and 3 mL of Omnipaque 300 was injected into the cephalic vein at a proximal site. Retrograde dissipation of the anesthetic was prohibited by venous valves; thus, anesthesia of the limb did not develop. **B:** The injection was repeated at a distal site 1 week later, thereby inducing anesthesia of the limb distal to the tourniquet. The *arrow* indicates the injection site.

is ideal for taking biopsy samples and removing a foreign body from the paws. Prolonged procedures (>90 min) may produce tourniquet-induced ischemia, which is associated with pain and increased blood pressure. If pain occurs, it is often difficult to control and requires induction of general anesthesia.⁶⁸ Reversible shock occurs if the tourniquet is removed after 4 h; and sepsis, endotoxemia, and death occur if the tourniquet is removed after 8 to 10 h. Bupivacaine should not be used for this technique because of the increased potential for cardiovascular collapse and death associated with its use IV.^{69–72}

Nerve Blocks of the Limbs

Specific nerve blocks in the front limbs (radial, ulnar, median, and musculocutaneous nerves) and hind limbs (tibial, peroneal, and saphenous nerves) of dogs have been described.⁷³ These

Fig. 20.17. **A:** Aseptic needle placement, using sterile surgical gloves, into the lumbar epidural space of a dog (A) and catheter placement for continuous epidural anesthesia using a local anesthetic and/or analgesia using an opioid (B). **B:** Dorsal view. Palpation of the dorsal spinous process of the L7 vertebra and dorsoiliac wings. **C:** Inset: (a) epidural space with fat and connective tissue, (b) dura mater, (c) arachnoid membrane, (d) spinal cord, (e) cerebrospinal fluid, (f) cauda equina, (g) seventh lumbar (L7) vertebra, (h) first sacral (S1) vertebra, (i) intervertebral disc, (j) interarcuate ligament (ligamentum flavum), and (k) interspinous ligament.

techniques are rarely used in clinical small animal practice because of difficulty in locating the proper site for injection of local anesthetic and the substitution of simpler methods (e.g., IVRA and epidural anesthesia).

Lumbosacral Epidural Anesthesia

This technique is noted for its simplicity, safety, and effectiveness, and is one of the most frequently used regional anesthetic techniques described for surgical procedures caudal to the umbilicus in dogs.⁷⁴⁻⁹⁸ Epidural anesthesia is frequently recommended for cesarean section because, unlike other anesthetic techniques, it does not depress the puppies. The bitch remains awake and able to take care of her puppies immediately after surgery.

Dogs are generally sedated, tranquilized, or anesthetized to reduce fear and apprehension and then are placed either in sternal recumbency (for bilateral anesthesia) or in lateral recumbency (for ipsilateral anesthesia). The hind limbs can be extended cranially to maximally separate the lumbar vertebrae, making identification of the lumbar space easier.

The anesthetic procedure is not technically difficult when performed by an experienced clinician. The epidural space is located between the inner and outer layers of the dura mater (Fig. 20.17).

It contains nerves (cauda equina), fat, blood vessels, lymphatics, and occasionally the end of the spinal cord with its surrounding meninges (arachnoid and dura mater). The subarachnoid space contains cerebrospinal fluid (CSF). After a thorough surgical preparation, the local anesthetic solution is injected through a disposable 2.5- to 7.5-cm, 20- to 22-gauge spinal needle as a single dose or is injected through a catheter that is inserted at least 1.5 to 2.0 cm beyond the end of an 18- or 17-gauge Huber-point (Tuohy) or 18-gauge Crawford needle (continuous technique [Figs. 20.17 and 20.20]). A 2.5-cm, 22-gauge spinal needle is used for small dogs, a 3.8-cm, 20-gauge needle for medium-sized dogs, and a 7.5-cm 18-gauge needle for large dogs. Important landmarks for needle placement are easily identified in most dogs. The iliac prominences on either side of the spine are palpated by using the thumb and middle finger of one hand (Fig. 20.17). The spinous process of the seventh lumbar (L7) vertebra is located with the index finger. The lumbosacral (L7-S1) interspace should be palpated from both the cranial and caudal directions by moving the finger on the dorsal spinous processes of L6 to L7 and S2 to S1. This will help to avoid inadvertent placement of the needle into the L6 to L7 interspace. The needle must be placed correctly on the midline and caudal to the L7 spinous process, and is inserted until a distinct popping sensation is felt as the needle point penetrates the interarcuate ligament. Tail

movement may indicate that the needle has engaged nerve tissue. The epidural space is best identified by the *loss-of-resistance test*, using either an air-filled or a saline-filled syringe. Deliberate injection of 3 to 4 mL of air into the epidural space of dogs weighing 20 to 27 kg results in bubble formation that can persist for 24 h. The bubbles, however, are not large or numerous enough to impede transfer of local anesthetic across the meninges and into the CSF, spinal roots, and cord, nor do they localize in any particular region (e.g., nerve roots); thus, subsequent injection of local anesthetic does not result in patchy anesthesia or inadequacies attributable to bubbles.⁹⁹ Subcutaneous crepitation may be felt at the site of skin penetration if air has been injected outside the epidural space.

After the needle has been placed, the stylet is removed from the needle hub and the stylet is carefully examined for CSF or blood smears. Also, the needle (or catheter) should be carefully inspected for flow of CSF or blood before the local anesthetic is administered. If inadvertent subarachnoid puncture occurs, as indicated by the presence of CSF, the procedure may either be abandoned or the intended epidural dose reduced by at least 50%. The presence of blood indicates penetration of the ventral venous plexus, after which the needle should be repositioned epidurally. Obtaining CSF at the L7 to S1 site is not uncommon, even though the subarachnoid space of dogs usually ends cranial to the lumbosacral interspace. The spinal cord and meninges in younger and smaller dogs may occasionally extend into the lumbosacral vertebral junction.¹⁰⁰ A subarachnoid injection may be made if CSF is encountered, with the precaution that 1 mL of local anesthetic per 10 kg of body weight is then injected over a 1-min period.^{90,93} The reduced dose should avoid *total spinal anesthesia* with cardiovascular and respiratory depression or collapse. If blood is encountered, the needle is withdrawn and cleansed, and another attempt is made to place it into the epidural space. Intravascular injection of local anesthetic can cause systemic toxicity, which is characterized by convulsions, cardiopulmonary depression, and the absence of regional anesthesia^{70,71,101} Inadvertent subarachnoid administration of small amounts (2 mL) of fresh autologous blood aspirated from the venous plexus during attempted lumbar epidural puncture in dogs may cause pelvic limb spasm. If this occurs, most dogs recover rapidly and demonstrate no signs of meningeal irritation, long-term neurological sequelae, or neuropathological changes.¹⁰² To avoid excessive cranial advancement of neural blockade, it is also good practice to elevate the dog's head for approximately 5 min immediately after completion of the epidural administration of the anesthetic.

The shape and bevel orientation of the spinal needle affect the size of the dural defect. Large dural defects in humans may result in post-lumbar puncture headache attributable to a postulated increased CSF leak. The dural defect produced by a 22-gauge needle is smaller than that produced by a 22-gauge Quincke needle (27,400 vs. 39,400 μm^2). Likewise, a bevel orientation parallel rather perpendicular to the dural fibers causes smaller dural defects (39,400 vs. 73,300 μm^2), because the needle splits rather than cuts the longitudinal dural fibers.¹⁰³ It is also important to administer the calculated dose of local anesthetic at the body

temperature of the dog and slow enough (over 45 to 60 s) to avoid causing pain.

Local Anesthetic Drugs

A variety of local anesthetics of different concentrations and doses, and combinations of different local anesthetic drugs, have been used to produce epidural anesthesia in dogs and have induced a wide spectrum of sensory and motor blockades.^{81,89,93,96,97,104–109} The selected local anesthetic and dosage (concentration and volume) depends on a dog's size, the desired extent of anesthesia, and the desired onset and duration of anesthetic effect. A test dose of 0.5 to 1.0 mL of 2% lidocaine hydrochloride solution produces almost immediate dilation of the external anal sphincter, followed by relaxation of the tail and ataxia of pelvic limbs, within 3 to 5 min. Approximately 1 mL of 2% lidocaine per 4.5 kg of body weight will completely anesthetize the pelvic limbs and posterior abdomen caudal to the first lumbar (L1) vertebra within 10 to 15 min after administration.⁸¹ The flexor-pinch reflex of pelvic limbs will be absent in 5 to 10 min after injection.⁷⁷ Clinical experience indicates that the disappearance of the toe reflexes is associated with surgical anesthesia from midthorax to coccyx sufficient for abdominal surgery.⁷⁸ The latent period is prolonged to 20 to 30 min if 0.75% bupivacaine hydrochloride is administered and is attributable to the drug's low solubility and slow uptake by nervous tissue.⁹³ Good anesthesia for abdominal and orthopedic surgeries caudal to the diaphragm is generally achieved by administering 1 mL/5 kg (maximum, 20 mL) of 2% lidocaine or 0.5% bupivacaine, both with freshly added 1:200,000 epinephrine.

A reduced volume of 2% lidocaine (1 mL/6 kg) is generally satisfactory for epidural anesthesia in dogs for cesarean section. The reason for the (approximately 25%) decrease in dose requirement during pregnancy is unclear.¹¹⁰ Several theories have been proposed: (a) distension of epidural veins, which decreases the size of the epidural space, and/or increase in the spread of local anesthetic;¹¹¹ (b) hormonal changes, which influence proteins that affect membrane sensitivity;¹¹² and (c) chronic exposure to progesterone, which alters the permeability of intercellular connective-tissue matrix, thereby facilitating diffusion of local anesthetics across the nerve sheath.¹¹³ It is rarely necessary to inject more than 3 mg of lidocaine/kg of body weight for epidural anesthesia during cesarean section in dogs.

The anesthesia duration obtained from the deposition of epidural local anesthetic drugs primarily depends on the drug selected, the dermatomal level of anesthesia, and the presence or absence of epinephrine (Table 20.2). Postoperative analgesia (after general anesthesia) lasts longer when epidural anesthesia is performed at the end of surgery, and is attributable to a diminished intensity of the painful stimulus. Two percent solutions of procaine, lidocaine, and carbocaine have provided satisfactory anesthesia and muscle relaxation for 60 to 120 min. Epidural bupivacaine (0.75%) and etidocaine (1%) have induced surgical anesthesia for periods lasting from 4 to 6 h. Surgical anesthesia caudal to the last rib is produced and gradually converted into a phase of postoperative analgesia lasting for 24 h without affecting motor activity or cardiopulmonary function, if a combination of 0.7 to 1.0 mL/10-cm vertex-coccyx distance of 0.5% bupiva-

Table 20.2. Commonly used local anesthetic drugs and doses for peripheral and epidural block procedures in conscious dogs.

Local Anesthetic		Usual Doses (mg/kg)			Toxic Doses, IV (mg/kg)			Approximate Onset of Motor and Sensory Block (min)	Approximate Duration of Motor and Sensory Block (h)	Motor Block

caine hydrochloride solution and 0.1 mg/kg of morphine hydrochloride is injected epidurally.¹¹⁴

The efficacy of bupivacaine and ropivacaine for producing lumbar epidural and subarachnoid anesthesia in dogs has been compared.¹⁰⁴ Various concentrations of ropivacaine (0.25%, 0.5%, 0.75%, and 1.0%) and bupivacaine (0.25%, 0.5%, and 0.75%) with a constant 3-mL epidural volume and 1-mL subarachnoid volume of ropivacaine and bupivacaine were assessed. Epidural blockade was also performed using solutions of ropivacaine and bupivacaine that contained epinephrine (1:200,000). There were no signs of adverse reactions, irreversible block, or other sequelae in any of the dogs studied. Onset of motor blockade (time from the completion of the injection until a dog's pelvic limbs cannot support weight) ranged from 1.7 to 4.1 min following subarachnoid injection. There were no differences in the onset of motor blockade between various anesthetic solutions. Duration of motor blockade (time from onset of motor blockade until the dog could support its own weight) ranged from 103 min (0.75% ropivacaine) to 163 min (0.75% bupivacaine). Solutions of 0.25% ropivacaine and 0.25% bupivacaine failed to induce complete loss of weight support following epidural injection. Onset of motor blockade varied between 5 and 9 min with the use of higher concentrations (>0.25%) and was inversely related to dose. Duration of motor blockade ranged from 141 min (0.5% ropivacaine) to 258 min (0.75% bupivacaine). The similar onset times for both drugs were related to their similar *pKa* (ropivacaine, 8.0; and bupivacaine, 8.1). The decreased motor-blocking potency of ropivacaine is consistent with its low lipid solubility. Epinephrine failed to prolong the duration of motor blockade for either drug. Little difference in vascular activity may exist between ropivacaine and bupivacaine when injected into the epidural space of dogs.¹⁰⁴

A direct comparison between the effect of epidural bupivacaine and ropivacaine, using 0.5% and 0.75% solutions and 0.14- and 0.22-mL/kg volumes, on analgesia at the perineum (S3 dermatome), right and left hind-toe web (L5 to L7 dermatomes), flank (L2 to L5 dermatomes), and caudodorsal rib areas (T12 to L1 dermatomes), and associated cardiopulmonary effects (heart rate, systemic arterial blood pressure, pH, PaCO₂, PaO₂ bicarbonate, and base excess) in six dogs sedated with acepromazine (0.075 mg/kg IM) has been reported.¹⁰⁹ Sterile local anesthetic drugs were slowly administered (rate, 3 mL/min) into the epidural space at the lumbosacral junction via implantable vascular access ports.¹¹⁵ The results of this study indicate that 0.22 mL/kg of 0.5% bupivacaine and ropivacaine produce greater anesthesia success at dermatomes L5 to L7 than does 0.5% at 0.14 mL/kg (>80% vs. <70% success), a similar extent of anesthesia, and mild cardiopulmonary changes. Varying the bupivacaine concentration did not affect the duration of perineal analgesia. Perineal analgesia with 0.5% and 0.75% ropivacaine has been reported to be slightly shorter than that achieved with 0.5% and 0.75% bupivacaine (115 to 140 vs. 137 to 145 min).¹⁰⁹

Lidocaine and Bupivacaine Combination

The effects of epidural administration of lidocaine (2%, 5 mg/kg with epinephrine 1:200,000), bupivacaine (0.5%, 1.25 mg/kg

with epinephrine 1:200,000), and lidocaine (2%, 2.5 mg/kg with epinephrine 1:200,000) combined with bupivacaine (0.5%, 0.61 mg/kg with epinephrine 1:200,000) on the time of interdigital reflex loss, duration of analgesia and muscle relaxation, and cardiorespiratory effects in six dogs, weighing 5 to 10 kg, have been compared.⁹⁷ The combination of epidural bupivacaine with lidocaine achieves a shorter time to sphincter relaxation than does bupivacaine alone (23 ± 2 vs. 84 ± 23 s), longer analgesia than lidocaine alone (94 ± 8 vs. 54 ± 5 min), and longer muscle relaxation than either lidocaine (102 ± 8 vs. 59 ± 6 min) or bupivacaine (102 ± 8 vs. 57 ± 20 min). The combination of epidural lidocaine and bupivacaine produces minimal changes in arterial oxygen saturation, end-tidal carbon dioxide, respiratory and heart rates, and mean arterial blood pressure, and appears to be the best choice for maintaining anesthesia when surgical time is prolonged.⁹⁷

Pharmacokinetics and Pharmacodynamic Properties

Local anesthetics injected epidurally may enter the CSF,^{74,116} epidural venous blood, or lymph⁸⁰ and become partitioned in epidural fat. Epidurally administered drugs are dispersed by entering the lymphatic system by diffusion into the dural lymphatic vessels located at the level of the nerve roots, by leakage of local anesthetic drug out of the vertebral canal through the intervertebral foramina, and by vascular absorption and systemic redistribution.¹¹⁷

The pharmacokinetics of bupivacaine and ropivacaine after lumbar epidural administrations of either drug (0.75% solution, 3-mL volume with or without 1:200,000 epinephrine) in dogs have been determined.⁷⁰ Both drugs have a similar pharmacokinetic profile. Peak arterial concentrations of bupivacaine and ropivacaine occur within 5 to 10 min after injection and were less than 1 µg/mL. The addition of epinephrine did not consistently decrease the clearance (*C*_{max}) of either agent.

The disposition and pharmacological effects of bupivacaine¹¹⁸ and, most recently, those of the S(−) isomer of bupivacaine¹¹⁹ after intravenous and epidural administration in dogs have been reported. Bupivacaine (1.0 mg/kg IV) resulted in a mean ± standard deviation half-life of 34.5 ± 7.8 min, a mean plasma clearance of 20.2 ± 7.4 mL/kg/min, and a mean volume of distribution at a steady state of 0.7 ± 0.2 L/kg. After epidural administration of 0.5% bupivacaine (1.8 mg/kg), the peak plasma concentration was 1.4 ± 0.4 µg/mL approximately 5 min after administration. Onset and duration of anesthesia were 2.3 ± 2.2 min and 158 ± 49 min, respectively. The mean bupivacaine plasma concentration ranged between 0.2 and 1.4 µg/mL, and the half-life was 179 ± 34 min.¹¹⁸ After intravenous administration of a 1-mg/kg dose of the S(−) isomer of bupivacaine (0.5%), the mean ± standard deviation half-life was 33.5 ± 17 min, the mean plasma clearance was 21 ± 11 mL/kg/min, and the mean volume of distribution at steady state was 0.8 ± 0.2 L/kg. Mean peak plasma concentration was 2.6 ± 0.7 µg/mL. Following epidural administration of the same dose peak plasma concentration decreased to 0.9 ± 0.5 µg/mL. Motor block began immediately after completion of epidural injection and lasted for 3 to 4 h.¹¹⁹

It has been shown that epidural anesthesia that extends as far

cranially as the anterior thoracic dermatomes (T3 to T5) does not adversely change cardiovascular function, respiratory rate, arterial blood pH, and gas tensions (PaO₂ and PaCO₂) in conscious dogs or those sedated with methadone (0.8 mg/kg), acepromazine (0.3 mg/kg), or atropine (0.6 to 1.2 mg).⁸⁹ In awake healthy dogs, it is thought that compensation for markedly attenuated spinal sympathetic outflow during thoracic epidural anesthesia is accomplished by increasing endogenous vasopressin concentrations to support arterial blood pressure.^{120,121} Severe hypotension (with mean arterial blood pressure < 60 mm Hg) can occur in aged and sick dogs with suppressed neurally mediated renin release or when endogenous vasopressin is prevented from acting on its vasopressin receptors.^{79,121} Hypotension should be treated with intravenous crystalloid solutions (20 to 30 mL/kg) and/or a vasopressor (e.g., phenylephrine or ephedrine).¹²² Hepatic and renal blood flow generally remains stable in dogs undergoing epidural anesthesia until the T1 to L3 spinal cord segments begin to be blocked. Arterial blood pressure can decrease to less than 30% to 40% of the preepidural anesthesia value with a high epidural block. Ephedrine (2.5 µg/kg/min) has been used successfully to rescue hypotensive dogs and return blood-flow values during high epidural anesthesia.¹²³

High epidural anesthesia to the T1 myotomal level has been associated with increased intrathoracic volume at end expiration via an increase in intrathoracic tissue volume and the amount of gas in the lungs at end expiration (functional residual capacity).¹²⁴ It has been postulated that the increases in thoracic tissue volume are attributable to increases in intrathoracic blood volume. Thoracic epidural block before the production of experimental hemorrhagic shock has been advocated as potentially therapeutic.⁹⁵ Endocardial blood flow improves, and determinants of myocardial oxygen consumption decrease.¹²⁵

Rectal temperature usually remains unchanged during epidural anesthesia in dogs. If hypothermia occurs after epidural injections, the cause might be redistribution of heat within the body.¹²⁶ In humans, fluctuation in skin temperature of the limbs (but not the trunk) and an absence of sweating (dogs have no sweat glands except in the paws)¹²⁷ may reflect changes in sympathetic activity after epidural nerve blockade.^{94,128} Increased skin temperature in the pelvic limbs (1.2°C) and paws (2.0°C), coupled with decreased skin temperature in the thoracic limbs and thorax (−0.6°C), after bupivacaine lumbar epidural administration has been observed in conscious dogs.

Epidural anesthesia likely suppresses the markers of stress as represented by serum levels of adrenocorticotropic hormone, beta-endorphin, epinephrine, and norepinephrine.^{120,129} In addition, epidural anesthesia may inhibit host-defense mechanisms against various microorganisms less than does general anesthesia.¹³⁰

Adverse Effects

Adverse effects associated with epidural and subarachnoid anesthesia in dogs include (a) hypoventilation secondary to respiratory muscle paralysis, which is attributable to the spread of local anesthetic to the cervical spinal segments; (b) hypotension, Horner's syndrome (Fig. 20.18), and hypoglycemia caused by

Fig. 20.18. Unilateral Horner's syndrome (i.e., ptosis, miosis, and enophthalmus) in a golden retriever (35 kg) with ipsilateral paresis of the left thoracic limb, after overdose (12 mL of 2% lidocaine) via lumbosacral epidural anesthesia.

sympathetic blockade; (c) Shiff-Sherrington-like reflexes; and (d) muscular twitches, coma, convulsion, and circulatory depression caused by toxic plasma concentrations of local anesthetic. Improper injection technique can cause delay in onset of anesthesia, unilateral hind-limb paresis, partial anesthesia of the tail or the perineal region, and sepsis.^{131,132}

Although epidural anesthesia has been referred to as the ideal anesthetic procedure for bitches in dystocia,^{77,133,134} respiratory depression can be a serious complication. Changes from a thoracic to a diaphragmatic (abdominal) pattern of breathing indicate at least partial motor block of the intercostal musculature, which may not be reflected by changes in arterial pH, PaO₂, or PaCO₂. The use of preblock oxygenation, proper doses of local anesthetic, and slight elevation of the head, neck, and thorax minimize this problem. The presence of paresis of the nictitating membrane of the eye (Fig. 20.18), which derives its sympathetic nerve supply from the first three thoracic spinal segments, is evidence that most, if not all, of the sympathetic outflow has been blocked by extensive epidural spread.

Fig. 20.19. Epidural trays for continuous epidural anesthesia. The basic sterile and single-use regional anesthesia delivery system contains (1) Tuohy needle (1.3 × 87 mm, 18 gauge × 31/2 inches), plastic hub, and detachable wing; (2) radiopaque (polytetrafluoroethylene) catheter with open end and stylet (0.9 × 1000 mm, 20 gauge × 36 inches); (3) catheter stylet; (4) catheter connector with luer plug; (5) 5-mL glass syringe; (6) epidural filter; (7) swabs; (8) iodine packet; and (9) 5 mL of lidocaine hydrochloride 1%, 1-mL epinephrine injection 1:200,000, and 10-mL sodium chloride injection 0.9%.

Anecdotal reports about delayed hair regrowth after epidural analgesia in dogs, though controversial, have been difficult to confirm. In one study, hair regrowth was complete after 4 months, and there was no difference in hair length among groups, indicating that neither epidural analgesia nor scrubbing or clipping seemed to affect hair regrowth in at least the limited number of dogs in this study.¹³⁵ In a more recent retrospective study, 8 of 72 dogs were reported to have delayed hair growth after epidural administration of morphine with or without bupivacaine.¹³⁶

Complications with epidural anesthetic techniques can be prevented in most instances by following several basic rules, which include careful selection of drugs and dosage, aspiration before injection (to assure that the tip of the needle is not in a blood vessel or subarachnoid space), and injection of test doses.⁹⁶

Absolute contraindications for epidural anesthetic techniques include infection at the lumbosacral puncture site, uncorrected hypovolemia, bleeding disorders, therapeutic or physiological anticoagulation, degenerative central or peripheral axonal diseases, and anatomical abnormalities that would make epidural anesthesia difficult. Bacteremia, neurological disorders, and minidose heparin therapy are relative contraindications. The benefits of epidural anesthesia often outweigh the risks.¹³⁷

Continuous Epidural Anesthesia

The indications, advantages, contraindications, and complications associated with continuous epidural anesthesia in dogs are similar to those of the single-injection method. Additional advantages of continuous epidural anesthesia are the ability to tailor the anesthesia duration to the length of operation and to maintain a route for injecting epidural opioids during surgery and postoperatively.^{86,114,138}

Despite numerous reports describing continuous epidural anesthesia in dogs, epidural catheters are not used routinely because of technical difficulties; the potential to damage the spinal

cord, meninges, and nerves; the risk of infection; and catheter-related problems. Nevertheless, insertion of plastic catheters into the epidural space of dogs is relatively simple and safe, once practiced. Local anesthetics and/or opioids may be administered to produce continuous epidural anesthesia by placing a commercially available epidural catheter through an 18- or 17-gauge Huber-point (Tuohy) needle or 18-gauge Crawford needle into the epidural space (Fig. 20.19). Self-prepared sterile 20-gauge catheters (e.g., polyethylene tubing PE 160) may also be used.

A comprehensive selection of epidural products and accessories exists for use in people and can be adapted for dogs, thus making the technique in dogs easier and safer. Epidural trays contain an 8.7-cm, 18-gauge Tuohy needle and a 20-gauge catheter set with a radiopaque Teflon (polytetrafluoroethylene) catheter that resists kinking, with either an open rounded-tip or a closed-tip atraumatic catheter with lateral flow side ports, a thread-assist guidewire that eliminates the need for a stylet, a catheter connector that attaches quickly and securely without possibility of crushing the catheter, a luer-slip glass syringe, and a variety of syringes, needles, sterile preparation solutions, and sponges (Fig. 20.19). The theoretical advantages of the multiple side-port epidural catheter include even distribution of local anesthetic, less chance of clotting (because fibrin is less likely to collect on the side), and the ability to have a completely rounded and therefore atraumatic tip. Catheters should be placed, following strict aseptic technique, by using mask, gown, drapes, and prophylactic antibiotics. A skin preparation, using dry gauze dressings with or without antibiotic ointment (povidone iodine, Neosporin ointment [bacitracin, neomycin, and polymyxin B], or Bactroban ointment [mupirocin]), is very effective in preventing infection. A sterile 4 × 4-inch gauze or OpSite IV 3000 brand of dressing, which collects only minimal fluid underneath it, is tightly adhered to the skin and should be replaced daily or more often as needed to keep the wound dry. Plastic occlusive dressings are not ideal because they collect bacteria of normal skin

Fig. 20.20. A greyhound (30 kg) with a pathological fracture of the left distal tibia and middiaphysis fibula. **A:** A sterile fenestrated drape is placed over the surgically prepared lumbosacral area of the dog in sternal recumbency, with its hind legs extended cranially. A sterile wire-enforced epidural catheter is inserted into the Tuohy needle aseptically placed into the lumbar epidural space at the lumbosacral junction. **B:** The epidural catheter is advanced to the level of the first lumbar vertebra, is connected to the screw connector and antibacterial injection filter, and is then sutured to the skin. **C:** Administration of preservative-free morphine (0.1 mg/kg) (Astramorph PF, 0.5 mg/mL, total dose = 3 mg = 6 mL) into the epidural catheter rendered the dog pain free and with intact motor function for at least 18 h after limb amputation. The *arrow* points to the epidural catheter filter.

and wound secretions in constant exposure to the catheter site. The use of postoperatively administered systemic antibiotics is debated and is usually reserved for patients with a compromised immune system (e.g., diabetics). A thorough surgical preparation, using soap, antiseptic, or Hibiclens scrub (chlorhexidine cleanser), dramatically reduces the concentration of bacteria on the skin.

The Tuohy needle is placed into the epidural space between the L7 and S1 intervertebral space, similar to the single-injection epidural block technique. Catheterization is facilitated by first desensitizing the lumbosacral space with a small amount (2 mL) of 2% lidocaine. The Tuohy needle is inserted at a 15° to 45° angle from the vertical position with the bevel directed cranially (Figs. 20.17 and 20.20) and is advanced until the epidural space has been entered. The three techniques previously discussed—hanging drop, loss of resistance to air, and loss of resistance to saline—may be more readily performed in dogs that are positioned in sternal rather than lateral recumbency. Because the techniques may not always be ultimate proof that the needle has been placed epidurally, aspiration of the plunger before injection

should verify whether a vein has been entered. At this point, catheters with a stylet are preferred. A slight resistance is usually encountered when the catheter passes through the tip of the Tuohy needle. Special markings on the catheter denote the distance the catheter has been advanced. The catheter is advanced at least two to three markings beyond the hub of the needle, which ensures that at least 2 to 3 cm of catheter has entered the epidural space. Flushing the needle with saline, rotating the needle, and advancing the catheter while slowly withdrawing the needle help to thread the catheter into the epidural space. If these maneuvers fail, the needle and catheter should be withdrawn together. No attempt should be made to withdraw the catheter back through the needle, because this may sever the catheter. If this does occur, most authorities believe that no attempt should be made to retrieve a severed catheter.¹⁰⁵ Wire-reinforced catheters have been inserted epidurally to the anterior lumbar (L4)¹³⁹ or thoracic (T1)¹¹⁶ vertebrae with minimal resistance and without coiling, turning on themselves, kinking, or knotting.

Tuohy needles have been epidurally placed at the second coccygeal (Co3 to Co2), third coccygeal (Co4 to Co3), or fourth coc-

cygeal (Co5 to Co4) intervertebral space of dogs. A wire-reinforced catheter can then be threaded epidurally for up to 15 cm to reach the thoracic vertebrae.¹¹⁷ Inserting a catheter for long distances increases the risk that the catheter tip may exit a paravertebral foramen. Fluoroscopy is recommended to facilitate catheter guidance.

A 20-cm-long intravenous catheter can be used to tunnel an epidural catheter subcutaneously if it is left in place for a prolonged period. Poor sterile technique when changing tubing and drugs is the most likely cause of catheters becoming infected. Such an infection is often heralded by radicular pain after bolus injections and decreasing analgesia, which generally precedes any sign of meningitis or systemic infection. The CSF (puncture site at C1-C2 to avoid going through an infected lumbar epidural space), epidural catheter (1-mL sterile 0.9% saline solution injected and withdrawn), and skin-insertion site should be cultured if an infection is suspected. After cultures have been obtained, the catheter is removed, and the patient is treated with systemic antibiotics.

Epidural Opioid Analgesia

Providing long-term analgesia while inducing minimal systemic effects is an important objective in medical care. Epidurally administered opiates (e.g., morphine) provide lengthy analgesia caudal to the umbilicus with very few systemic side effects.^{30,32,107,136,138–154} A single epidural injection of 5 mg of morphine before major intra-abdominal surgery consistently relieves intraoperative and postoperative pain in people for at least 3 days.¹⁵⁵

Preservative-free preparations of morphine (e.g., Duramorph PF [Elkins-Sinn, Cherry Hill, NJ] and Astramorph PF [Astra Pharmaceutical Products, Westborough, MA])^{156,157} have not been associated with spinal cord histopathological changes. In contrast, parenterally administered morphine, which contains various preservatives—such as sodium bisulfite, metabisulfite, chlorbutanol, edetate disodium, formaldehyde, or phenol—has neurotoxic effects when placed directly on the spinal cord.¹⁵⁸ Any remaining opioid from single-dose vials that contain no bacteriostatic agents should be discarded.¹⁴⁵ Contraindications to epidural opioid analgesia are primarily associated with the epidural catheterization technique itself.

The presence of a large number of opiate receptors in the substantia gelatinosa of the dorsal horn of the spinal cord suggests that the administration of small doses of opioids into the epidural space should produce effective analgesia.¹⁵⁹ The administration of epidural opioids offers the advantage of producing more profound and prolonged analgesia with significantly smaller doses and less sedation than the analgesia produced by comparable parenterally administered (intramuscular or intravenous) opioids. Epidural opioids relieve somatic and visceral pain by selectively blocking nociceptive impulses without interfering with sensory and motor function or depressing the sympathetic nervous system (selective spinal analgesia).^{159–165} Studies using subanalgesic doses of the μ -specific agonist (Tyr-D-Ala-Gly-NMe-Phe-Gly-ol [DAGO]) and the δ -specific agonist (D-Pen2-5-Enkephalin

[DPDPE]) in cats have demonstrated a supra-additive interaction that significantly suppresses noxious stimuli.¹⁶⁶

Morphine

The major advantages of selective nociceptive blockade by the use of epidural morphine are long-term pain relief without producing muscle paralysis or weakness, or significant hemodynamic effects. For example, a single dose of morphine (1 mg, diluted in 3 to 4 mL of physiological saline solution) administered via a catheter introduced into the epidural space between the lumbosacral vertebrae and advanced to the fourth and fifth lumbar vertebrae in dogs weighing 10 to 15 kg relieved pain caudal to the costal arch for up to 22 h without affecting heart rate, arterial blood pressure, pulmonary arterial pressure, cardiac output, systemic vascular resistance, PaO₂, mixed venous oxygen tension (PvO₂), PaCO₂, and arterial pH (pH_a).¹³⁹ Similarly, 0.1 mg of oxymorphone/kg in 3 mL 0.9% of sodium chloride solution administered epidurally in dogs via a catheter positioned between the lumbar L5 to L6 or L6 to L7 intervertebral space alleviated postthoracotomy pain for 10 h without affecting heart rate, respiratory rate, systolic and diastolic blood pressure, and PaO₂ and PaCO₂.¹⁶⁷

The effects of epidural and intravenous morphine on analgesic effectiveness, vital signs, and cortisol and catecholamine concentrations in dogs (18 to 26 kg) after experimental thoracotomy have been compared.¹⁶⁸ Dogs were administered either 0.15 mg/kg of preservative-free morphine epidurally in 5 to 6 mL of 0.9% sodium chloride via a catheter 8 to 10 cm cranial to the entrance of the epidural space 30 to 40 min before the end of surgery or 0.15 mg/kg of morphine IV 5 to 10 min before the end of surgery. The efficacy of the opioid was increased if given before onset of pain. Dogs with epidural morphine administration demonstrated lower subjective pain scores and lower serum cortisol concentrations, plasma adrenaline and noradrenaline concentrations, noninvasive systolic arterial blood pressure, heart rates, and respiratory rates than did dogs with intravenous morphine for the first 10 h postoperatively.¹⁶⁸ A single epidural injection of morphine has been shown to be effective for up to 24 h in preventing physiological responses to postthoracotomy pain, one of the most severe causes of stress in the early postoperative period. In contrast, dogs given morphine IV often require supplemental morphine within 4 to 5 h.¹⁴³

Epidural morphine (0.1 mg/kg diluted in 0.26 mL/kg of saline) decreases the minimum alveolar concentration of halothane and improves arterial blood pressure, cardiac index, stroke volume, left ventricular work, and pulmonary artery pressure in dogs.¹⁶⁹ The explanation for morphine's efficacy at such a low dose when given by the epidural route may be related to its low lipid solubility. Epidural administration of morphine (0.1 mg/kg) is typically one-tenth of the systemically administered dose, yet analgesia lasts significantly longer than that provided by other routes.

Postoperative evaluation of dogs undergoing major orthopedic surgery, using either a 100- μ g/h transdermal fentanyl patch applied 24 h before surgery or epidural morphine (0.1 mg/kg) after induction of anesthesia, demonstrated a lower pain score with epidural morphine at 6 h after surgery than with transdermal fen-

Table 20.3. Physiochemical properties and doses of opioids for epidural analgesia in dogs.

Opioid	Molecular Weight of Base	pK ^a (25°C)	Oil-water Partition Coefficient ^a	Dose (mg/kg)	Approximate Time for Pain Relief (min)	Approximate Duration of Analgesia (h)
Morphine sulfate	285	7.9	1.42	0.05–0.15	30–60	10–24
Meperidine hydrochloride	247	8.5	38.8	0.5–1.5	10–30	5–20
Methadone hydrochloride	309	9.3	116	0.05–0.15	15–20	5–15
Oxymorphone hydrochloride	301	—	—	0.05–0.15	20–40	10–22
Fentanyl citrate	336	8.4	813	0.001–0.01	15–20	3–5

^aOctanol–pH 7.4 buffer partition coefficient.

tanyl. However, when all periods (6, 18, 30, and 42 h) after surgery were combined, analgesia with transdermal fentanyl was equivalent to that achieved with epidural morphine.¹⁷⁰

Epidural administration of morphine sulfate (30 mg) in a multivesicular liposome (Depot Foam) formulation has also been evaluated.¹⁷¹ Epidural morphine (5 mg and 30 mg), but not liposomes without morphine, produced potent analgesia, as measured by latency of thermally evoked skin twitch. The analgesic index (area under the time effect curve) was significantly greater in dogs treated with encapsulated morphine (30 mg) than in those treated with morphine sulfate (3 mg). The epidurally administered encapsulated morphine formulation produced significantly lower morphine concentrations in lumbar CSF and greater residency time than did epidural morphine. This study indicates that the action of epidural morphine can be extended by delivering higher doses of morphine (30 mg) in an encapsulated, persistent-release form.

Pharmacokinetic and Pharmacodynamic Properties

The physiochemical properties of opioids, particularly their lipid solubility, molecular weight, pK^a, and receptor-binding affinity, are important in determining their pharmacokinetic and pharmacodynamic properties and the onset and duration of analgesia (Table 20.3). Relatively hydrophilic morphine (oil-water partition coefficient, 1:42) remains in the CSF for longer periods, allowing rostral spread and analgesia distant from the site of injection (nonsegmental distribution of analgesia). For example, the lumbosacral epidural administration of 0.1 mg of morphine/kg has been reported to produce adequate postthoracotomy analgesia in dogs.^{26,32,48,140,146}

Epidurally administered morphine is distributed by at least four different pathways: (a) transdural passage to the CSF and neural axis, (b) vascular uptake by epidural venous plexi and spinal radicular arteries, (c) lymphatic uptake, and (d) deposition into epidural fat.^{117,141,172,173} The distribution in CSF, blood, and lymph of lumbar epidurally administered morphine (molecular weight, 285; and pK_a, 7.9) into the lumbar area in dogs has been determined.¹¹⁷ The fraction of morphine crossing the dura after epidural injection of 2 mg into a 30-kg dog has been calculated to be 0.3%.¹¹⁷ Maximal morphine concentration in lumbar CSF ranged from 5 to 93 ng/mL and was reached 5 to 60 min after injection. Morphine clearance from the CSF was 106 min (mean

18) independent of the dose.¹¹⁷ In another study, the maximal concentration of a 0.1-mg/kg dose of morphine in cisternal CSF was 102.3 ± 28.0 ng/mL at 180 min after lumbar epidural administration.¹⁴¹ The maximal concentration of morphine in serum of the same dogs was 95.7 ± 27.0 ng/mL at 31.0 ± 15.2 min.¹⁴¹

This large variability in CSF and plasma concentrations is a striking finding that emphasizes the need for adjusting the dose of epidural morphine for each patient. Practically, this can be accomplished by using an epidural catheter while observing the degree of analgesia and the severity of side effects. Pharmacodynamic studies evaluating the degree of analgesia and CSF and plasma drug concentrations of epidurally administered morphine support a spinal mechanism of action. These studies also indicate that rapid but short-lasting serum concentrations and delayed long-lasting CSF concentrations are often achieved with epidurally administered doses of morphine in dogs.

Oxymorphone

Oxymorphone, in comparison to morphine, is a relatively lipid-soluble opioid that binds more rapidly to opiate receptors in the spinal cord and has a smaller area of distribution in the CSF (segmental analgesia) (Table 20.3).

The analgesic and cardiorespiratory effects of epidurally administered bupivacaine (0.5%, 1.0 mg/kg), oxymorphone (0.1 mg/kg) in 0.75% bupivacaine (1 mg/kg), and intravenous oxymorphone (0.05 mg/kg) on halothane requirements have been evaluated.¹⁵⁰ There were no differences in end-tidal halothane requirements for dogs among the three groups. Respiratory depression was increased and heart rate was decreased with epidural oxymorphone-bupivacaine and intravenous oxymorphone treatments. Postoperative requirements of oxymorphone (0.05 mg/kg IV) were significantly less in dogs receiving the epidural oxymorphone-bupivacaine combination.¹⁵⁰

The postoperative analgesic and cardiopulmonary effects of oxymorphone administered epidurally (0.05 mg/kg) and intramuscularly (0.15 mg/kg) or medetomidine administered epidurally (0.015 mg/kg) have also been evaluated in dogs undergoing pelvic or hind-limb orthopedic surgery.^{174,175} The average duration of analgesia obtained with both epidural oxymorphone and medetomidine was 7 h, whereas intramuscular oxymorphone provided approximately 5 h of analgesia. All treatments decreased heart rate. There was no difference in arterial blood pres-

sure with epidural and intramuscular oxymorphone, but pressure was increased with epidural medetomidine.

Butorphanol

Epidural butorphanol (0.25 mg/kg) administration in dogs reportedly reduces the inhalant anesthetic requirement (decreased isoflurane minimum alveolar concentration by 32%) without any cardiovascular and neurological side effects.¹⁷⁶ However, the rather brief analgesic action (80 min), as assessed by dogs not responding to toe-pinch stimulation of the hind limbs and forelimbs, limits the value of epidural butorphanol administration in clinical practice. Pharmacokinetic data from epidural butorphanol (0.25 mg/kg) administration in halothane-anesthetized dogs indicated that the maximum concentration of butorphanol and time to reach this concentration are 42.3 ng/mL at 13.9 min in blood and 18 ng/mL at 30 min in CSF. The authors concluded that the pharmacokinetic data suggest that analgesia is predominantly due to butorphanol's action on supraspinal structures following its vascular systemic absorption.¹⁷⁷

Buprenorphine

The efficacy of epidural buprenorphine (4 µg/kg) versus epidural morphine (0.1 mg/kg) administered in a total volume of 0.2 mL/kg for postoperative pain relief in dogs undergoing cranial cruciate ligament rupture repair has been compared.¹⁵⁴ Epidural buprenorphine appeared to be as effective as epidural morphine for relief of postoperative hind-limb orthopedic pain in healthy dogs and may offer some advantages over morphine, such as lower abuse potential and reduced cost.¹⁵⁴

Side Effects of Epidural Opioids

Potential side effects in patients include respiratory depression, dysphoria, urinary retention, delayed gastrointestinal motility, vomiting, rubbing of the face, and catheter-related problems such as catheter displacement, occlusion, and infection from chronic epidural catheterization.^{145,158,178}

The analgesic efficacy, duration of action, and adverse side effects of epidurally administered morphine are dose related.¹⁷⁹ The most serious adverse effect is respiratory depression, which is biphasic. Respiratory depression has been attributed to the absorption of morphine into epidural veins and subsequent circulatory redistribution to the brain (early depression), and cephalad movement of morphine in CSF to the brain stem (late respiratory depression).¹⁸⁰ Lumbar epidural administration of excessive doses of morphine (20 mg of morphine sulfate in a 3-mL saline solution) in awake dogs (30 kg) increased PaCO₂ by 10 mm Hg at 1.5 to 2.0 h after administration, with no further ventilatory depression thereafter.¹⁶³ The maximal concentration of morphine in the CSF of these dogs was 64 ng/mL at 45 min after administration but gradually declined to 50% of maximum concentration at 6 h. The morphine concentration in arterial plasma was maximal at 30 min and declined to 20% of maximal by 6 h.

Administration of increasing concentrations (0.1 to 100.0 ng/mL) of morphine into the fourth ventricle or cisterna magna in awake dogs produced reduced tidal volume but not respiratory

rate, suggesting that larger doses (20 mg) of epidural morphine can produce respiratory depression in dogs. This effect is most likely caused by the delivery of morphine to the brain-stem respiratory centers via the blood rather than via the CSF.¹⁶³ The time course of ventilatory depression following subarachnoid administration of morphine in dogs corresponded poorly with morphine concentration changes in the CSF.¹⁶⁴ Severe respiratory depression should not occur in dogs when therapeutic doses (0.1 mg/kg) of morphine are administered epidurally.

Preemptively administered epidural morphine with or without bupivacaine given to 242 dogs has produced mild respiratory and cardiovascular depression during anesthesia, whereas urinary retention, pruritus, and vomiting were seen in only seven, two, and six dogs, respectively. Six dogs vomited when a second dose of morphine was given epidurally the day after surgery.¹³⁶ Side effects are more common when intrathecal injection is performed as opposed to epidural injection, and side effects can usually be reversed by a low-dose intravenous infusion of naloxone, with minimal effect on the analgesia produced.¹⁸¹

Myoclonus¹⁸²⁻¹⁸⁴ and neuroexcitation^{185,186} are very rarely observed complications in human patients after the epidural or intravenous administration of opioids. Similarly, involuntary muscle contractions in dogs, after either epidural or subarachnoid administration of preservative-free morphine, are extremely rare. Myoclonus and urinary retention have been reported in a 5-year-old German shepherd 90 min after subarachnoid injection of preservative-free morphine sulfate (0.15 mg/kg) diluted in 4 mL (0.1 mL/kg) of a sterile isotonic saline solution.¹⁸⁷ Muscle twitches started at the tail and then progressed to the hind limbs, trunk, and even partly the shoulders of the dog, which had just recovered from a 5-h oxymorphone-acepromazine-thiopental-isoflurane-oxygen anesthesia to complete a total hip-prosthesis surgery. The twitches became very strong with time and were not diminished by diazepam (0.2 to 1.0 mg/kg IV) or atracurium injected twice at 45-min intervals (0.2 and 0.1 mg/kg). The spasms were eventually controlled with pentobarbital administration (130 mg IV) and intermittent positive-pressure ventilation for 4 h.¹⁸⁸ The following day, the spasms were absent, but proprioceptive ataxia and hind-limb paresis, with urinary retention, persisted for another day. Bethanechol chloride (5 mg) was given by mouth every 8 h, and the bladder was emptied by catheterization once. The dog recovered over the next few days without further sequelae.¹⁸⁷

In another report, a dog exhibiting hyperesthesia and extreme neuritis of the pelvic area and tail lasting 24 h slowly resolved over a 4-day period.¹⁸⁹ Overall, the incidence of severe complications was reported to be 0.75% in 365 dogs and 4 cats that received epidural morphine for a wide variety of procedures, including fracture repair or arthrodesis, limb and tail amputation, total hip replacement, thoracotomy, laparotomy, and laminectomy.¹⁸⁹

Opioid-induced hyperalgesia, myoclonus, and seizures have been reproduced and studied extensively in rats.^{182,183,190,191} Direct opioid receptor-mediated and nonopioid receptor-mediated excitatory and inhibitory mechanisms, metabolites (normorphine, morphine-3 glucuronide, and hydromorphone-3 glucuronide), and preservatives (sodium bisulfite) have all been

implicated in these observed neurological side effects. Intrathecal naloxone has also been implicated in the potentiation of intrathecal morphine-induced hind-limb myoclonus and seizure activity in rats.¹⁸²

Nonopioid Epidural Analgesia

Drugs from other classes—such as α -adrenoceptor agonists, *N*-methyl-D-aspartate (NMDA) receptor antagonists (e.g., ketamine), and serotonergic, cholinergic, and γ -aminobutyric acid (GABA) receptor agonists¹⁹²—upon direct spinal administration in laboratory animals, have inhibited behaviors elicited by noxious stimuli.^{193,194} With the exception of epidurally administered α_2 -adrenoceptor agonists, such as xylazine,^{147,148,195–200} medetomidine,^{144,153,174,175,200,201} and NMDA receptor antagonist, such as ketamine,^{202–207} there is little information on the clinical efficacy of nonopioid spinal analgesic drugs in dogs.

α_2 -Adrenoceptor Agonists

Similar to morphine, the administration of α_2 -agonists can produce a powerful effect on nociceptive processing by activating a dense population of α_2 receptors (i.e., α_{2A} , α_{2B} , α_{2C} , and α_{2D}) (heteroceptors) in the CNS and periphery.^{208–210} In addition, some α_2 -agonists can also activate imidazoline receptors (I_1 and I_2) and produce direct effects on sensory transmission (e.g., xylazine). Spinally administered α_2 -agonists mediate analgesia by activating presynaptic α_2 -adrenoceptors, which are located on primary afferent C fibers terminating in the superficial laminae of the dorsal horn of the spinal cord.²¹¹ This activation induces G_0 proteins that decrease calcium influx, which results in a decreased release of neurotransmitters and/or neuropeptides (e.g., glutamate, substance P, neurotensin, calcitonin gene-related peptide, and vasoactive intestinal peptide), resulting in antinociception.^{212,213} Activation of the α_2 heteroceptors, which are located postsynaptically on wide-dynamic-range projection neurons targeted by primary afferent fibers in the dorsal horn, results in hyperpolarization of neurons via G_i protein-coupled potassium channels, producing postsynaptically mediated spinal analgesia.

Epidural Xylazine and Medetomidine

The effects of epidural xylazine on electroencephalogram (EEG) responses to surgical stimuli of varying intensity during experimental orthopedic procedures have been reported.^{197,198} After epidural xylazine administration (L7-S1), anesthesia was maintained with isoflurane (end-tidal concentration, 1.5%) in oxygen. The EEG and hemodynamic variables (heart rate and mean arterial blood pressure) were evaluated at prestimulation, skin incision, removal of a bone graft from the dorsoiliac spine, opening and reaming of the medullary canal of the tibia for bone graft installation, and wound closure. Skin incision and removal of bone graft produced a significantly higher increase in α/δ ratio in the EEG in the saline group when compared with the xylazine group. In addition, the prestimulation 80% spectral edge frequency of the EEG in the xylazine group was significantly lower than in the saline group. The results of this study suggest that epidural xylazine (0.25 mg/kg) suppresses responses in the α/δ ratio to sur-

gical stimulation and may exert its antinociceptive effect in dogs in part by a supraspinal action.¹⁹⁸

The most obvious physiological effects of activating spinal α_2 -adrenoceptors, other than their effect on altering nociceptive threshold, are bradycardia and hypotension.²⁰⁰ Medetomidine (15 μ g/kg) or xylazine (0.25 mg/kg) both produced similar cardiovascular and respiratory changes after lumbosacral epidural administration in dogs. Both drugs reduce heart rate, mean arterial blood pressure, and respiratory rate from baseline values. First-degree atrioventricular block was observed more often after xylazine administration (50% vs. 33%), whereas second-degree block was more frequently observed with the use of medetomidine (66% vs. 33%).²⁰⁰

Epidural medetomidine administration (0.015 mg/kg) reportedly produces analgesia lasting 7 to 8 h.^{174,175} The duration of analgesia is comparable to that achieved with epidurally administered oxymorphone (0.05 mg/kg) for similar procedures. However, all medetomidine-treated dogs developed a decrease in heart rate and a transient increase in arterial blood pressure. Dogs typically develop second-degree atrioventricular block associated with sinus arrhythmia for a brief period during the first 20 min after medetomidine epidural injection.

Epidural Dexmedetomidine

Dexmedetomidine is the pharmacologically active D-isomer of medetomidine, a highly lipid-soluble α_2 -receptor agonist²¹⁴ and, as such, is rapidly absorbed into the circulation and CNS. A dose-dependent effect of dexmedetomidine on antinociception and effects on respiratory function have been documented.²¹⁵ Different dose ranges of dexmedetomidine were used after each route of drug administration, with 4 to 6 days elapsing between the experiments. Dexmedetomidine by intrathecal (1, 3, or 10 μ g), epidural (3, 15, and 50 μ g), and intravenous (1, 3, and 10 μ g/kg) routes produced a rapid dose-dependent increase in the thermal ($60^\circ \pm 1^\circ\text{C}$ for a maximum of 10 s) skin-twitch response latency at lumbar and thoracic areas and paw withdrawal to mechanical compression of the toes of the front and hind limbs. The dose required to reach 50% of maximal effect for skin-twitch response after intrathecal, epidural, and intravenous administration of dexmedetomidine was 1.8, 10, and 15 μ g, respectively. The maximal effective dose produces approximately 90 min of hypoalgesia. The spinal effects do not appear to be associated with changes in behavioral alertness, motor function, or carbon dioxide response. Intravenous dexmedetomidine (1 to 10 μ g) also elevates the nociceptive threshold significantly, as measured by thermal or mechanical nociceptive end points. In contrast to the spinal administration, however, intravenous dexmedetomidine produces dose-dependent sedation, significantly reduces heart and respiratory rates, and diminishes response to increased carbon dioxide. The α_2 -adrenoceptor antagonist atipamezole (30 to 300 μ g/kg IV), but not the opioid antagonist naloxone (30 μ g/kg IV), antagonizes all of the observed effects of dexmedetomidine. These results suggest that spinally administered dexmedetomidine produces a powerful antinociceptive effect, mediated via α_2 -adrenoceptors at the spinal level, whereas systemic redistribution of the drug produces sedation with significant cardiovascular and respiratory side effects.²¹⁵

Ketamine

Ketamine has an analgesic action at many sites both centrally and peripherally. The mechanism of analgesic action of epidurally and intrathecally administered ketamine has not been clearly defined, and investigation into the contribution of supraspinal and/or spinal sites related to its analgesic and anesthetic action has not provided conclusive results. While reports regarding the efficacy of ketamine as a spinal analgesic are controversial, ketamine may block NMDA receptors and interact with subtypes of opioid, propionate, kainate, γ -aminobutyric acid A receptors,²¹⁶ and/or monoaminergic (serotonergic, noradrenergic, and dopaminergic) neural systems.²¹⁷ Ketamine also inhibits voltage-gated sodium-ion and potassium-ion channels, thereby suppressing myelinated nerve conduction.^{218,219} Ketamine may reverse opioid tolerance by interacting with NMDA receptors, the nitric oxide pathway, and μ opioid receptors.²²⁰ Evidence of the efficacy of ketamine for treatment of chronic pain in human patients has been reviewed and is considered moderate to weak.²²¹

The analgesic action of epidurally injected ketamine has been assessed in anesthetized dogs by using cutaneous electrical stimulus (10 V) to the ischial and masseter muscle region.^{204,205} The number of dogs responding to cutaneous electrical stimulation was significantly less following epidural ketamine-lidocaine administration than following epidural ketamine-saline administration. Similarly, the lumbosacral epidural injection of ketamine (20 mg/mL) at a dose of 2 mg/kg did not provide significant analgesia in dogs with chemically induced synovitis.²⁰⁷

The hemodynamic effects of ketamine when injected into the lumbosacral epidural space typically include increases in heart rate, mean arterial blood pressure, cardiac index, and stroke work index within 15 to 20 min.²⁰⁵ It is not yet conclusive that epidural ketamine consistently decreases the requirement of inhalation anesthetics. Nevertheless, epidural and intrathecal doses of 1 to 3 mg of ketamine/kg of body weight have shown analgesic efficacy in canine studies.^{202,203} Ketamine is rapidly distributed to the plasma and CSF (0.4 and 0.3 h, respectively) from the epidural space of dogs.²⁰²

Diazepam

Diazepam has been administered epidurally to dogs.¹⁹² With a 2-mg/kg dose, the tail, perineum, anus, sacral, lumbar, abdomen, and hind limbs are desensitized and the hind limbs paralyzed for variable periods (50 to 100 min). Pulse rate is significantly increased, whereas skin temperature, rectal temperature, respiratory rate, mean arterial blood pressure, and central venous pressure are not affected. Neurological damage or toxicity, and inflammatory infiltration in histological preparations of the spinal cord, are not evident.¹⁹² There has been little clinical use of benzodiazepines as analgesics when placed epidurally in dogs or other companion animals.

Ketorolac

Ketorolac (0.4 mg/kg) has been administered into the lumbar epidural space in dogs.^{222,223} Gross necropsy revealed gastrointestinal ulceration of varying degrees in dogs administered epidural ketorolac. Histopathological analysis of the spinal cord

and meninges revealed minimal focal leptomeningeal phlebitis in 25% of the dogs given this drug. Gastrointestinal ulceration induced by ketorolac is common and limits its use to a single injection. At present, both efficacy and safety need to be further evaluated before epidural administration of ketorolac or any other nonsteroidal anti-inflammatory drug can be recommended for clinical practice.^{222,223}

Glucocorticoids

Glucocorticoids (e.g., prednisone, prednisolone, and methylprednisolone) are most commonly administered by systemic routes, either oral or injectable, to relieve pain and reduce inflammation. Perineural injection, either to spinal nerve roots or to peripheral nerves, to alleviate pain caused by nerve root disease or peripheral neuropathies is common in human patients.²²⁴ The beneficial effects of epidurally administered betamethasone in a rat model of lumbar radiculopathy have been reported.²²⁵ However, a series of lumbar epidural steroid injections for chronic back pain has produced life-threatening *Staphylococcus aureus* meningitis and cauda equina syndrome in one person²²⁶ and transient blindness caused by retinal and vitreal hemorrhages from increased intracranial pressure in another person.²²⁷ As of this writing, recommendations or dosages for the use of epidural glucocorticoids in dogs and other small companion animals have not been developed.

Epidural Drug Combinations

Epidural opioids (e.g., morphine or oxymorphone) with local anesthetics (e.g., lidocaine, bupivacaine, or ropivacaine) or α_2 -adrenoceptor agonists (e.g., xylazine, medetomidine, or dexmedetomidine) have been administered to dogs before surgery to reduce general anesthetic requirements and provided intraoperative and postoperative pain control.

Local Anesthetics and Opioids

In rats, the combined intrathecal administration of morphine with lidocaine or bupivacaine reportedly produces antinociceptive effects that are more rapid in onset, last longer, and are greater in peak effect than when agents are administered alone at the same dose level.²²⁸ Subsequently, several investigators have reported additive or synergistic effects of epidurally administered opioids and local anesthetics in people,^{194,229–232} dogs,^{30,107,151} and rats.²²⁸ Although various local anesthetics and opioids have been administered epidurally in dogs, morphine, bupivacaine, and their combination effects have been the most critically evaluated.^{93,107,118,140,169,233} For example, the epidural administration of morphine-bupivacaine provided longer-lasting analgesia and required a lower number of supplemental doses of analgesic agent than did morphine or saline alone. The times for rescue-oxymorphone administration in dogs treated with either epidural morphine alone, bupivacaine alone, the morphine-bupivacaine combination, or saline were 5.4, 9.1, 24, and 2.6 h, respectively.¹⁰⁷ Likewise, the coadministration of epidural lidocaine and fentanyl (100 μ g in 0.3 mL of 0.9% sodium chloride with epinephrine 1:200,000) produces scrotal analgesia with faster onset

(1.3 ± 0.3 vs. 4.4 ± 0.4 min) and longer duration (143 ± 11 vs. 98 ± 8 min) than does lidocaine with epinephrine alone. The epidural coadministration of lidocaine and fentanyl consistently produces forelimb rigidity in dogs.²³⁴

α_2 -Adrenoceptor Agonists and Opioids

Synergistic antinociceptive interactions have been observed between a variety of α_2 -adrenoceptor and opioid receptor agonists.^{235–237} The epidural administration of α_2 -adrenoceptor agonists (xylazine or medetomidine) alone or in combination with morphine has gained some degree of use in veterinary practice during the last 5 years. A few studies documenting this synergy have been performed.

For example, dogs receiving low-dose epidural medetomidine ($5 \mu\text{g}/\text{kg}$) administration alone did not show evidence of analgesia, as evidenced by response to tail clamping. However, the addition of medetomidine to morphine prolonged the analgesia beyond that achieved with morphine alone (13.1 ± 3.1 vs. 6.3 ± 1.2 h), indicating a supra-additive effect with the administration of both drugs.²³⁸ In another study, postoperative analgesia was assessed in dogs given either preservative-free morphine ($0.1 \text{ mg}/\text{kg}$) or morphine ($0.1 \text{ mg}/\text{kg}$) with medetomidine ($5 \mu\text{g}/\text{kg}$) via lumbosacral epidural injection.¹⁵³ Based on numerical rating scale, pain scores, posture, vocalization, and facial expression, epidurally administered morphine combined with medetomidine was associated with superior analgesic benefits when compared with morphine alone.

Ketamine and Opioids

In a more recent study, epidural ketamine (40 to $320 \mu\text{g}$), morphine (0.6 to $160 \mu\text{g}$), or fentanyl (0.16 to $10 \mu\text{g}$), and a combination of $80 \mu\text{g}$ of ketamine with either morphine (2.5 to $80 \mu\text{g}$) or fentanyl (0.04 to $10 \mu\text{g}$) have all been assessed for analgesic properties.²³⁸ Epidural ketamine produced only limited antinociception, whereas morphine and fentanyl exhibited a dose-related antinociception. Morphine's action was slow in onset and lasted long, whereas fentanyl had a fast onset and briefer action. In combination, ketamine improved maximal possible effect as well as duration of action of morphine-induced, but not fentanyl-induced, antinociception. Moreover, increasing doses of the highly lipophilic ketamine tended to decrease the maximal response of various doses of the highly lipophilic fentanyl. Competition, at least in part, for the same μ receptor or μ receptor subtypes, via P glycoprotein, could have been one mechanism by which higher doses of ketamine decreased the antinociceptive properties of fentanyl. These data indicate that ketamine and perhaps other drugs may actually have antagonistic effects with various opioids when coadministered in the epidural space to induce an analgesic action.²³⁹

Ganglion Blocks

Anesthesia of the cervicothoracic ganglion and lumbar sympathetic chain in dogs has been described to treat paralysis of the radial, facial, and trigeminal nerves and muscle and joint diseases:^{240,241} 5 to 8 mL of 0.5% procaine hydrochloride solution has been administered in close proximity to the cervicothoracic

ganglion and lumbar sympathetic chain without ill effects.

Conclusion

Local and regional anesthetic techniques in dogs have been used extensively to relieve the pain related to a variety of medical and surgical procedures. Appropriately selected topical, local, or regional (e.g., epidural) techniques can provide safe, effective, and reliable analgesia with minimal physiological alterations. Similarly, the interpleural administration of local anesthetic drugs or the epidural administration of opioids can provide unparalleled long-term relief of pain while preserving consciousness. Novel systems for the delivery of analgesics and other therapeutic modalities designed to be used with local anesthetics, opioids, and nonopioid analgesics may greatly facilitate the future management of perioperative pain in companion animals.²⁴²

Chapter 21

Local and Regional Anesthetic and Analgesic Techniques: Cats

Roman T. Skarda and William J. Tranquilli

- Introduction
- Topical Anesthesia
- Infiltration Anesthesia
- Regional Anesthesia of the Head
 - Anesthesia of the Maxilla and Upper Teeth
 - Anesthesia of the Mandible and Lower Teeth
- Anesthesia of the Limbs
 - Blockade of the Radial, Ulnar, and Median Nerves
 - Blockade of the Common Peroneal and Tibial Nerves
- Brachial Plexus Block
- Intravenous Regional Anesthesia
- Intercostal Nerve Block
- Lumbosacral Epidural Anesthesia
- Epidural Opioid Analgesia
- Conclusion

Introduction

This chapter reviews the use of selective local and regional anesthetic and analgesic techniques in cats as an adjunct to light general anesthesia. The techniques are easily performed for diagnostic and surgical procedures to produce postoperative analgesia. A basic knowledge of the regional anatomy of the area to be desensitized and the pharmacology of drugs used to induce effective local anesthesia is required if the full potential of local anesthetic and analgesic techniques is to be realized.^{1,2} Commonly used techniques in cats are topical anesthesia, local infiltration, nerve blocks (e.g., selective blockade of distal branches of nerves about the head, forelimb, and hind limb), brachial plexus block, intravenous regional anesthesia, epidural anesthesia, and epidural analgesia. Because of restraint problems, local and regional anesthetic techniques are typically administered to heavily sedated or anesthetized cats. A number of local anesthetic drugs that vary in potency, toxicity, and cost are available for these purposes. Most commonly, 0.5% to 2.0% lidocaine hydrochloride is used to anesthetize cats for 60 to 120 min, whereas 0.2% to 0.5% ropivacaine hydrochloride or 0.25% to 0.5% bupivacaine hydrochloride produce anesthesia for 240 to 360 min. The applied pharmacology of local anesthetic drugs in animals has been described in Chapter 14. Advantages of using regional anesthetic/analgesic techniques include (a) reduction of the required dose of general anesthetic drugs and thus minimal cardiopulmonary depression, (b) complete blockade of sensory and motor nerve fibers, and (c) prevention of the secondary (central) sensitization to pain. Preemptive analgesia theoretically (a) decreases the severity of

pain during surgery, (b) reduces drug requirement for pain control, and (c) provides analgesia after surgery.³⁻⁶

Topical Anesthesia

Local anesthetics, either as lidocaine spray (10%, 100 mg/mL) or lidocaine hydrochloride solution, can be applied topically. One spray delivers 10 mg of lidocaine, which usually is sufficient to desensitize small areas of oral, nasal, and pharyngeal mucous membranes. Administration of 20 mg of lidocaine to the mucous membrane produces surface anesthesia up to 2 mm deep within 2 min, which lasts for about 15 min. Topical lidocaine (spray or instillation) is useful for minor diagnostic, therapeutic, and surgical procedures (e.g., endoscopy, placement of nasal catheters for tube feeding, foreign-body removal, biopsies, and repair of small mucosal wounds). Instillation of 1.0 mL of lidocaine (20 mg), ropivacaine (2 mg), or bupivacaine (2.5 mg) into the wound of skin incisions or lacerations provides good analgesia in cats (4 kg). These local anesthetics are ineffective when applied topically to intact skin. Sterile lidocaine jelly (2%, 20 mg/mL) provides good analgesia of the urethra during catheter placement, because lidocaine is absorbed across mucous membranes. The eutectic mixture of lidocaine and prilocaine (EMLA cream [lidocaine 2.5% and prilocaine 2.5%]) penetrates the stratum corneum of the skin. Cream is placed on the skin and covered with a clean dressing for at least 20 min to enable painless placement of arterial and venous catheters in nervous cats.⁷ Proparacaine 0.5%, tetracaine 0.5%, or butacaine 2% can be applied topically to desensitize the cornea for 10 to 20 min. Repeated doses have been reported to prolong anesthesia up to 2 h without causing harmful effects.⁸

Infiltration Anesthesia

Local infiltration is primarily used for repair of superficial lacerations, cutaneous biopsy, and removal of dermal or subcutaneous tumors. Lidocaine hydrochloride (2 to 5 mg/kg), ropivacaine, or bupivacaine hydrochloride (3 mg/kg) is injected in the form of a subcutaneous bleb, line block, inverted V-block or triangular or rectangular pattern around a small tumor to be surgically removed, using a 25-gauge (G) × 0.6-inch needle or 22-G × 1-inch needle.⁹ The dose of the local anesthetic should be carefully calculated to prevent toxicity. The syringe is aspirated before each injection and great care must be taken that the local

Fig. 21.1. Needle placement for nerve blocks of the head: (A) inferior alveolar (mandibular), (B) mental, and (C) infraorbital.

anesthetic is not inadvertently administered intravenously.^{10–12} Sterile saline solution can be used to decrease the concentration and increase the volume of lidocaine (2 mL of a 1% solution instead of 1 mL of a 2% solution) to allow infiltration of a larger lesion. The total dose (20 mg) should be reduced by 30% to 50% in sick cats.

Regional Anesthesia of the Head

Commonly used nerve blocks to manage pain during and after surgical and dental procedures are the infraorbital, inferior alveolar and mental nerves (Fig. 21.1).^{2,13,14} These nerves can be desensitized by injecting 0.1 to 0.3 mL of either 1.0% to 2.0% lidocaine, 0.2% to 0.5% ropivacaine, or 0.25% to 0.5% bupivacaine hydrochloride solutions, using a 30-G × 0.5-inch to 22-G × 1-inch needle.

Anesthesia of the Maxilla and Upper Teeth

The upper lip and muzzle, roof of the nasal cavity, soft and hard palates, and teeth in the upper dental arcade are supplied by sensory fibers of the infraorbital nerve. The nerve is blocked at the infraorbital foramen as it emerges from the infraorbital canal, ventral to the eye, approximately 1.0 cm dorsal to the third premolar at the junction of the maxilla and zygomatic arch. Improper identification of the infraorbital foramen and branching of a nerve proximal to the region of local anesthetic may cause failure to produce regional anesthesia.¹³ The block is facilitated by angling the needle tip slightly medially. The needle is then advanced approximately 0.5 cm into the infraorbital canal, which is not a true canal in cats (Fig. 21.1C).

Anesthesia of the Mandible and Lower Teeth

The lower dental arcade, including the molars, canines, and incisors, and the skin and mucosa of the chin and lower lip are sup-

plied by sensory fibers of the mandibular nerve. The nerve can be easily blocked at the point of its entry into the mandibular canal at the mandibular foramen. The needle is inserted percutaneously at the ventromedial aspect of the ramus of the mandible, approximately 1.0 cm rostral to the angular process, and for a depth of 0.5 cm (Fig. 21.1A). In an alternative technique, the inferior alveolar nerve can be blocked intraorally, under the buccal fold.

The inferior alveolar nerve branches into the free rostral, middle, and caudal mental nerves, which supply sensory fibers to the lower lip and the medial half of the canine and three incisors. The mental nerve can be blocked at the mental foramina, caudal and ventral to the lower canine (Fig. 21.1B). The extremely small size of the mental foramina precludes the insertion of a needle or catheter into the termination of the mandibular canal.¹³

Anesthesia of the Limbs

Blockade of the distal branches of the radial, median, and ulnar nerves, blockade of cervical and thoracic nerves (brachial plexus block), and intravenous regional anesthesia are cost- and time-effective techniques for providing perioperative anesthesia and managing pain after surgical procedures of the forelimb in cats. In the hind limb, selective blockade of the common peroneal and tibial nerves is easily produced. Injection of the local anesthetic or opioid into the epidural space at the lumbosacral junction provides analgesia of the pelvic limbs and perineum.

Blockade of the Radial, Ulnar, and Median Nerves

Selective blockade of the distal branches of the radial, ulnar, and median nerves produces brief surgical anesthesia and postoperative analgesia after onychectomy or tenectomy. The nerve blocks are easily performed to supplement anesthesia or provide an alternative to wound irrigation with local anesthetic following ony-

Fig. 21.2. A: Needle placement for nerve blocks on the foreleg: (a) dorsal branch of ulnar nerve, (b1) lateral branch and (b2) medial branch of superficial branch of radial nerve, (c) median nerve, and (d) palmar branch of the ulnar nerve.

chectomy.^{15–21} The superficial branches of the radial nerve are blocked on the dorsomedial aspect proximal to the carpal joint. The palmar and dorsal cutaneous branches of the ulnar nerve are blocked just proximal and lateral to the accessory carpal bone. The median nerve is blocked proximal to the median carpal pad. A 22-G \times 1-inch needle can be used, and approximately 0.3 mL of the anesthetic solution is administered subcutaneously at each site (Fig. 21.2A). In two alternative techniques, the local anesthetic (3 mg/kg body weight) is injected subcutaneously distal to the carpal joint to each of the dorsal and palmar proper digital nerves either as a four-point digital nerve block²² or ring block.²³

Blockade of the Common Peroneal and Tibial Nerves

Selective blockade of the distal branches of the common peroneal and tibial nerves produces perioperative and postoperative analgesia in the hind limb for onychectomy or tenectomy. The superficial branches of the common peroneal nerve are easily blocked by subcutaneous infiltration of the local anesthetic on

the dorsomedial aspect of the tarsus distal to the tarsal joint. The superficial branches of the tibial nerve are blocked by subcutaneous injection of the local anesthetic ventromedially and distally to the tarsal joint (Fig. 21.2B).

Brachial Plexus Block

Blockade of the ventral branches of the cervical (C6, C7, and C8) and thoracic (T1) spinal nerves can be used to anesthetize the forelimb and manage pain after surgical repair of the radius and ulna in cats.¹⁴ The procedure is performed in well-sedated or anesthetized cats. A needle (22 G \times 1 inch) is placed into the axillary space proximal to the shoulder, and approximately 0.5 mL of either 2% lidocaine (10 mg), 0.5% ropivacaine, or 0.5% bupivacaine (2.5 mg) is injected once the needle tip is cranial to the first rib and caudal to the cranial border of the scapula (Fig. 21.3). The same amount of the anesthetic is administered as the needle is withdrawn. The syringe is aspirated prior to each injection to avoid injection into the axillary artery and vein, which are close to the brachial plexus. The brachial plexus should not be

Fig. 21.3 (continued). **B:** Needle placement for nerve blocks on the hind leg: (a) superficial peroneal nerve, (b) deep peroneal nerve, (c) tibial nerve, (d) lateral plantar nerve, and (e) medial plantar nerve.

blocked bilaterally because of potential bilateral phrenic nerve blockade and subsequent compromised respiratory function.

Intravenous Regional Anesthesia

Intravenous regional anesthesia (IVRA) may be suitable for anesthetized cats undergoing surgery, including onychectomy, of the distal limbs. First, a 22-G \times 1-inch intravenous catheter is inserted into the cephalic vein proximal to the carpus and with the catheter tip pointing distally.²⁴ Second, an inflatable blood pressure cuff (neonatal no. 2; Criticon, Tampa, FL) is placed proximal to the cephalic catheter and is inflated and maintained at 100 mm Hg greater than systolic pressure. Third, a second tourniquet, 6.25-mm rubber tubing, is tied above the elbow and left in place for 20 min. Lidocaine (1%, 3 mg/kg) is then injected into the distal cephalic venous catheter to anesthetize the entire limb distal to the tourniquet, as determined by lack of response to toe pinch.

After the tourniquet has been removed, analgesia still remains for approximately 20 min. No neurotoxicity or adverse hemodynamic or respiratory effects have been reported in cats breathing either a low (1.5%) or high (2.3%) concentration of isoflurane during IVRA. No adverse effects were noted during recovery from anesthesia 20 min after tourniquet removal.²⁴ The plasma lidocaine concentrations may vary. The reported highest mean lidocaine concentration was 2.8 ± 1.0 $\mu\text{g}/\text{mL}$ after the injection of lidocaine (3 mg/kg) and was 3.1 ± 1.1 $\mu\text{g}/\text{mL}$ after a second injection of lidocaine (3 mg/kg) 20 min later.²⁴ The model described simulated a 20-min onychectomy procedure per each front leg of the cat. Significant leakage under the tourniquet may occur, as determined by measurable venous plasma lidocaine concentrations (maximum, 4.42 $\mu\text{g}/\text{mL}$) prior to tourniquet release. Placement of the tourniquet and thus occlusion of blood supply distal to the tourniquet should be limited to 30 min to prevent complications (e.g., lameness or endotoxemia) (Fig. 21.4).

Fig. 21.3. Needle placement for brachial plexus block. **Inset:** ventral branches of (a) sixth, (b) seventh, and (c) eighth cervical, and (d) first thoracic spinal nerve; (e) tuberosity of humerus; and (f) first rib.

Intercostal Nerve Block

This technique is used to control pain following lateral thoracotomy, rib fractures, or pleural drainage. Two adjacent intercostal nerves, cranial and caudal to the incision site or wound (four sites in total), are blocked (Fig. 21.5). A needle (27 G \times 1 inch) is inserted into the intercostal muscle close to the insertion of the epaxial muscles. The needle is directed dorsomedially and, using caution not to puncture the lung, its tip is walked off the caudal border of the rib. The syringe is aspirated before each injection of the anesthetic solution (3 mg/kg body weight), which is equally divided among the injection sites. Cats should be observed for development of pneumothorax during the first 30 min after the procedure. Cats with severe lung disease and those that rely on their intercostal muscles for maintaining ventilation and oxygen saturation must be monitored closely.¹⁴

Lumbosacral Epidural Anesthesia

Lumbosacral epidural anesthesia is safe and inexpensive and provides a reversible loss of sensation to a reasonably well-defined area of the body caudal to the diaphragm. This procedure is relatively easy to perform in heavily sedated or anesthetized cats.^{25–27} Epidural injection of a local anesthetic may be used alone in cats that are at high risk of medical complications, that are aged, or that require immediate surgery of the rear quarter. The skin of the lumbosacral area is surgically prepared with an aseptic technique. A needle (22 G \times 1 inch) is placed into the skin surface at the midline of the lumbosacral space. Except in

obese cats, this space can be easily palpated halfway between the dorsoiliac wings and just caudal to the dorsal spinous process of the seventh lumbar vertebra. The needle is pushed ventrocaudally at a 45° angle to the dorsum to avoid pinching the seventh lumbar spinous process (Fig. 21.6). Resistance is encountered on reaching the ligamentum flavum. A distinct pop is usually felt when the needle is advanced through this ligament. Needle depth to reach the epidural space may vary from 6 to 25 mm (0.25 to 1.0 inch), depending on the cat's size. Further insertion of the needle will meet resistance, indicating the needle tip has encountered the bony floor of the vertebral canal, and thus necessitates the withdrawal of needle for 1 to 2 mm. The hub of the needle is observed for blood and cerebrospinal fluid (CSF). Because the dura sack terminates in the sacral area of cats, CSF may escape from the needle. If CSF is observed or aspirated, either the epidural injection is abandoned or only one-third to one-half of the original calculated dose of the drug is administered. Observation of blood within the needle indicates that the ventral venous sinus has been punctured; therefore, the needle should be removed. Intravascular injection of epidural drugs should be avoided to prevent toxicity. Lidocaine 2%, ropivacaine 0.2%, or bupivacaine 0.25% at the dose of 1.0 mL/4 kg produces analgesia up to the umbilicus area.^{1,2,25} Analgesia usually lasts for at least 1 h with the use of lidocaine and 4 to 6 h with ropivacaine or bupivacaine injection. A regular local anesthetic dose (1.0 mL/4 kg) administered subarachnoidally (into the CSF) or a larger dose (>3 mL) administered epidurally produces a more cranial blockade that may be associated with decreased sympathetic activity and direct myocardial depression, and can cause

Fig. 21.4. Severe 18-h lameness of a cat, which had a rubber tourniquet in place above the right carpus during onychectomy for approximately 40 min.

hypotension, respiratory insufficiency, respiratory paralysis, and convulsions.

Epidural Opioid Analgesia

Preservative-free morphine (Astramorph/PF, 0.5 or 1.0 mg morphine/mL; or Duramorph, 0.5 or 1.0 mg morphine/mL) can be administered through a sterile needle or indwelling epidural catheter into the epidural space of cats to provide moderate to excellent intraoperative analgesia and postoperative pain control. An aseptic technique, as described for epidural injection of local anesthetic drugs, must be used. Placement of a vascular access device (access port model SLA-3.5H; Access Technologies, Division of Norfolk Medical Products, Skokie, IL) used as an indwelling epidural catheter in cats has been described (Fig. 21.6A).^{28–30} In contrast to the administration of a local anesthetic drug by the epidural route, epidural morphine provides more prolonged analgesia (>6 h) with no effect on motor and sympathetic pathways.³¹ The dose of morphine (0.1 mg/kg) must be calculated carefully and, to avoid inadvertent intravascular administration, the syringe should be aspirated before injection. A cat weighing 4 kg can be administered 0.4 mg morphine, which is 0.8 mL of Astramorph (0.5 mg/mL). If the needle tip has entered the intrathecal (subarachnoid) space, as recognized by free flow

of CSF from the needle hub or aspiration by the syringe,³² the dose is reduced by 50% to 0.2 mg of morphine (0.4 mL of Astramorph). Administration of 0.05, 1.0, and 2.0 mg of epidural morphine per kilogram of body weight decreased the minimum alveolar isoflurane concentration requirements in cats by $21.4\% \pm 9.7\%$, $30.8\% \pm 9.6\%$, and $30.2\% \pm 6.8\%$, respectively.³³ Increasing the dose of morphine was not found to be significant, probably because of a saturation of opioid receptors with increasing doses of morphine. These cats demonstrated a significant decrease in systolic, mean and diastolic blood pressure, heart and respiratory rates, and arterial pH, whereas the arterial carbon dioxide tension increased with epidural morphine administration.³³ Mild hind-limb ataxia, but no excitement, licking, retch-

ing, or vomiting, was observed up to 60 min into recovery. Such side effects can be observed in nonanesthetized cats receiving epidural administration of morphine. Analgesia generally develops first, lasts longer, and is more profound in somatic areas of spinal cord segments, which are presumably exposed to the highest concentration of morphine.³⁴ The depressant effects of epidural morphine on the hemodynamic and respiratory centers are likely the result of interaction with opioid receptors in the central nervous system (general analgesia) after diffusion to the brain via the blood and CSF.

Analgesia and behavioral effects of epidural oxymorphone (0.025, 0.05, and 0.1 mg/kg mixed in 0.13 mL saline/kg) and saline placebo have been evaluated in four cats.³⁵ A spinal nee-

dle (22 G × 1.5 inches) was inserted into the epidural space at the lumbosacral junction, and the doses were given randomly to each cat anesthetized with isoflurane at 7-day intervals. Isoflurane was discontinued, and scores for pain, behavior, and sedation were recorded along with indirect blood pressure and respiratory rate at 30 and 60 min and hourly thereafter to 480 min. A noncrushing clamp was briefly placed 5 cm from the tail base to produce nociception at each time interval. No significant changes were observed in blood pressure, respiratory rate, behavior, or sedation of healthy cats. Analgesic effects were present for 52 ± 22 min in nontreated cats but increased to 332 ± 111 min with the highest oxymorphone dose (0.1 mg/kg).

Lumbosacral epidural injection of fentanyl (4 µg/kg) diluted to a total volume of 1 mL with physiological saline reportedly increases the pain threshold of the hind limb for up to 245 min after injection. No visible side effects or behavioral changes were observed, nor was analgesia detected in the forelimbs of these cats.²⁹ Epidural fentanyl injection was associated with a decrease in heart and respiratory rates and mean arterial blood pressure.³⁰ Epidural fentanyl also increased arterial PCO₂ and decreased arterial pH from 15 to 120 min after injection.³⁰ In these same studies, medetomidine (10 µg/kg) in 1 mL of saline significantly increased the pain threshold up to 245 min (hind limb) and 120 min (forelimb), respectively. Epidural medetomidine was associated with mild sedation and emesis in 12 of the 15 cats studied.²⁹ The hemodynamic profile during isoflurane (2.4%) anesthesia was a biphasic blood pressure response: first a significant increase (5 to 20 min after injection) and then a significant decrease (30 to 120 min after injection). Arterial PCO₂ and blood bicarbonate concentration were significantly increased, while arterial pH was significantly decreased for up to 2 h after epidural medetomidine administration.³⁰

The *N*-methyl-D-aspartate (NMDA) receptor antagonistic action of ketamine may be useful in patients with chronic pathological pain states refractory to opioids, anticonvulsants, or antidepressants.³⁶ However, the safety of neuraxially administered ketamine remains unclear. No inflammatory reactions have been reported in animal studies when preservative-free ketamine has been used. Ketamine with benzethonium chloride preservative administered intrathecally has caused radicular demyelination in rats.³⁷ Subpial vacuolar myelopathy³⁸ and focal lymphocytic vasculitis have been observed adjacent to the catheter tip in humans, but no neurological deficit or other histological changes were evident.³⁹

Based on the observations to date, the epidural use of α₂-receptor agonists (xylazine and medetomidine), dissociative anesthetics (ketamine and tiletamine-zolazepam), and anti-inflammatory drugs (ketoprofen) cannot be advocated for routine epidural use in cats.⁴⁰

Conclusion

Local and regional anesthetic techniques can safely be used in heavily sedated or anesthetized cats. The local and regional anesthetic and analgesic techniques described are compatible with systemically administered opioids (e.g., morphine, butorphanol,

and fentanyl patch), α₂-receptor agonists (e.g., xylazine and medetomidine), dissociative anesthetics (e.g., ketamine and tiletamine-zolazepam), anti-inflammatory drugs (e.g., ketoprofen), and/or inhalation anesthetic drugs (e.g., halothane, isoflurane, and sevoflurane). These techniques are both practical and effective when applying a multimodal pain-management strategy in cats.

Introduction

Many diagnostic and surgical procedures are performed safely and humanely in horses by combining local anesthetic techniques with physical restraint and/or sedation. Sedation can be induced by drugs such as acepromazine, xylazine, or detomidine, either alone or in combination with morphine or butorphanol, among others, to facilitate handling of fractious horses.

The techniques in performing nerve and joint blocks vary considerably, depending on such factors as operative size; expected duration of surgery; size, temperament, and health of the patient; technical skill and personal preference of the veterinarian; and economics of time and material. Currently, the most common techniques used in horses are surface (topical) anesthesia, infiltration anesthesia, and a considerable number of peripheral nerve blocks (regional anesthesia). Peripheral nerve blocks, intra-articular and intrabursal injections, and local infiltrations (ring block) are commonly used to aid diagnosis of equine lameness and as a means of providing analgesia to a surgery site. Peripheral nerve blocks, which are performed at the end of an operation under general anesthesia, are helpful to control emergence excitement caused by pain in the recovery period. More complex infiltration techniques (e.g., cervicothoracic ganglion block or sympathetic ganglion block) are used by specialists to relieve vasoconstriction and pain. Similarly, central neural blockade techniques such as caudal epidural anesthesia, caudal subarachnoid anesthesia, segmental thoracolumbar epidural anesthesia, and thoracolumbar subarachnoid anesthesia are usually the province of specialists. Caudal epidural administration of morphine can provide bilateral analgesia over various sacral and thoracic (S5 to T9) dermatomes, with slow onset (6 to 8 h) and long duration of effect (17 to 19 h), and minimal sedation and cardiopulmonary effects in horses.

The technique of caudal epidural injection of local anesthetics, which traditionally is used to induce perineal analgesia in standing horses, has been markedly expanded in the recent years by the use of novel analgesics (opioids, α_2 -adrenoceptor agonists, ketamine, and tramadol), and drug combinations. Motor nerve blockade induced by epidurally applied opiates or α_2 -adrenoceptor agonists is minimal, whereas some relief of inflammatory, traumatic, perioperative, and chronic pain is possible. Ataxia, sedation, and cardiovascular side effects after epidural administration of opiates or α_2 -adrenoceptor agonists can be reversed with antagonistic drugs (e.g., naloxone, yohim-

bine, or atipamezole). Additionally, the use of epidural catheters and accessories, which are commercially available in various epidural kits, greatly facilitates long-term analgesic drug administration in standing horses.

Improper injection technique contributes to inadequate anesthesia and complications. Each time a technique is performed, it will have its own rate of onset and duration, which is related to the specific local anesthetic used, neuroanatomy (thickness of the coverings of the nerve, arrangement of fibers within the mixed nerve, and blood supply to the area of injection), and personal interpretation of the animal's response.

The equipment for performing local anesthesia should include sharp and sterile needles, syringes in good working condition, sterile catheters and stylets, and sterile anesthetic solution. Chances of infection must be minimized by surgically preparing the injection sites, especially puncture sites into joints and epidural and subarachnoid spaces. Desired anesthetic effects without complications can be better obtained by using proper techniques, including aspiration before injection to avoid placing drug into the vascular system and avoidance of injections through or into inflamed tissues.

Choice of Local Anesthetic

The most commonly used local anesthetics in equine practice are 2% lidocaine (Xylocaine; Astra Pharmaceutical, Worcester, MA) or mepivacaine (Carbocaine-V; Winthrop Laboratories, New York, NY) hydrochloride (HCl) solution, both having an intermediate duration of action (1 to 2 h). In general, anesthesia begins most rapidly (within 3 to 5 min) during infiltration techniques and subarachnoid administration, followed in order of increasing onset time by minor nerve blockade (5 to 10 min), major nerve blocks, and epidural anesthesia (10 to 20 min).¹ The addition of epinephrine at concentration of 5 µg/mL (1:200,000) to the local anesthetic solution can improve the quality and duration of regional and epidural anesthesia. Ropivacaine is a novel local anesthetic recently evaluated in horses that provides local anesthesia for 3 to 6 h, similar to bupivacaine.

Regional Anesthesia

Anesthesia of the Head

The most frequently desensitized nerves of the head are the supraorbital, infraorbital, mandibular alveolar, and auriculopalpebral; other techniques, which desensitize the maxillary,^{2,3} mandibular,^{4,5} and ophthalmic nerves,^{6,7} are not without danger and seldom used.

Eyelids

Anesthesia of the eyelids requires sensory denervation of four individual branches of the trigeminal (fifth) cranial nerve: the supraorbital (or frontal), lacrimal, zygomatic, and infraorbital. Voluntary closure of the eyelids (*palpebral akinesia*) is prevented by desensitizing the dorsal and ventral branches of the palpebral nerve (*auriculopalpebral nerve block*). A 1.5- to 2.5-cm, 22- to 25-gauge needle is used to inject local anesthetic without epinephrine to each of the listed nerves (Fig. 22.1).

Fig. 22.1. Sites for needle placement to desensitize the supraorbital (A), auriculopalpebral (E and F), infraorbital (G and H), mental (I), and alveolar mandibular (K) nerves.

Upper Eyelid

The supraorbital (or frontal) nerve is the most commonly desensitized.^{8,9} The nerve emerges through the supraorbital foramen, which can be easily palpated with the index finger about 5 to 7 cm dorsal to the medial canthus and in the center of an imaginary triangle formed by grasping the supraorbital process of the frontal bone with the thumb and middle finger and sliding medially (Fig. 22.2A). Approximately 2 mL of local anesthetic are injected subcutaneously over the foramen, 1 mL as the needle is inserted into the foramen and 2 mL as the needle is inserted to its full depth (2.5 cm) into the foramen (Fig. 22.2B). Successful administration of local anesthetic desensitizes the forehead, including the middle two-thirds of the upper eyelid and palpebral motor supply from the auriculopalpebral nerve (A in Fig. 22.3). Auriculopalpebral nerve block has no significant effect on intraocular pressure or peripheral corneal thickness in horses.¹⁰

The lateral canthus and lateral aspect of the upper eyelid are desensitized by administering local anesthetic to the lacrimal nerve.^{9,11} The needle is inserted percutaneously at the lateral canthus and directed medially along the dorsal rim of the orbit (B in Fig. 22.4). A deep injection of 2 to 3 mL of the anesthetic at this site also desensitizes the lacrimal gland, local connective tissue, and temporal angle of the orbit (B in Fig. 22.3).

Medial canthal anesthesia is achieved by inserting the needle through the bony notch or irregularity on the dorsal rim of the orbit near the medial canthus and injecting 2 to 3 mL of local anesthetic around the infratrochlear nerve (C in Fig. 22.4). This procedure also desensitizes the nictitans, lacrimal organs, and connective tissues (C in Fig. 22.3).^{9,11}

The lower two-thirds of the lower eyelid, skin, and connective tissue are desensitized by placing the needle subcutaneously on the lateral aspect of the bony orbit and supraorbital portion of the zygomatic arch (the site where the rim begins to rise), and infiltrating the zygomatic nerve with 3 to 5 mL of the anesthetic (D in Figs. 22.3 and 22.4).^{9,11}

Fig. 22.2. A: Palpation of the supraorbital nerve. B: A 2.5-cm, 25-gauge needle is inserted into the supraorbital foramen.

Fig. 22.3. Area of skin desensitization after blocking the supraorbital (A), lacrimal (B), infratrochlear (C), zygomatic (D), infraorbital (G), and mental (I) nerves.

Fig. 22.4. Needle placement to supraorbital (A), lacrimal (B), infratrochlear (C), zygomatic (D), and (E and F) auriculopalpebral nerves.

Paralysis of the Orbicularis Oculi Muscles

Desensitization of the auriculopalpebral nerve is most frequently used for examination of the eye and temporary relief of eyelid spasms, since voluntary closure of the eyelids (akinesia) is prevented. The eyelids remain sensitive. In combination with topical anesthesia, this block is useful for removal of foreign bodies from the cornea and other ocular surgery. At least two injection sites have been suggested for paralyzing the palpebral musculature: either the most dorsal point of the zygomatic arch (E in Fig. 22.1)⁴

or the depression caudal to the mandible at the ventral edge of the temporal position of the zygomatic arch (F in Fig. 22.1).¹¹⁻¹³ In each location, the needle is placed subfascially, and 5 mL of the local anesthetic is administered in a fan-shaped manner.

Upper Lip and Nose

Anesthesia of the upper lip and nose requires a 2.5-cm, 20-gauge needle and deposition of 5 mL of local anesthetic to the infraorbital nerve as it emerges from the infraorbital canal (G in Fig.

22.1).^{4,8} After displacing the flat levator labii superioris muscle dorsally, the bony lip of the infraorbital foramen can be palpated by the index finger about half the distance and 2.5 cm dorsal to a line connecting the nasomaxillary notch and the rostral end of the facial crest. Successful perineural infiltration of the local anesthetic at this site results in anesthesia of the entire anterior half of the face from the foramen rostrally (G in Fig. 22.3).

Upper Teeth and Maxilla

If a 5.0-cm, 20-gauge spinal needle is inserted into the infraorbital foramen and is advanced into the infraorbital canal for a depth of up to 3.5 cm (H in Fig. 22.1), the deposition of 5 mL of local anesthetic is adequate to desensitize the teeth as far as the first molar, the maxillary sinus, the roof of the nasal cavity, and the skin almost to the medial canthus of the eye.^{14,15} Although local anesthesia can be produced for premolars and maxilla, extraction of these teeth and trephination of the maxillary sinus are more easily accomplished using general anesthesia.

Lower Lip

Anesthesia of the lower lip is induced by using a 2.5-cm, 22-gauge needle and successfully desensitizing the mental nerve rostrally to the mental foramen with 5 mL of local anesthetic. (I in Figs. 22.1 and 22.3).^{4,13} The lateral border of the mental foramen is easily palpated at the horizontal ramus of the mandible in the middle of the interdental space, after the tendon of the depressor labii inferioris muscle is dorsally displaced.

Lower Incisors and Premolars

A 7.5-cm, 20-gauge spinal needle is inserted into the mental foramen and is advanced into the mandibular canal as far as possible in a ventromedial direction to inject 10 mL of local anesthetic to desensitize the mandibular alveolar nerve, thereby extending the area of anesthesia caudally as far as the third premolar (K in Fig. 22.1).^{4,5,8,16} The technique is difficult, so extraction of teeth is better accomplished under general anesthesia.

Anesthesia of the Limbs

Regional anesthesia (peripheral nerve blocks),^{1,17–32} intra-articular injection,^{1,32–48} intrabursal injection^{1,49–51} and local infiltration (ring block) are used to provide intraoperative and postoperative anesthesia to a surgery site and aid in accurate diagnosis, prognosis, and especially recommendation and treatment of equine lameness.

These techniques for the diagnosis of lameness are seldom used, however. Instead, review of the horse's medical history; observation of the horse at rest (standing normally with all feet on the ground); examination for exostosis or lumps; palpation of areas that are inflamed, enlarged, or seem sore; use of the hoof tester to determine painful areas or to determine whether the horse becomes more lame after a specific part of the leg has been manipulated; and observation of the horse in motion are relied upon in making the diagnosis. In some cases the diagnosis is not obvious, and nerve blocks and good-quality radiographs with adequate view are required to make a specific diagnosis. Rectal palpation of ovaries, uterus, aorta, iliac vessels, pelvis, kidney, and

viscera of a female and palpation of the inguinal canal of a stallion or gelding are additional examinations in cases of difficult diagnosis of hind-limb lameness. Restraint is best achieved physically with a twitch applied to the horse's upper lip and a man picking up the front leg on the same side as the operator.

To prevent infection, sterile syringes, needles, and local anesthetic should be used for each injection. Subcutaneous injections, as a minimum, require an alcohol preparation. Show-horse owners object to clipping and shaving of the site of needle penetration.⁴¹ Intra-articular injections require a surgical scrub because of the risk of introducing contaminants; clipping the site is considered optional by many practitioners. Care must be taken not to place fingers on the end of the needle hub or especially on the tip of the syringe because of risk of contamination. To improve aseptic technique, it is wise to use surgical gloves when performing more complicated nerve and joint blocks.

Nerve blocks and intra-articular injections are performed first on the most distal branches of nerve trunks and joints, and proceed proximally with a systematic approach. Performing nerve blocks proximal to the carpus and tarsus is very uncommon. Proximal to the metacarpus, diagnostic anesthesia of the equine pectoral limb is nonspecific and best accomplished by joint anesthesia.²⁰ All corresponding digital nerves can be blocked on the hind limb as with the front limb (Figs. 22.5 and 22.6). A needle that is inserted in a distal to proximal direction and then attached to the syringe is less likely to break off if the horse makes a sudden leg movement. Adequate amounts of local anesthetic should be administered and enough time given for maximal effect. Post block examination is best accomplished by using deep digital pressure and pressure exerted by either a hoof tester, or a ballpoint pen for 1 to 2 s to test skin sensation distal to the block. Pressure from a blunt-tip instrument, such as a ballpoint pen, is preferable over a needle and avoids the production of numerous bleeding points.²⁶ The limb should be rubbed down and wrapped to prevent swelling and inflammation after the use of local anesthetic.

Local diagnostic blocks may fail or partially fail for several reasons, most common of which are incorrect anatomical deposition, inadequate anesthetic volume, dilution or hemodilution of anesthetic agent, presence of fibrous connective tissue inhibiting diffusion of anesthetic agent, multiple sites of pain, and the incorrectly perceived location of lameness.⁴⁸ Horses may become ataxic after nerve blockade in the limbs. Ataxia may lead to self-trauma because the horse may not know where the limbs are actually being placed.³¹

Digital Nerves

The palmar (or plantar) digital nerve is desensitized with the leg either bearing weight or elevated. It is palpated on the palmar (or plantar) aspect of the pastern medially and/or laterally midway between the coronary band and fetlock just palmar (or plantar) to the digital vein and artery (A in Figs. 22.5 and 22.6). A 2.5-cm, 25-gauge needle is inserted anteriorly to a depth equal to the length of the needle, and approximately 2 mL of local anesthetic is injected. Proper nerve blockade desensitizes the posterior one-third of the foot, including the navicular bursa, 5 to 10 min after the injection (Fig. 22.7A).

Fig. 22.5. Needle placement for nerves of the distal part of the left thoracic limb of the horse, lateral (L), palmar (P), and medial (M) views: lateral and medial palmar digital nerves (A), dorsal branches (B), lateral and medial palmar digital nerves (base sesamoid) (C), lateral and medial palmar nerves (D and G), lateral and medial palmar metacarpal nerves (E), communicating branch (F), and location of high suspensory block (H).

Fig. 22.6. Needle placement for nerves of the distal part of the left pelvic limb of the horse, lateral (L), plantar (P), and medial (M) views: lateral and medial plantar digital nerves (A), dorsal branches (B), lateral and medial plantar digital nerves (base sesamoid) (C), lateral and medial plantar nerves (D and G), lateral and medial plantar metatarsal nerves (E), communicating branch (F), and location of high suspensory block (H).

Anterior (or Dorsal) Digital Nerve Block

To block the dorsal or anterior digital nerve, which supplies sensory fibers to the anterior two-thirds of the hoof, the needle is directed anteriorly to the site of the posterior digital nerve and is inserted to a depth equal to the length of the needle while infiltrating subcutaneously 3 to 5 mL of local anesthetic (B in Figs. 22.5 and 22.6). All structures of the entire digit distal to the injection become anesthetized, including phalanges P1, P2, and P3; the proximal and distal interphalangeal joints; the entire corium; the dorsal branches of the suspensory ligament; and the distal extensor tendon.

Abaxial (Basilar) Sesamoidean Nerve Block

This can be done at the anterior and posterior digital nerves at the abaxial surface of the proximal sesamoids, to provide better analgesia of the pastern and proximal pastern joints (C in Figs. 22.5 and 22.6). Successful injections of 3 to 5 mL of local anesthetic subcutaneously at that site desensitize the entire foot distal to the injection, including the back of the pastern area and distal sesamoidean ligaments.

Low Palmar (or Plantar) Nerve Block

This is performed by injecting approximately 2 to 3 mL of local anesthetic at the following four points (four-point block) while the limb is bearing weight: the medial and lateral palmar or plantar nerves (D in Figs. 22.5 and 22.6) and the medial and lateral

palmar metacarpal or plantar metatarsal nerves (E in Figs. 22.5 and 22.6) distal to the communicating branch of the medial and lateral palmar or plantar nerves (F in Figs. 22.5 and 22.6). The injections are made between the flexor tendon and suspensory ligament (blocks medial and lateral palmar or plantar nerves) and between the suspensory ligament and the splint bone (blocks medial and lateral palmar metacarpal or plantar metatarsal nerves). This procedure desensitizes almost all structures distal to the fetlock and fetlock joint, except for a small area, dorsal to the fetlock joint, that is supplied by sensory fibers of the ulnar and musculocutaneous nerves (D in Fig. 22.7).

High Palmar (or Plantar) Nerve Block

Performing this block proximal to the communicating branch (F in Figs. 22.5 and 22.6) of the medial and lateral palmar (or plantar) nerves assures that the palmar metacarpal (or plantar metatarsal) region, the fetlock, and all of the digits are desensitized (G in Figs. 22.5 and 22.6). A 3.75-cm, 22-gauge needle is placed subfascially into the groove between the suspensory ligament and deep flexor tendon on both the medial and the lateral sides approximately 5 cm distal to the carpometacarpal (carpometatarsal) joint, where 5 mL of the local anesthetic is injected.⁵² The dorsal metacarpal (or metatarsal) region will still have sensation, but can be desensitized by injecting local anesthetic subcutaneously around the front of the cannon bone (ring block) (D + E in Fig. 22.7).

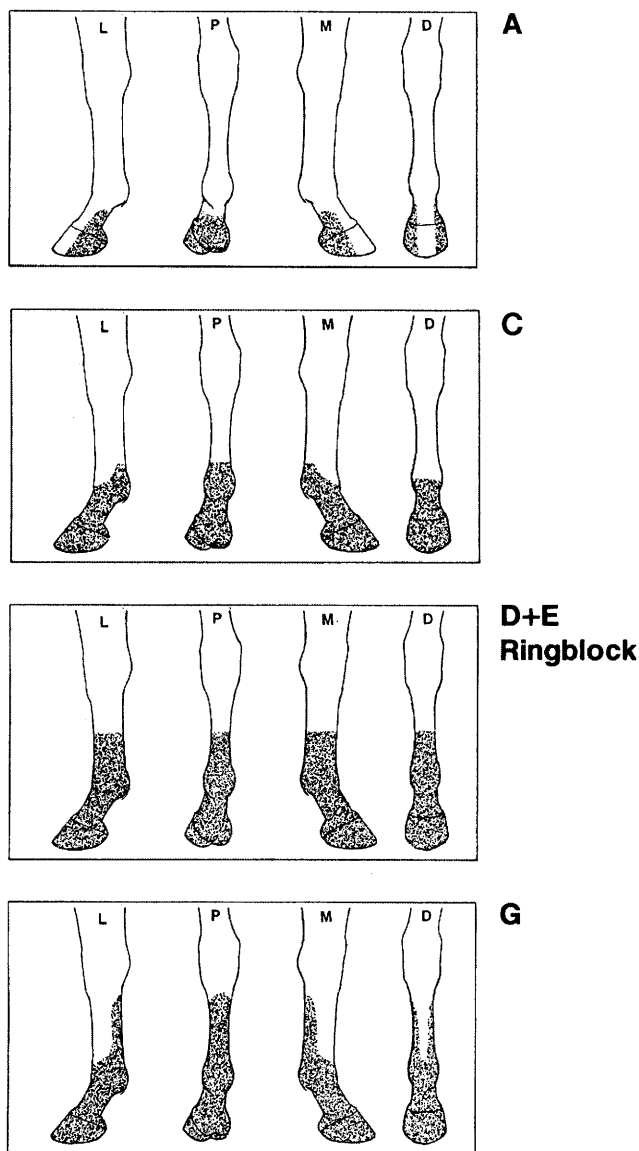

Fig. 22.7. Desensitized subcutaneous area after A, D, D + E, and G blockade.

High Suspensory Block

Deposition of 5 mL of local anesthetic solution to the medial and lateral palmar metacarpal (or plantar metatarsal) nerves (H in Figs. 22.5 and 22.6), which are subfascial between the superficial digital flexor tendon and the suspensory ligament, desensitizes the interosseous muscle (suspensory ligament) and inferior check ligament, the caudal aspect of the metacarpus (metatarsus), and the adjacent splint bones (G in Fig. 22.7).

Nerve Blocks Proximal to the Carpus

It is very uncommon to perform higher nerve blocks than the high suspensory block on the forelimb; however, to induce anesthesia of the carpus and distal forelimb, three nerves must be desensitized: the median, ulnar, and branches of the musculocutaneous nerve. The median nerve is desensitized on the medial

aspect of the forelimb, approximately 5 cm ventral to the elbow joint, by using a 3.75-cm, 20-gauge needle and injecting 10 mL of the anesthetic (A in Fig. 22.8). The ulnar nerve is desensitized by inserting a 2.5-cm, 22-gauge needle 10 cm proximal to the accessory carpal bone between the flexor carpi ulnaris and ulnaris lateralis muscles and injecting 5 mL of the anesthetic solution 1.5 cm deep beneath the fascia (B in Fig. 22.8). The medial cutaneous antebrachial nerve, a branch of the musculocutaneous nerve, is easily palpated just cranially to the cephalic vein at the anteromedial aspect of the forelimb halfway between the elbow and carpus. Approximately 10 mL of the anesthetic solution is deposited subcutaneously at that site by using a 2.5-cm, 22-gauge needle (C in Fig. 22.8).

Nerve Blocks Proximal to the Tarsus

It is very uncommon to do any higher blocks than the high suspensory block in the hind limb, but, to complete anesthesia of the hind limb from the tarsus distally, four nerves must be desensitized: tibial, saphenous, superficial peroneal (superficial fibular), and deep peroneal (deep fibular). The tibial nerve is desensitized by using a 2.5-cm, 22-gauge needle to inject 15 to 20 mL of local anesthetic subfascially between the combined tendons of the gastrocnemius muscle and superficial flexor tendon. Injection is best made on the medial aspect of the partially flexed limb, approximately 10 cm proximal to the point of the tarsus. Successful blockade desensitizes the posterior metatarsal region and most of the foot (A in Fig. 22.9). A ring block of the dorsal metatarsal region may be necessary to desensitize the anterolateral region. The saphenous nerve is desensitized by inserting a 2.5-cm, 22-gauge needle subcutaneously on the cranial or caudal aspect of the median saphenous vein, proximal to the tibiotarsal joint, and injecting 5 mL of the local anesthetic (B in Fig. 22.9). The medial aspect of the thigh and part of the metatarsal region will be anesthetized. The superficial and deep peroneal (fibular) nerves can be simultaneously desensitized by inserting a 3.75-cm, 22-gauge needle between the long and lateral digital extensor muscles approximately 10 cm proximal to the lateral malleolus of the tibia (C in Fig. 22.9). The superficial branch of the nerve is infiltrated subcutaneously with 10 mL of the local anesthetic. The needle is then advanced 2 to 3 cm to penetrate the deep fascia and to deposit 15 mL of the anesthetic around the deep branch. Anesthesia should include the anterolateral tarsal and metatarsal regions and the joint capsule of the tarsus.

Intra-articular Injections

Although arthrocentesis implies aspiration of synovial fluid, it allows for instillation of local anesthetic for the purpose of diagnostic anesthesia and use of therapeutic agents (e.g., saline flushes, antibiotics, hyaluronic acid, and anti-inflammatory drugs) as a therapy for certain diseases. The two most common local anesthetic agents used in intra-articular injections are mepivacaine and lidocaine HCl solution. Mepivacaine appears to cause less irritation than lidocaine for use in intra-articular injections.⁵³ Proper restraint, either physical or chemical, is indicated, and each horse should be considered potentially fractious.

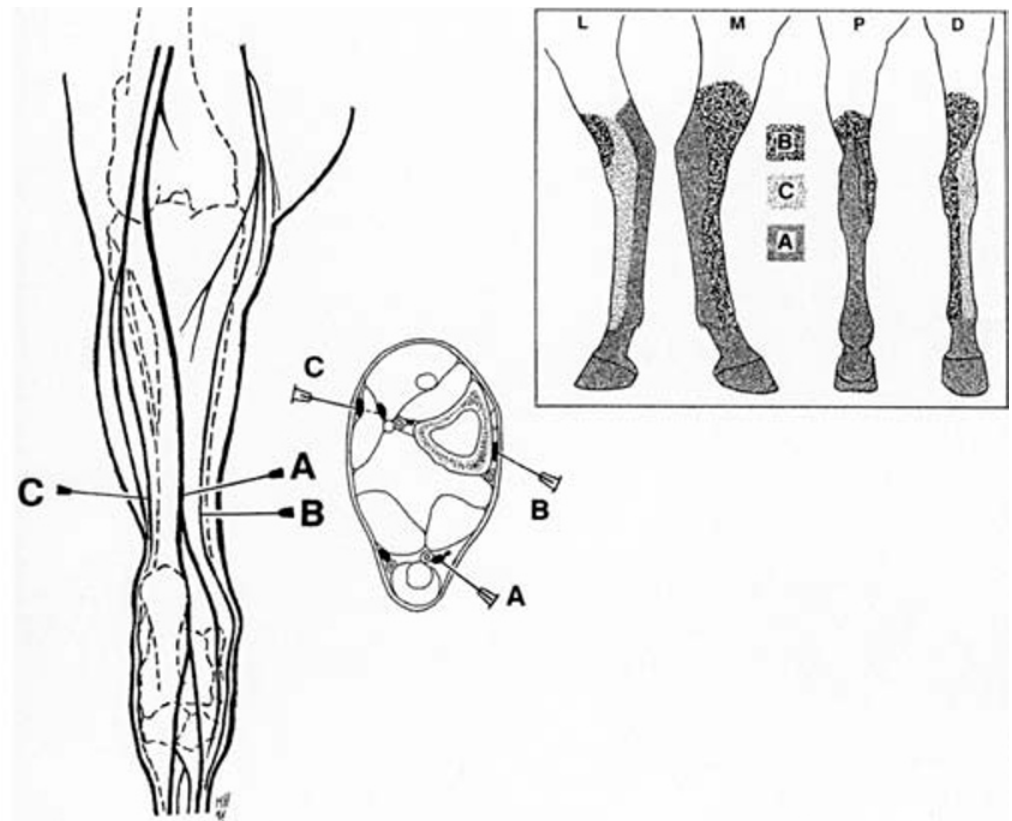

Fig. 22.9. Needle placement for tibial nerve (A), saphenous nerve (B), and peroneal nerve (C); cross sections and desensitized subcutaneous areas of left rear limb; L, lateral; M, medial; P, plantar; and D, dorsal aspects.

Podotrochlear (Navicular) Bursa Block

Numerous different techniques for injection of the navicular bursa have been described, but there is little conformity among these descriptions.⁵⁴ The procedure is best performed while the

limb is bearing weight. The position of the navicular bone is highly predictable as a point 1.0 cm distal to the coronary band and halfway between the most dorsal and most palmar aspect of the coronary band. Irrespective of foot confirmation, anesthesia

Fig. 22.10. Needle placement into the podotrochlear bursa (A), coffin joint (B), pastern joint (C), volar pouch of fetlock joint capsule (D), and digital flexor tendon sheath (E).

of the podotrochlear (navicular) bursa is induced by inserting a 5- to 7.5-cm, 18-gauge spinal needle through the digital pad between the bulbs of the heel until the needle strikes the bone along the midline at a point approximately at the level of the coronary band (A in Fig. 22.10). The needle is then slightly withdrawn until very little synovial fluid is aspirated, and 3 to 5 mL of local anesthetic is injected. Analgesia of the navicular bursa is more effective in desensitizing the dorsal margin of the sole than in desensitizing the angles of the sole.⁵⁵

Coffin Block

Pain arising from the dorsal margin of the sole in horses can be attenuated by anesthesia of either the distal interphalangeal (coffin) joint (P2-P3) or palmar digital nerves.⁵⁶ The distal interphalangeal joint is desensitized with 5 to 10 mL of local anesthetic. A 3.75-cm, 18- to 20-gauge needle is inserted 1.5 cm proximal to the coronet approximately 2 cm lateral to the vertical center of the pastern and is directed obliquely ventral to the tendon toward the extensor process (B in Fig. 22.10). Anesthesia of the podotrochlear (navicular) bursa depends on diffusion of the local anesthetic through the suspensory ligament to the bursa, because the coffin joint and podotrochlear (navicular) bursa do not communicate. The combination of lidocaine HCl (20 mg/mL), epinephrine (0.012 mg/mL), and sodium penicillin (800,000 IU) must not be injected into the coffin joint of horses, because it can cause irreversible lameness through ossifying arthrodesis.⁵⁷

Pastern Block

The proximal interphalangeal (pastern) joint (P1-P2) can be entered with ease by inserting a 3.75-cm, 20- to 22-gauge needle medially or laterally to the midline on the palpable epicondyles of P2, and injecting 5 to 8 mL of local anesthetic. The needle is directed vertically and inserted for approximately 2.5 cm (C in Fig. 22.10).

Fetlock Block

The metacarpophalangeal or metatarsophalangeal (fetlock) joint is one of the commonly and easily injected joints. A 3.75-cm, 20- to 22-gauge needle is inserted into the lateral pouch distal to the splint bone and dorsal to the annular ligament of the fetlock at a depth of approximately 0.5 to 1.5 cm (D in Fig. 22.10). When distended, this joint capsule may also be penetrated on the cranial surface of the joint. Approximately 8 mL of local anesthetic solution is injected.

Digital Flexor Tendon Sheath Block

This can be desensitized by inserting a 3.75-cm, 18- to 20-gauge needle to the distal end of the splint (“button”) either medially or laterally cranial to the deep and superficial flexor tendons and caudal to the suspensory ligament, and injecting 10 mL of local anesthetic (E in Fig. 22.10).

Carpal Block

The radiocarpal (antebrachial carpal) and intercarpal (middle carpal) joints are the two most commonly injected carpal joints. The carpometacarpal joint communicates with the middle (intercarpal) joint and therefore does not require separate entry.⁵² In one commonly used technique, the carpus is flexed and a 3.75-cm, 20-gauge needle is inserted on either side of the palpable extensor carpi radialis tendon to inject 5 to 10 mL of local anesthetic into each joint (A and B in Figs. 22.11 and 22.12). In an alternative method, which is used by many racetrack practitioners in standing horses, the needles are inserted perpendicularly through the skin on the posterolateral aspect of the radiocarpal and intercarpal joint spaces (C and D in Fig. 22.12). To locate the lateral site for penetration of the radiocarpal joint, the lateral digital extensor tendon and tendon of the ulnaris lateralis muscle are identified at the distal end of the ulna. These tendons narrow to form a depressed “V” anterior to the accessory carpal bone. The needle is then inserted approximately 1 to 2 cm distal to this V in the radiocarpal joint (C in Fig. 22.12). The intercarpal joint is approximately 2.0 to 2.5 cm distal to the first injection site (D in Fig. 22.12). The needles are inserted 1 to 2 cm until the joint spaces are encountered. Advantages of this technique include minimal risk of injuring the articular surfaces of the bones and injecting local anesthetic into a larger space of a more stable position of the leg from a safe lateral approach.^{44,47}

Cubital (Elbow) Block

This is not a usual source of lameness, so it is rarely desensitized. A 5-cm, 18-gauge needle is inserted into the depression between the lateral epicondyle of the humerus and the lateral tuberosity of the radius at the anterior edge of the lateral collateral ligament (A in Fig. 22.13). Repeated flexion of the elbow joint greatly facilitates the identification of the palpable landmarks. The needle is directed obliquely in a caudomedial direction to reach the elbow joint at a depth of 3 to 4 cm; up to 20 mL of local anesthetic is required.

Olecranon Bursa Block

This is performed by inserting a 3.75-cm, 18-gauge needle caudal to the olecranon, directing the needle obliquely from proxi-

Fig. 22.11. Needle placement into the radiocarpal joint (A) and the intercarpal joint (B) of the right forelimb.

mal to distal and injecting about 10 to 15 mL of the local anesthetic (B in Fig. 22.13).

Bicipital Bursa Block

After the biceps brachii muscle is palpated, a 7.5-cm, 18-gauge spinal needle is inserted between the muscle and the proximal humerus from below and approximately 4 cm ventral and 2 cm posterior to the palpable anterior prominence of the lateral tuberosity of the humerus (C in Fig. 22.13). The needle is advanced up to 5 cm obliquely dorsomedial toward the opposite point of the shoulder to penetrate the bursa. At least 10 mL of local anesthetic is injected, and a 20-min period is allowed for maximal effect.

Shoulder Block

The scapula humeral (shoulder) joint can be difficult to enter because of its relative depth. Limb motion or muscle contraction must be prevented to avoid bending of a positioned needle. The tendon of the infraspinatus muscle can be palpated as a tense band extending from the scapula to the proximal humerus. A 7.5- to 12.5-cm, 18-gauge spinal needle is inserted just cranial to the tendon and between the palpable projections of the anterior and posterior parts of the lateral tuberosity of the humerus, and is directed to the opposite elbow (D in Fig. 22.13). Penetration from skin is up to 7.5 cm or until synovial fluid is aspirated. A volume of 30 mL or more of the anesthetic is injected. The shoulder joint may communicate with the bicipital bursa in some horses; therefore, injection of local anesthetic into the shoulder joint may diffuse the anesthetic to the bicipital bursa and improve a lameness associated with that structure.^{45,46}

Fig. 22.12. Needle placement into the radiocarpal (A and C) and intercarpal (B and D) joints of the left forelimb (a, lateral digital extensor tendon; b, tendon of ulnaris lateralis muscle; and c, accessory carpal bone).

Fig. 22.13. Needle placement into the elbow joint (A), olecranon bursa (B), bicipital bursa (C), and shoulder joint (D) of the left forelimb.

Cunean Bursa Block

This block is more commonly performed in standardbreds and less commonly in horses that are ridden.^{49,50} The cunean tendon is the tendon of the medial branch of the tibialis anterior muscle extending diagonally from anterior to posterior and inserting in the tarsal bone on the medial aspect of the tarsus (A in Fig. 22.14). A 2.5-cm, 22-gauge needle is inserted approximately 1.5 cm distal to the cunean tendon and then advanced between the cunean tendon and the tarsal bone to penetrate the bursa from distally. This approach is safe and, should the horse move, is less likely to break off the needle in the surrounding tissues. At least 10 mL of local anesthetic is frequently required and administered as the needle enters the skin, coming from under the tendon to fill the entire bursa after penetration (Fig. 22.15). One way to confirm the correct location of the block is to observe the increased intrabursal pressure causing local anesthetic to flow forcefully from the needle after removal of the syringe. A period of at least 20 min is required for maximum anesthetic effect.

Tarsal Block

Desensitizing the distal intertarsal and tarsometatarsal joints with local anesthetic improves lameness associated with early bone spavin. The tarsometatarsal joint is most easily entered by a 2.5-cm, 22-gauge needle on the posterior lateral aspect of the hock over the lateral head of the splint (metatarsal IV) (Fig. 22.16 and B in Fig. 22.14). The intertarsal joint is entered by a 2.5-cm, 22-gauge needle at a right angle to the skin ventral to the cunean ten-

Fig. 22.14. Needle placement into the cunean bursa (A), tarsometatarsal space (B and D), distal intertarsal space (C), and tibiotarsal space (E) of the left hock joint; medial aspect.

don on the medial aspect of the tarsus (C in Fig. 22.14). Approximately 6 mL of local anesthetic solution is injected into the intertarsal joint space with pressure. Considerable resistance will be encountered, even with the needle placed in the joint. Sometimes the needle must be turned to be sure that the bevel is not against bone and allows for injection of the anesthetic solution. In an alternative method, a 2.5-cm, 22-gauge needle can be placed into the tarsometatarsal joint approximately 2.5 cm distal to the intertarsal joint while injecting the local anesthetic (D in Fig. 22.14). Communication between the distal intertarsal and tarsometatarsal joints is variable, but can be demonstrated by placing one needle in each of the two joints and observing the local anesthetic flowing from one needle after the anesthetic is injected into the other needle.^{37,40} There is a higher pressure in the distal joint and, to get good dispersion of local anesthetic in both joints, both sites should be injected with local anesthetic solution.

Tibiotarsal Block

One of the most common joints in which arthrodesis is performed is the tibiotarsal (tarsocrural) joint. It is the easiest of all the equine joints to inject.³⁵ This joint is penetrated with a 3.75-cm, 18-gauge needle at the craniomedial aspect 2 to 3 cm ventral to the medial malleolus of the tibia on either the medial or lateral side of the saphenous vein (E in Fig. 22.14). The capsule is thin, superficial, and easily observed, and may also be distended caudomedially and craniolaterally in cases of tarsal osteoarthritis (bone spavin).³⁷ The needle is inserted to a depth of less than 2 cm in a slightly dorsal direction toward the anterior medial aspect of the hock. Approximately 15 mL of local anesthetic is injected after synovial fluid is recovered on aspiration. Complete anesthe-

Fig. 22.15. Injection of local anesthetic (10 mL) into the cunean bursa of the right rear limb; medial aspect.

Fig. 22.16. Collection of fluid from the tarsometatarsal joint (left rear leg).

sia of the tibiotarsal joint has been achieved in healthy horses (250 to 680 kg) by intra-articular administration of 2 mL of 4% procaine HCl solution. The intra-articular concentration of procaine ranged from 3.7 to 5.4 mg of procaine/mL at 1 h after administration, which is above the anesthetic threshold concentration (0.2 mg/mL).³⁹

Stifle Block

The stifle (genual) joint, which is the largest joint in the hind limb, consists of the femoropatellar and femorotibial joint spaces, which consist of medial and lateral pouches. The medial femoropatellar pouch is the common site where the stifle joint is injected for diagnostic blocks. It is most easily entered dorsal to the tibial crest between the middle and medial patellar ligaments (A in Fig. 22.17). The medial femoropatellar pouch enclosing the femoropatellar joint communicates with the medial femorotibial pouch of the femorotibial joint in most horses. The communicating opening, however, can be obstructed in an inflamed stifle joint, necessitating the injection of local anesthetic or medication into each individual compartment.²² Entering the medial pouch of the femorotibial joint is technically difficult, but is accom-

plished between the medial patellar ligament and the medial collateral ligament approximately 4 cm dorsal to the proximal medial edge of the tibia (B in Fig. 22.17). The medial femorotibial pouch is chosen by some clinicians as the injection site because it is the area that is most likely to have injury and pain causing lameness. There is seldom an indication for injecting the lateral femorotibial pouch of the stifle joint because there is seldom injury in this area. The lateral femorotibial pouch can be entered and injected between the lateral patellar ligament and the lateral collateral ligament (C in Fig. 22.17). In some cases (approximately 25%), a communicating opening between the femoropatellar pouch and the lateral femorotibial pouch exists. A 5- to 7.5-cm, 18-gauge spinal needle is satisfactory for penetrating the joint capsule and injecting 30 to 40 mL of anesthetic into each pouch. To make the injection, it is best to feel around with the needle and insert it to a depth of 3 to 4 cm, until some resistance is encountered, during penetration of the joint capsule. Additional resistance is felt as local anesthetic solution is injected. A few drops of joint fluid can be recovered after some local anesthetic has been administered, but seldom is joint fluid aspirated before the injection of local anesthetic. It is important to use a

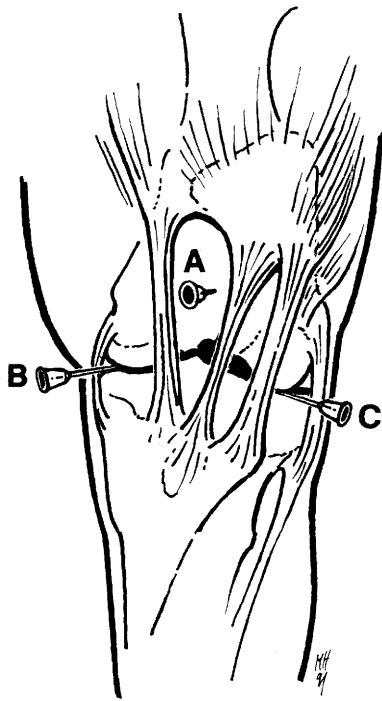

Fig. 22.17. Needle placement into the femoropatellar pouch (A), medial femorotibial pouch (B), and lateral femorotibial pouch (C) of the stifle joint.

larger rather than a smaller amount of local anesthetic and allow at least 20 min for maximal effect. Many horses will continue to improve for up to an hour after the injection. Any improvement in lameness is significant, because few horses are entirely sound after local anesthetic has been injected into the stifle joint. This is probably because most lameness involves the medial collateral ligaments and/or cruciate ligaments and structures adjacent to, but not inside, the joint capsule.

Coxofemoral Block

The coxofemoral (hip) joint is the most difficult of all joints to inject, so several approaches have been described.^{22,35,36,43} The skin between the anterior and posterior eminences of the great trochanter of the femur is desensitized by injecting a small amount of local anesthetic. A wide-bored needle (3.75-cm, 14-gauge) is first inserted at that site, through which a thinner (15-cm, 18-gauge) and more flexible needle is inserted. The needle is then advanced anteromedially along the femoral neck until the joint capsule is penetrated (A in Fig. 22.18). The injection of 30 to 50 mL of local anesthetic is adequate, after synovial fluid is recovered on aspiration. Improvement in lameness should be assessed only after a minimum period of 30 min has passed to allow time for maximal anesthetic effect.

Trochanteric Bursa Block

The trochanteric bursa is located on the lateral aspect of the hip, between the anterior crest of the great trochanter of the femur and the middle gluteal muscle. The bursa is entered and injected by a 7.5-cm, 18-gauge needle, which is inserted 3 to 5 cm ventral to the anterior crest of the great trochanter and is directed dorsally and medially (B in Fig. 22.18). Synovial fluid is recovered by using continuous suction of a syringe that is attached to the needle, and then 10 to 15 mL of local anesthetic can be injected.

Anesthesia for Laparotomy

At least four techniques for obtaining anesthesia of the paralumbar and abdominal wall in standing horses have been described: (a) infiltration anesthesia, (b) paravertebral thoracolumbar anesthesia, (c) segmental dorsolumbar epidural anesthesia, and (d) segmental thoracolumbar subarachnoid anesthesia. Although infiltration of the incision line is the easiest and probably the most commonly used technique, any of these techniques may be used for abdominal surgery required for exploratory laparotomy, in-

Fig. 22.18. Needle placement into the coxofemoral joint (A) and the trochanteric bursa (B).

testinal biopsy, ovariectomy, cesarean section, embryo transfer, castration of stallions with abdominal cryptorchidism, and liver or kidney biopsy.

Infiltration Anesthesia

Simple infiltration of the incision line (*line block*) is commonly used in equine practice. A 2.5-cm, 20-gauge or smaller needle is used for multiple subcutaneous injections of 1 mL of local anesthetic for each centimeter of incision. This can be repeated until the entire length of the desired incision is blocked. Pain is minimized by slow and continuous injections as the needle is inserted at the edge of the desensitized skin. This technique assures that the horse senses only the initial needle penetration. The needle can be advanced in multiple directions to produce a fan-shaped area of desensitization. Usually 10 to 15 mL of anesthetic is adequate for the skin and subcutaneous line block, whereas 50 to 150 mL of the anesthetic may be required to desensitize the deeper layers of muscle and peritoneum, depending on the area to be desensitized. A 7.5- to 10-cm, 18-gauge needle is used for deep deposition of the anesthetic. Toxicity is not to be expected with dosages of less than 250 mL of 2% lidocaine HCl solution, which is equivalent to 5 g, for infiltration of the paralumbar fossa in adult horses (500 kg),^{2,58} whereas the intravenous bolus administration of much smaller doses (150 mL, 3 g/adult horse) may cause convulsions. At least 15 min should be allowed for maximal anesthetic effect. The primary advantages of local infiltration anesthesia are the ease of performing the technique and that precise knowledge of nerve location is not necessary. The disadvantages include disruption of normal tissue architecture, with excessive amount of fluid, hematoma, and trauma; incomplete anesthesia (particularly of the peritoneum); incomplete muscle relaxation of the deeper layers of the abdominal wall; toxicity after inadvertent injection into the peritoneal cavity; and increased cost and time required for long incisions (>1 m) as might be required for a cesarean section surgery.

Paravertebral Thoracolumbar Anesthesia

If a longer (>1 m) incision of the skin, musculature, and peritoneum of the midflank region is required, paravertebral thoracolumbar anesthesia (*paravertebral block*) can be used as an alternative to infiltration anesthesia.^{7,59-61} This block is technically more difficult and less popular than other techniques, but can be accomplished in thin-muscled horses with palpable landmarks. The last thoracic (T18) and first and second lumbar (L1 and L2) spinal nerves are desensitized approximately 10 cm from the midline, after they have emerged from the intervertebral foramina and ramified into dorsal and ventral branches and their medial and lateral ramifications, respectively (Fig. 22.19). Approximately 10 mL of local anesthetic is injected to desensitize the lateral cutaneous branches of the dorsal spinal nerves T18, L1, and L2 subcutaneously at three sites: halfway between the last rib and the distal end of the first lumbar transverse process (for T18), between the first and second lumbar transverse processes (for L1), and between the second and third lumbar transverse processes (for L2). The injection sites for desensitizing the spinal nerves are easily identified by locating the third

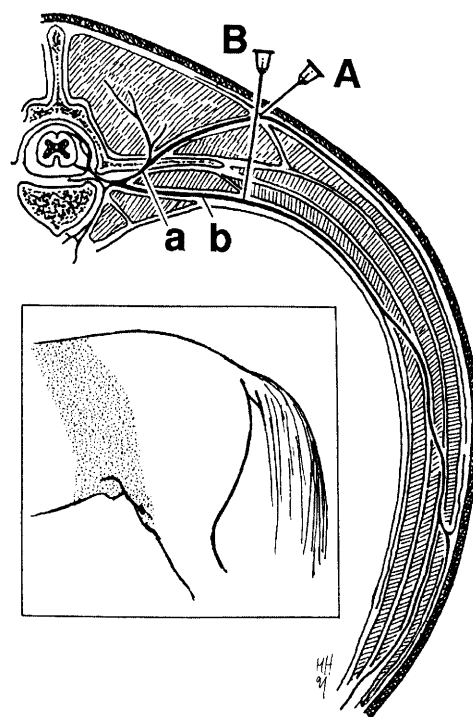

Fig. 22.19. Needle placement for paravertebral nerve blockades: A cranial view of a transection of the first lumbar vertebra at the location of the intervertebral foramen: (A) subcutaneous infiltration and (B) retroperitoneal infusion (a, dorsal branch, and b, ventral branch, of the L1 vertebral nerve). **Inset:** Desensitized subcutaneous area after blockade of T18, L1, and L2 vertebral nerves.

lumbar transverse process, which lies on a line between the most caudal extension of the last rib and perpendicular to the long axis of the spinal vertebrae.⁶¹ The distance between the injection sites ranges from 3 to 6 cm (Fig. 22.20). After the skin is desensitized, a 7.5-cm, 18-gauge needle is inserted at each site to reach the ventral branches of T18, L1, and L2. The needle is first advanced until the peritoneum is punctured, which is indicated by either a loss of resistance to needle insertion or a slight sucking sound as air enters the needle. The point of the needle is then withdrawn to a retroperitoneal position, where a second deposit of 15 mL of local anesthetic is injected (B in Fig. 22.19). The advantages of paravertebral anesthesia when compared with infiltration anesthesia include the use of smaller doses of anesthetic, a wide and uniform area of anesthesia and muscle relaxation, and absence of local anesthetic from the operative wound margin, thus minimizing edema, hematoma, and possible interference with healing. The disadvantage is difficulty in performing the technique for the inexperienced practitioner. The fat and muscles in some horses almost put the transverse processes out of range of palpation, making the technique more time consuming or unpractical. There is some bowing of the back toward the desensitized side, making it more difficult to close the incision and navigate tissue landmarks. Inadvertent desensitization of the third lumbar spinal nerve, which carries motor fibers to the femoral and ischial nerves, causes loss of motor control of the ipsilateral pelvic limb.

Fig. 22.20. Right thoracolumbar area of a standing adult horse with injection sites (arrows) for distal paravertebral block (R18, last rib; L1 and L2, spinous processes of first and second lumbar vertebrae). The dotted line transects the corresponding interspaces between spinous and transverse processes. Subcutaneous injection of L2 is shown. From Skarda.³

Segmental Dorsolumbar Epidural Anesthesia

This technique is not routinely used in horses because it is difficult to perform, requires a special catheter-stylet unit to catheterize the T18-L1 epidural space from the lumbosacral epidural space (Fig. 22.21),⁶² and is associated with the risk of the catheter either kinking or curling within the epidural space. Catheter curling and injection of local anesthetic near spinal nerve roots contributing to femoral and ischial nerve outflow could result in motor nerve deficits in rear-limb function.

Segmental Thoracolumbar Subarachnoid Anesthesia

This is easier to master than segmental dorsolumbar epidural anesthesia. It produces the fastest and best-controlled surgical anesthesia of the flank in horses; however, special equipment and maintenance of aseptic technique are required.⁶³ A 17.5-cm, 17-gauge Huber-point Tuohy needle with stylet and with the bevel directed cranially is inserted into the subarachnoid space at the lumbosacral (L6-S1) intervertebral space (Fig. 22.22). This interspace is located 1 to 2 cm caudal of a line drawn between the cranial edge of each tuber sacral and the dorsal midline. Rectal palpation of the ventral lumbosacral eminence may be used to locate the L6-S1 intervertebral space.⁶³ The skin and lumbosacral fascia adjacent to the interspinous (L6-S1) ligaments are injected with 5 mL of 2% lidocaine HCl solution to help minimize pain during the puncture procedure. To prevent loss of motor control of the pelvic limbs, care must be taken not to inject the entire volume (5 mL) of local anesthetic into the subarachnoid space. The needle is advanced along the median plane perpendicularly to the spinal cord until entering the subarachnoid space. The stylet is removed, and 2 to 3 mL of cerebrospinal fluid (CSF) is aspirated. A Formocath polyethylene catheter (Becton-Dickinson, Rutherford, NJ), 100 cm long with a 0.095-cm outside diameter, reinforced with a stainless-steel spring guide (0.052-cm outside di-

Fig. 22.21. Lateral view of sagittal section of the sixth lumbar (L6) and first sacral (S1) vertebrae. A 17.5-cm, 17-gauge Huber-point Tuohy needle (TN) is in place for catheterization of the lumbar epidural space. The arrow indicates the interarcuate ligament (IAL).

ameter), is passed through the needle and advanced approximately 60 cm to the midthoracic area. First the needle is withdrawn over the catheter, and then the spring guide is removed and the catheter is withdrawn a calculated distance to place its tip at T18-L1. Precise catheter positioning requires radiography for confirmation. A 23-gauge needle on a three-way stopcock is attached to the catheter, and 1.0 to 2.0 mL of CSF is removed. A small dose (1.5 to 2.0 mL) of a 2% mepivacaine HCl solution is injected through the catheter at a rate of approximately 0.5 mL/min. The previously collected CSF is used to remove the remaining local anesthetic from the catheter. Bilateral segmental anesthesia, extending from spinal cord segment T14 to segment L3, is maximal 5 to 10 min after injection and lasts 30 to 60 min. Surgical anesthesia is easily maintained by fractional bolus administration of 0.5 mL of the anesthetic at 30-min intervals or as needed (Fig. 22.23). The duration of anesthesia is determined by the decline of the subarachnoid mepivacaine concentration owing to absorption of drug into the systemic circulation and not due to hydrolysis of the drug within the CSF.⁶⁴

Investigators have threaded a subarachnoid catheter to the thoracolumbar area in standing horses to use ketamine (12 to 15 mg/100 kg body weight [BW]) to produce segmental spinal block

Fig. 22.22. Needle and catheter placement for thoracolumbar subarachnoid anesthesia. between the T17 and L3 spinal nerves.⁶⁵ The analgesic effect of ketamine appeared after 5 to 10 min and lasted between 35 and 65 min. Horses did not react to surgical intervention on the abdominal wall and viscera, and significant changes in heart and respiratory rates, rectal temperature, and intestinal motility of horses were not observed after subarachnoid ketamine injection.⁶⁵

There has been one report of lumbosacral subarachnoid catheterization in healthy horses that resulted in an acute inflammatory reaction after 12 h of catheterization, although there was no bacterial contamination.⁶⁶ The horses did not show any clinical

signs of neurological dysfunction, such as ataxia, proprioception deficits, or changes in locomotor activity, and rectal temperature remained unchanged even though an inflammatory reaction in CSF occurred.

The advantages of thoracolumbar subarachnoid anesthesia as compared with dorsolumbar epidural anesthesia include simplicity of needle and catheter placements, minimal dosage, deposition of the anesthetic at nerve roots, rapid onset of anesthesia, and minimal physiological disturbance. The disadvantages include potential for traumatizing the conus medullaris, kinking

and curling of the catheter in the subarachnoid space if the guidewire is recessed from the catheter tip, loss of motor control of the pelvic limbs and/or injecting the proper dose in a misplaced catheter, and meningitis after septic technique.

Caudal Anesthesia

Caudal epidural anesthesia, continuous caudal epidural anesthesia, and caudal subarachnoid anesthesia are possible techniques to produce regional anesthesia of the anus, perineum, rectum, vulva, vagina, urethra, and bladder in horses. Success in producing regional anesthesia of pelvic viscera and genitalia without losing locomotor function of the hind legs depends on cranial flow of local anesthetic to desensitize the caudal and the last three pairs of sacral nerves in the epidural space as they emerge either from the meninges (epidural technique) or the spinal cord (subarachnoid technique). In horses, the spinal cord and its meninges end in the midsacral region, and only the coccygeal nerves and the thin phylum terminale remain in the spinal canal.⁶⁷ The coccygeal nerves are not easily damaged at the site of needle penetration to produce caudal epidural blockade. Caudal subarachnoid blockade, however, requires the insertion of a spinal needle into the subarachnoid space at the lumbosacral intervertebral space and the passage of a catheter to the midsacral region; thus, the potential for trauma to the conus medullaris and nerve fibers by the needle or catheter exists. The neuroanatomy and effects of sensory, motor, and autonomic nerve blockade of various spinal cord segments are summarized in Table 22.1.^{68,69}

Caudal Epidural Anesthesia

This is routinely used in horses because it is simple and inexpensive and requires no sophisticated equipment. The technique's use in horses was first described in 1925;⁷⁰ subsequently, many have reported its use for relieving pain and control of rectal tenesmus associated with irritation of the perineum, anus, rectum, and vagina during difficult labor; correction of uterine torsion, fetotomy, and various obstetric manipulations and surgical procedures such as amputation of the tail, rectovaginal fistula repairs, Caslick's closure (operation for pneumovagina), prolapsed rectum, urethrostomy; or anal, perineal, vulvar, and bladder procedures.^{7,71–86}

The injection site is the epidural space between the first and second coccygeal vertebrae. The first coccygeal interspace (Co1-Co2) is identified as the first obvious midline depression caudal to the sacrum. It can generally be felt with the finger as the first movable coccygeal articulation when the tail is raised and lowered. The sacrococcygeal joint in many horses is fused and generally intersects with the midline and a line drawn over the back joining the two coxofemoral joints. The Co1-Co2 interspace may be more difficult to palpate in obese or well-developed horses, but generally lies at the most angular portion of the bend of the tail, approximately 5 cm cranial to the origin of the first tail hairs and the caudal fold of the tail. Correct needle placement requires the horse to be properly restrained and stand squarely with the croup symmetrical. In the standard technique, a 5- to 7.5-cm, 18-gauge spinal needle with fitted stylet is inserted through the disinfected skin in the center of the Co1-Co2 joint space while the

needle is directed at almost right angles to the general contour of the croup or ventrocranially at an angle of approximately 10° to vertical. The needle is inserted in a median plane until it contacts the floor of the vertebral canal and is then withdrawn for approximately 0.5 cm to avoid injection into the intervertebral disk or ligamentous floor of the canal (E in Fig. 22.24). Painful reaction to the epidural needle is minimized if a 2.5-cm, 25-gauge needle is used to inject 2 to 3 mL of a 2% lidocaine HCl solution subcutaneously and adjacent to the interspinous and interarcuate ligaments. A popping sensation is often detected as the interarcuate ligament is penetrated. A hissing sound at the needle hub may often be heard upon penetration of the epidural space as air is drawn into the needle. Proper needle placement may be verified by applying 1 or 2 drops of local anesthetic to the needle and observing the drop(s) to be drawn into the epidural space by the negative pressure (*hanging-drop technique*) or confirmation can be made by resistance-free injection of 3 to 5 mL of air or local anesthetic solution (test dose), with no blood upon aspiration.

In the alternative technique, the spinal needle is inserted at the caudal part of the first intercoccygeal depression and directed cranioventrally at almost 30° to the horizontal plane until its point glides along the floor of the neural canal (F in Fig. 22.24). The spinal needle can be inserted to its full length (5 to 7.5 cm). Depth from skin surface to the neural canal varies between 3 to 7.5 cm, depending on the size and condition of the horse. The alternative technique is useful in horses that have fibrous connective tissue from previous epidural injections, which limits the diffusion of local anesthetic agents. However, unilateral analgesia is more likely to occur if the spinal needle has been inserted a considerable distance into the vertebral canal, allowing the needle tip to deviate from the midline, and if a small amount of local anesthetic has been given, to bathe the nerve roots primarily on one side of the spinal column.^{7,87,88}

Epidural Local Anesthetics

Local anesthetics can provide profound relief from pain by inhibiting depolarization of the nerve membrane and conduction of nerve impulses. The amount of anesthetic injected is determined by considering the type of local anesthetic, the size and conformation of the horse, the depth of needle insertion into the vertebral canal (the actual distance of the needle bevel to the spinal cord), and the extent of regional anesthesia required (Fig. 22.25).

Lidocaine This has been shown to be most effective as an epidural analgesic. A mature mare (450 kg) may require a total of 6 to 8 mL of a 2% lidocaine HCl solution (0.26 to 0.35 mg/kg) to anesthetize the anus, perineum, rectum, vulva, vagina, urethra, and bladder. The order and magnitude of neural blockade are dose dependent but generally profound, and selective sensory blockade of nociceptive and motor fibers in dermatomes ranging from coccygeal to the second sacral vertebra is produced within 5 to 15 min and lasts 60 to 90 min. Additional local anesthetic should not be administered during this period, so as to prevent overdosing, which can result in marked ataxia and potentially recumbency, hypotension, and occasionally bradycardia from sympathetic blockade.^{62,89–91}

Table 22.1. Neuroanatomy and action of caudal epidural analgesia.

Nerves	Ventral Branches	Spinal Cord Segment	Action			
			Sensory	Motor	Parasympathetic	Sympathetic
Caudal		Coccygeal	Most of the tail and skin between anus and tail root	Coccygeal muscle		
Caudal rectal (hemorrhoidal)		S5	Anal region, tail folds, and tail base	Coccygeus and levator ani externus muscle	Fibers in caudal rectal nerve	Straining in anorectal region due to excessive sympathetic stimulation
Middle rectal	Perineal nerve, caudal scrotal nerves, and labial nerves	S4, S5	Perineum, posterior croup, scrotum along its caudal aspects, and vulva without clitoris		Pelvic nerves, hypogastric plexus	Relaxation of bladder without sphincter, distal colon, rectum, and sexual organs
Pudendal	Dorsal nerve of penis, and deep perineal nerve	S4, S3, S2	Penis (corpus cavernosum and spongiosum); and clitoris and vulva	Perineal muscles fascia of ischio-rectal fossa, and constrictor vulvae muscle	Retractor penis muscle	Prolapse of penis; and relaxation of vulva and vagina
Caudal gluteal	Caudal cutaneous femoral nerve	S2, S1	Lateral and posterior surfaces of hip and thigh	Extension of hip		
Cranial gluteal		S1, L6, L5	Lateral aspect of thigh	Flexor and abductors of hip	Splanchnic lumbar nerves (in part)	Relaxation of bladder and sphincter of bladder, distal colon, rectum, and sexual organs
Sciatic		S1, L6, L5	Middle to tibial region to foot	Flexor and abductors of hip; and flexor of stifle (in part) and extensors of hock and digit		Ataxia, and knuckling of hind fetlock

From Skarda,⁶⁸ p. 105.

Fig. 22.24. Lateral (**A**) and caudal (**B**) drawings of the lumbosacral, sacral, and sacrococcygeal areas of a standing mare with marked loss of skin sensation from coccyx to S4 (a), coccyx to S3 (b), and coccyx to S2 (c), respectively, 60 min after epidural administration of ropivacaine (0.5% solution, 9 mL/500 kg body weight). Placement of spinal needle (E) and Tuohy needle (F) with the catheter for caudal epidural anesthesia. L6, sixth lumbar; S1, first sacral; and Co1, first coccygeal vertebrae. Modified from Skarda and Muir.⁸⁸

Mepivacaine Mepivacaine HCl solution (2%) acts very similarly to lidocaine in producing caudal regional anesthesia in horses. Epidural injection of 60 to 100 mg of 2% mepivacaine HCl in aqueous solution (3 to 5 mL) at the caudal sacral (S5-C1 to S3) vertebrae (via catheter) can produce either unilateral or bilateral analgesia extending from spinal cord segment S1 to the coccyx in adult mares. Analgesia usually becomes evident in 20 min and lasts approximately 80 min.^{62,92}

Ropivacaine This is the newest commercially available drug for use as a local and regional anesthetic. Its effect (0.5%, 8 mL/500 kg) has been evaluated when injected epidurally at the sacrococcygeal vertebral interspace in adult mares.^{87,88} Lack of sensory perception to electrical stimulation (>40 mA) and absence of response to deep needle pricks extending from coccyx to S2 dermatomes indicated the presence of regional anesthesia. Epidurally administered ropivacaine induced variable analgesia extending bilaterally from the coccyx to S2 (three mares), coccyx to S3 (four mares), and coccyx to S4 (three mares), with minimal

sedation, ataxia, and cardiovascular and respiratory disturbances. Analgesia at the perineal area lasts 2 to 4 h.⁸⁸

The efficacy of caudal (Co1-Co2) epidural administration of either 1% ropivacaine, 2% lidocaine, or a combination of 1% ropivacaine and 2% lidocaine for producing perineal anesthesia in mares has also been evaluated.⁹¹ Local anesthetics were combined with adrenaline (1:200,000) and administered at a volume of 0.018 mL/kg. Perineal analgesia lasted 3 to 4.5 h. Three of the mares became recumbent: two that received lidocaine and one that received the combination of ropivacaine and lidocaine. It was concluded that the high incidence of ataxia and recumbency was probably attributable to the higher concentration (1% vs. 0.5%) of ropivacaine and admixture of adrenaline with these two local anesthetics.⁹¹

Bupivacaine The caudal epidural administration of hyperbaric bupivacaine (0.5%, 0.06 mg/kg BW) produces not only very rapid (<6 min) but prolonged (>5 h) bilateral perineal analgesia effects in adult horses.⁹³ Heart and respiratory rates, arterial

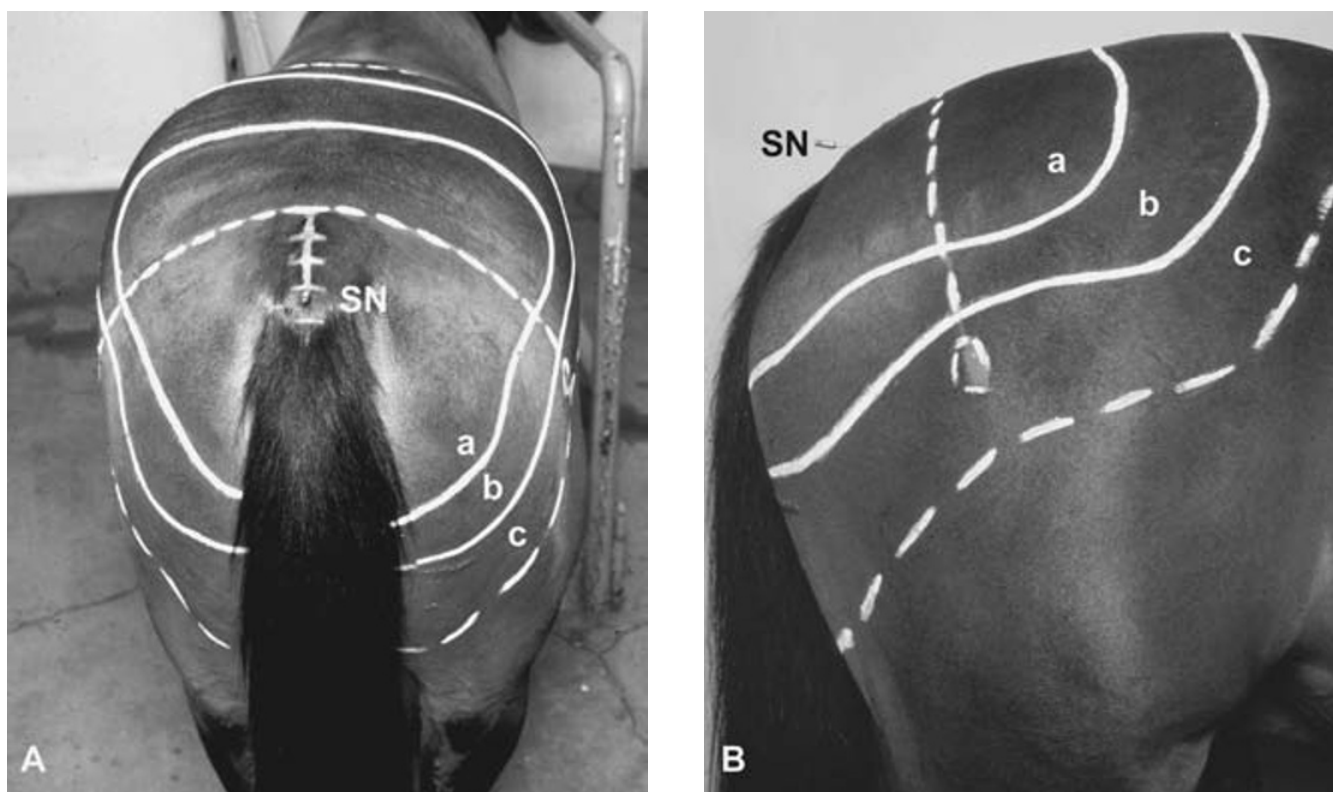

Fig. 22.25. Desensitized skin area in a standing horse 20 min after epidural injection of 6 mL (a), 8 mL (b), and 10 mL (c), respectively, of 2% carbocaine via a 15-cm, 18-gauge spinal needle inserted at the third coccygeal interspace to its full length horizontally (SN, spinal needle with stylet). Dorsocaudal (**A**) and lateral (**B**) aspects. From Skarda.³

blood pressure, and rectal temperature did not change after the epidural administration of bupivacaine.

Other Local Anesthetics Other local anesthetics that have been used to achieve caudal epidural anesthesia in standing horses (weighing 500 kg) include 10 to 12 mL of 2% procaine HCl solution, 5 to 7 mL of 5% procaine HCl solution, and 3 to 5 mL of 5% hexylcaine HCl solution. The duration of anesthesia is dose related and ranges from 45 to 60 min for 2% procaine, 60 to 90 min for 5% procaine, and 90 to 120 min for 5% hexylcaine, respectively.⁵³ All of these local anesthetics provide relatively brief analgesia (45 to 120 min) and may necessitate readministration to enable completion of the procedure. If the needle is left in place and an injection cap is attached, additional amounts of local anesthetic can be administered to the desired effect.

Epidural α_2 -Adrenoceptor Agonists

The caudal epidural administration of an α_2 -adrenoceptor agonist, such as xylazine or detomidine, may be more appropriate for procedures requiring lengthy periods (>2 h) of analgesia. Following epidural administration, these agents bind to nonopioid receptors in the substantia gelatinosa layer of the spinal cord and produce spinal analgesia that can be attenuated by intravenous administration of α_2 -antagonists such as atipamezole (0.1 mg/kg)^{94–97} or yohimbine (0.05 mg/kg).^{98,99} Because the equine

spinal cord terminates in the lumbosacral area, agents administered into the caudal epidural space must diffuse cranially to bind with receptors in the spinal cord. In addition, xylazine may have a direct local anesthetic effect on the cauda equina.¹⁰⁰

Xylazine This drug has been injected into the caudal epidural space of ponies^{100–102} and horses^{90,103–108} for a variety of diagnostic, obstetric, and surgical procedures performed in the anal and perineal regions. In the first report of epidural administration of xylazine in horses, a dose of 0.17 mg of xylazine per kilogram of BW, diluted to a volume of 10 mL by use of sterile 0.9% NaCl solution, was used.¹⁰³ This dosage was considered safe and effective for producing 2½ h of perineal analgesia in horses and infrequently induced ataxia of the pelvic limbs. Subsequent studies, assessing the analgesic effects of caudal epidural xylazine (0.25 mg/kg BW expanded to a 6-mL volume with 0.9% NaCl) injection have supported these initial observations.^{106,107} Maximal dermatomal analgesic spread ranges from the first coccygeal to S3 spinal cord segments and usually lasts 2 to 3 h. Blockade of parasympathetic nerves may relax the genitalia and dilate the rectum.¹⁰⁷ Sedation and ataxia are minimal, and circulatory and respiratory variables—such as cardiac output, stroke volume, mean right atrial pressure, mean pulmonary artery pressure, systemic and pulmonary vascular resistance, oxygen consumption, core and rectal temperature, and arterial and mixed ve-

nous pH and gas tensions (partial pressure of oxygen [PO₂], and partial pressure of carbon dioxide [PCO₂])—do not change appreciably.¹⁰⁷

Epidural xylazine (0.15 mg/kg) administration reportedly decreases the halothane requirement of horses by 35% in the thoracic limbs and by 40% in the pelvic limbs, supporting the involvement of α_2 receptors in spinal analgesia.^{101,102} In a second study, a 1.5 minimum alveolar concentration of halothane alone and halothane with epidural xylazine (0.15 mg/kg BW diluted in 0.15 mL/kg of saline) administration did not induce a similar anesthetic response to hind-limb surgery.¹⁰⁸ Horses with epidural xylazine injection required less halothane (end-tidal halothane concentration, 0.9% vs. 1.4%) and inotropic support to maintain arterial blood pressure above 60 mm Hg and a higher cardiac index than did horses anesthetized with halothane alone.

Xylazine and Lidocaine A mixture of lidocaine (0.22 mg/kg, 2% solution) and xylazine (0.17 mg/kg, 2% solution) can be safely used for long-lasting caudal epidural anesthesia in healthy adult horses.⁹⁰ This combination provides longer anesthesia of the perineum than does either drug given alone (5 h vs. 3 h), thereby minimizing the need for additional drugs. Pulse and respiratory rate are not altered appreciably, though some ataxia may be present. Usually sedation is not evident after the epidural administration of these doses of lidocaine–xylazine HCl. Although the combined use of lidocaine and xylazine at this dose range appears to have a wide margin of safety, there has been one report of a sudden collapse in the hindquarters of a thoroughbred mare (450 kg) undergoing urogenital surgery 90 min after completion of the epidural injection.¹⁰⁹ As would be expected, overdosing either of these agents can depress CNS, respiratory, and cardiovascular activity; can cause postural instability and/or recumbency; and can induce excitement in conscious horses.

Detomidine Detomidine HCl (1%) at a dose of 60 μ g of detomidine/kg BW, expanded to a 10-mL volume with sterile water, injected into the epidural space at the caudal sacral (S5 to S4) vertebrae (catheter technique) induces selective caudal analgesia and sedation (Fig. 22.26), mild ataxia, cardiopulmonary depression, and diuresis similar to the effects of intravenously or intramuscularly administered detomidine.^{110–114} The analgesia induced with this technique can be variable, with bilateral spread from the coccyx as far cranially as T14 in some horses. Analgesia is often accompanied by mild ataxia and occasionally by buckling of the pelvic limbs. Horses appear deeply sedated and in a sleeplike state, evidenced by the lowering of their head and drooping of the upper eyelids. These signs are observed 5 min after drug administration and last 3 h. Doses of less than 30 μ g of detomidine/kg BW appear ineffective in producing reliable analgesia, although the sedation produced can be greater than expected. Higher doses (>80 μ g of detomidine HCl/kg) typically produce marked sedation, cardiopulmonary depression, increased frequency of second-degree atrioventricular heart block, renal diuresis, and recumbency, and cannot be recommended.¹¹² An initial dose of no more than 20 μ g of detomidine HCl/kg BW should be used in horses that are debilitated.

Fig. 22.26. Desensitized skin area between T14 and coccyx and sedation in a standardbred mare (475 kg) 60 min after administration of 2.9 mL of 1% detomidine hydrochloride solution, diluted to a 10-mL volume with sterile water, into the epidural space of the first coccygeal intervertebral space. The epidural needle (white arrow) is left in position. A catheter is placed into the subarachnoid space at the lumbosacral intervertebral space for collection of cerebrospinal fluid (CSF). From Skarda and Muir.¹¹⁰

In general, results indicate that xylazine is perhaps a more desirable α_2 -adrenoceptor agonist than is detomidine for inducing caudal epidural analgesia in horses. Xylazine exerts more potent antinociceptive action at the perineal dermatomes, with minimal cardiovascular depression, head ptosis, changes in pelvic limb position, and less renal diuresis.¹¹⁴

Should signs of rear-limb ataxia or motor blockade after caudal epidural administration of xylazine¹⁰⁹ or detomidine¹¹⁵ develop, a tail-tie support is indicated until full hind-limb control is regained. Use of general anesthesia may be necessary to immobilize an excited horse completely. If general anesthesia is induced, anesthesia in horses given detomidine as a caudal epidural injection should be maintained with a lower concentration of inhalant. In one case report,¹¹⁵ when a 364-kg, 15-month-old, sexually intact, cryptorchid male quarterhorse was positioned in standing stocks for castration, the horse unexpectedly collapsed to the floor, first to sternal and then into lateral recumbency, 15 min after epidural administration of 50 μ g of detomidine HCl/kg at the first intercoccygeal space and infusion of 60 mL of 2% lidocaine in an inverted “L” pattern to desensitize the left flank.¹¹⁵ Because the horse would not rise, general anesthesia was induced with intravenous diazepam (35 mg) and ketamine (750 mg). The horse was orotracheally intubated, and transported to the operating table. Anesthesia was maintained with halothane in oxygen (5 L/min) and surgery performed in the horse in dorsal recumbency. An expected smaller dose of halothane (<1.25%) was required to maintain a surgical plane of anesthesia in this horse, which recovered uneventfully 1 h and 55 min after discontinuation of halothane.¹¹⁵

α_2 -Agonist-induced adverse side effects can be eliminated by the intravenous, epidural, or subarachnoid administration of α_2 -adrenoceptor antagonists, such as atipamezole (Fig. 22.27), ida-

Fig. 22.27. Recording (10 mm/s) of lead II electrocardiogram (ECG), right atrial pressure (RAP), carotid arterial blood pressure (CAP), cerebrospinal fluid pressure (CSF), and cardiac output (Q) (thermodilution curve) before (control) **(A)**; 15 min after caudal epidural administration of 60 μ g of detomidine hydrochloride solution per kilogram body weight, diluted to a 10-mL volume, using sterile water **(B)**; and 15 min after intravenous administration of 120 μ g of atipamezole/kg **(C)**.

zoxan, yohimbine, or tolazoline.^{94–98} The antagonistic effects of intravenous yohimbine (0.05 mg/kg BW) given after caudal (Co1-Co2) epidural administration of detomidine HCl solution (60 µg/kg BW) on antinociceptive, cardiorespiratory, and postural changes have been documented. Intravenously administered yohimbine rapidly reduced detomidine-induced perineal analgesia, reversed head ptosis, improved pelvic limb position, terminated sweating and diuresis, and antagonized detomidine-induced decreases in heart rate and cardiac output; but did not affect detomidine-induced decreases in respiratory rate.⁹⁸

Medetomidine and Romifidine Medetomidine (15 µg/kg BW, diluted in 0.9% NaCl solution to 8 mL) injected into the epidural space at the first intercoccygeal vertebral space does not appear to produce surgical analgesia in the perineal region of adult horses.¹¹⁶ Likewise, romifidine (80 µg/kg BW diluted in 0.9% NaCl solution to 8 mL) injection into the epidural space at the first intercoccygeal vertebral space has not resulted in a sufficient analgesic effect, even though signs of sedation (drooping of the lower lip and leaning the head against the stocks) are evident.¹¹⁷ Based on the results of these studies, medetomidine and romifidine do not appear to be as efficacious as xylazine or detomidine when placed into the epidural space.

In summary, when choosing an α_2 -adrenoceptor agonist for epidural analgesia, either 0.17 mg of xylazine/kg¹⁰³ or 60 µg of detomidine/kg¹¹² diluted in 10 mL of 0.9% NaCl solution has proven efficacious in achieving similar anesthesia of pelvic viscera and genitalia with minimal ataxia. With these doses, maximum analgesic effect should occur within 10 to 30 min and can last several hours. It is not advisable to redose during this time. If the needle is left in place and an injection cap is attached, additional amounts of local anesthetic or α_2 -adrenoceptor agonist can be administered but should be regulated to keep the horse standing. In comparison, when relying solely on epidural local anesthetics, the duration of caudal analgesia is dose related and usually lasts 60 to 90 min with lidocaine (2%) or procaine (5%), and 90 to 120 min with either mepivacaine (2%) or hexylcaine (5%). Caudal epidurally administered local anesthetic solutions, when injected at recommended dosages, have minimal systemic side effects.

Epidural Ketamine

Ketamine is thought to produce analgesia primarily by its non-competitive antagonism of *N*-methyl-D-aspartate (NMDA). High concentrations of ketamine may also produce local anesthetic-like effects by blocking sodium-ion channels.¹¹⁸ The slow (1 min) injection of ketamine (0.5, 1.0, or 2.0 mg/kg BW) into the epidural space at the midsacral area (via a 17-gauge epidural catheter) has been reported to be effective in producing analgesia of the tail, perineum, and upper hind limb in horses.¹¹⁹ Ketamine can be diluted in 0.9% NaCl solution and the volume adjusted to a final volume of approximately 10 mL for a 450-kg horse. Dosages of 0.5, 1.0, and 2.0 mg of ketamine/kg BW provide analgesia of the tail for 30, 50, and 80 min and in the perineum and upper hind limb for 30, 35, and 75 min, respectively. A sedative effect is also observed in a dose-response manner, with a

peak effect between 15 and 30 min after ketamine epidural deposition. Heart and respiratory rates, arterial blood pressure, arterial blood gases (PO₂ and PCO₂), and pH are generally unaffected when these doses of ketamine are used for epidural deposition.¹¹⁹ Further studies are necessary to evaluate whether the analgesia produced by epidural ketamine is sufficient for surgery in horses.

The preemptive administration of ketamine (10%, 1.0 mg/kg BW, diluted with 0.9% NaCl solution to a total volume of 3.4 mL + [BW (kg) × 0.013]) into the epidural space at the midsacral vertebrae consistently reduced pain produced by a 10-cm skin incision in horses.¹²⁰ Cutaneous sensitivity was measured using von Frey filaments around the incision immediately after, 15 min after, and 2, 4, 6, and 8 h after suturing. When using this same method of assessing cutaneous sensitivity after skin incision, S+ ketamine (1.0 mg/kg BW, diluted with 0.9% NaCl solution to a total volume of 3.4 mL + [BW (kg) × 0.013]) reduced cutaneous sensitivity to mechanical stimuli for 75 min.¹²¹ From these direct comparisons of the preemptive analgesic effects of epidurally administered S+ ketamine and racemic ketamine, it appears that both forms produce similar postincisional analgesic effects.^{120,121}

Ketamine and Xylazine

A combination of ketamine (1.0 mg/kg) and xylazine (0.5 mg/kg) have been mixed in a syringe and injected into the epidural space at the first intercoccygeal (Co1-Co2) vertebral space in adult horses to produce good analgesia of the tail, perineal region, anus, and vulva. Analgesia is evident in 5 to 9 min and lasts on average 120 min.¹²² The region of analgesia extends to the thigh and flank in some horses. As could be expected, the ketamine-xylazine combination usually induces mild sedation, as assessed by drooping of the head and the lower lip 20 min after injection. Heart and respiratory rates are often reduced after epidural drug administration.

Other Agents

Epinephrine

At a concentration of 5 µg/mL (1:200,000), epinephrine can be added to the local anesthetic solution to hasten the onset, prolong the duration, and improve the quality of epidural anesthesia. Carbonization of the base preparations of lidocaine increases pH and favors the anesthetic nonionic state and lipid solubility but does not demonstrate the theoretical advantage of increased diffusion and drug effect during caudal epidural anesthesia in horses.⁸⁹

Alcohol

Alcohol (ethyl alcohol) has been injected into the caudal epidural space in horses to denervate coccygeal nerves and alter tail function, although its efficacy and safety for producing neurolysis in horses have not been reported. Axonal degeneration appears 20 min after injection and lasts several months to 1 year, depending on the completeness of neurolysis. Alcohol-induced alteration of tail motor function in horses can be diagnosed by electromyography and used as evidence to prosecute owners and exhibitors who may be inappropriately using this technique in show-ring

horses.¹²³ Inaccuracy of the technique and injection of excessive volumes of alcohol into the caudal epidural space produce painful paresthesias, neuritis, and paralysis of the bladder, rectum, and pelvic limb.

Continuous Caudal Epidural Anesthesia

Continuous caudal epidural anesthesia can be used in horses for extended surgery in the anal and perineal region, for obstetric procedures, and for relief of tenesmus.^{124–128} A 10.2-cm, 18-gauge thin-walled Tuohy needle with stylet is aseptically inserted on the midline into the Co1-Co2 interspace. Pain from needle insertion is minimized with a subcutaneous wheal of 2 to 3 mL of 2% lidocaine HCl. Once through the skin, the needle, with the bevel pointed cranially, is directed at approximately 45° to vertical and advanced until an abrupt reduction in resistance to needle passage is noted, indicating piercing through the interarcuate ligament and entry into the vertebral canal. The injection of 5 mL of air or 2 to 3 mL of local anesthetic (test dose) should not encounter resistance. Apparently, the injection of 10 mL of sterile 0.9% NaCl solution into the epidural space does not greatly facilitate the advancement of an epidural catheter and is therefore not routinely recommended.¹²⁹ A commercially available 91.8-cm, 20-gauge Teflon epidural catheter with graduated markings and stylet or a medical-grade vinyl tubing (0.036-cm outside diameter) can be introduced into the needle and advanced cranially 2 to 4 cm beyond the tip of the needle (A in Fig. 22.28). The needle can then be removed from the catheter while the catheter is left in position. A catheter adapter (provided in the kit) or a three-way stopcock and 2.5-cm, 23-gauge needle is placed on the free end of the catheter for an injection port. A newer technique, which greatly facilitates epidural catheter insertion in horses, and has also been used by the author, involves the use of the Tuohy needle to which a Y piece with a latex balloon and catheter are attached (Fig. 22.29A). The needle is inserted until the balloon collapses under the negative pressure of the epidural space; the epidural catheter is then introduced into the needle from the other arm of the Y piece and advanced cranially as required (Fig. 22.29B). If the first of the four mark strips of the Teflon epidural catheter has reached the needle hub, the catheter has advanced 9 cm beyond the tip of the needle, thereby placing the epidural catheter tip at the midsacral S3 vertebral level in an adult horse (450 kg). The needle is then carefully removed while the catheter is left in position. A catheter adapter with luer lock (provided in the kit) is placed on the free end of the catheter, and an epidural filter (provided in the kit) is placed between the syringe and catheter adapter. All connections should be without leaks. The epidural catheter is sutured to the skin, and the skin-puncture site is covered with a sterile gauze, which is also sutured to the skin (Fig. 22.29C). Approximately 5 mL of anesthetic solution is then injected into the catheter over a 1-min period. Surgical anesthesia is easily maintained by fractional bolus administration of 3 mL of the anesthetic at 1-h intervals or as needed.

In an alternative, but more difficult, method, a 19.5-cm, 17-gauge Huber-point Tuohy needle with the bevel directed caudally is aseptically inserted into the epidural space at the lumbosacral (L6-S1) intervertebral space.¹²⁴ A Formocath polyethylene

Fig. 22.28. Lateral radiograph of the sixth lumbar to second coccygeal area. **A:** A 10.2-cm, 18-gauge thin-walled Tuohy needle inserted at the Co1-Co2 interspace to insert a 20-gauge Teflon epidural catheter into the caudal (S5) sacral epidural space. **B:** A 19.5-cm, 17-gauge Huber-point Tuohy needle inserted at the lumbosacral (L6-S1) intervertebral space to insert a Formocath polyethylene catheter reinforced with a steel spring guide into the midsacral (S2-S3) epidural space.

catheter (0.095-cm outside diameter) reinforced with a stainless-steel spring guide is introduced into the needle and advanced 10 to 20 cm, to place the catheter tip at the caudal position of the sacral (S3 to S5) epidural space in an adult horse (450 kg) (B in Fig. 22.28).

A safe and convenient route for repeated administration of small fractional doses of the local anesthetic during surgery, while the tail is dorsally reflected for immobilization and surgical exposure, is the major advantage of the catheter technique when compared with the needle technique. In addition, the catheter tip is placed at the nerve roots of the pudendal and pelvic nerves, thus minimizing the dose of anesthetic required to produce caudal anesthesia. Fibrosis of the extradural space from repeated standard epidural blocks is avoided. The disadvantages of the catheter technique include greater cost of equipment, and complications from kinking and curling of the catheter and occlusion of the tip with fibrin. Optimal timing and amounts of repeated anesthetic doses, development of tachyphylaxis (acute tolerance to repeated injections), and augmented responses to long-term effects of repeated caudal epidural anesthesia in horses have not been reported.

Continuous Caudal Subarachnoid Anesthesia

This may be induced by repeated injections of local anesthetic solution (mepivacaine or ropivacaine) or α_2 -adrenoceptor agonists (xylazine or detomidine) through a catheter introduced into the caudal subarachnoid space with a Tuohy needle (Fig. 22.30). The use of continuous caudal subarachnoid anesthesia in practice is limited owing to technical difficulty and potential trauma to the conus medullaris and nerve fibers by the needle or catheter, but it can be accomplished safely in horses while maintaining pelvic limb function with certain advantages when compared with epidural administration: Subarachnoid administration of local

Fig. 22.29. **A:** A 10.2-cm, 18-gauge thin-wall Tuohy needle is inserted at the Co1-Co2 interspace. The needle is attached to a Y piece containing a latex balloon. The tip of a 91.8-cm, 20-gauge Teflon epidural catheter is inserted into the other free end of the Y piece. **B:** The Tuohy needle is inserted until the latex balloon collapses under the negative pressure of the epidural space (as indicated by the two arrows). The catheter is then advanced rostrally for a desired distance. **C:** The epidural catheter is sutured to the skin, and the skin-puncture site covered with a sterile gauze pad, which also is sutured to the skin.

anesthetics or α_2 -adrenoceptor agonists requires approximately threefold less drug for a similar degree of caudal anesthesia, and the onset of anesthesia is twice as fast and the action lasts half as long as after epidural injection.¹²⁴

The roots of the spinal nerves within the subarachnoid space are not covered by protective dural sheets and are more readily desensitized, making caudal subarachnoid analgesia the fastest and best-controlled surgical analgesia in horses. Incomplete or asymmetrical analgesia because of septa within the epidural space or inadequate dispersal of the anesthetic because of epidural fat is avoided.

In most adult horses, a 19.5-cm, 17-gauge Huber-point directional needle with the bevel directed caudally can be introduced through disinfected desensitized tissue at the lumbosacral (L6-S1) intervertebral space. Depth of needle penetration ranges from 11 to 14 cm in adult horses. When the needle point is judged to have passed through the tough interarcuate ligament (ligament flavum), by noticing an abrupt reduction in resistance to needle passage, the stylet is removed and approximately 1 mL of 2% carbocaine HCl solution or its equivalent is injected. The syringe

is filled with 2 mL of air and attached to the needle, which is then advanced continuously until a second sudden loss of resistance to air injection is noted, indicating that the dura has been penetrated. The subarachnoid space is then identified by free flow of CSF from the needle hub or aspiration of CSF. With full aseptic precaution, a 30-cm Formocath polyethylene catheter (0.062-cm outside diameter), reinforced with a stainless-steel spring guide, is passed and advanced approximately 25 cm to the midsacral region. The catheter tip cannot be advanced beyond this point, which is usually the end of the subarachnoid space (Fig. 22.30).

When using this technique, not more than 1.5 to 2.0 mL of 2% mepivacaine HCl is injected over a 3-min period (0.5 mL/min) to produce excellent bilateral caudal anesthesia from spinal cord segment S2 to coccyx within 5 to 10 min. Surgical anesthesia lasts approximately 0.5 to 1.5 h and is easily maintained by fractional bolus administration of 0.5 mL of the anesthetic at 30-min intervals or as needed.¹²⁴ A similar pattern of local anesthetic spread (faster absorption of drug from the epidural space and similar maximum venous plasma concentrations after epidural and subarachnoid injections) has been reported after midsacral epidural (S2-3 to

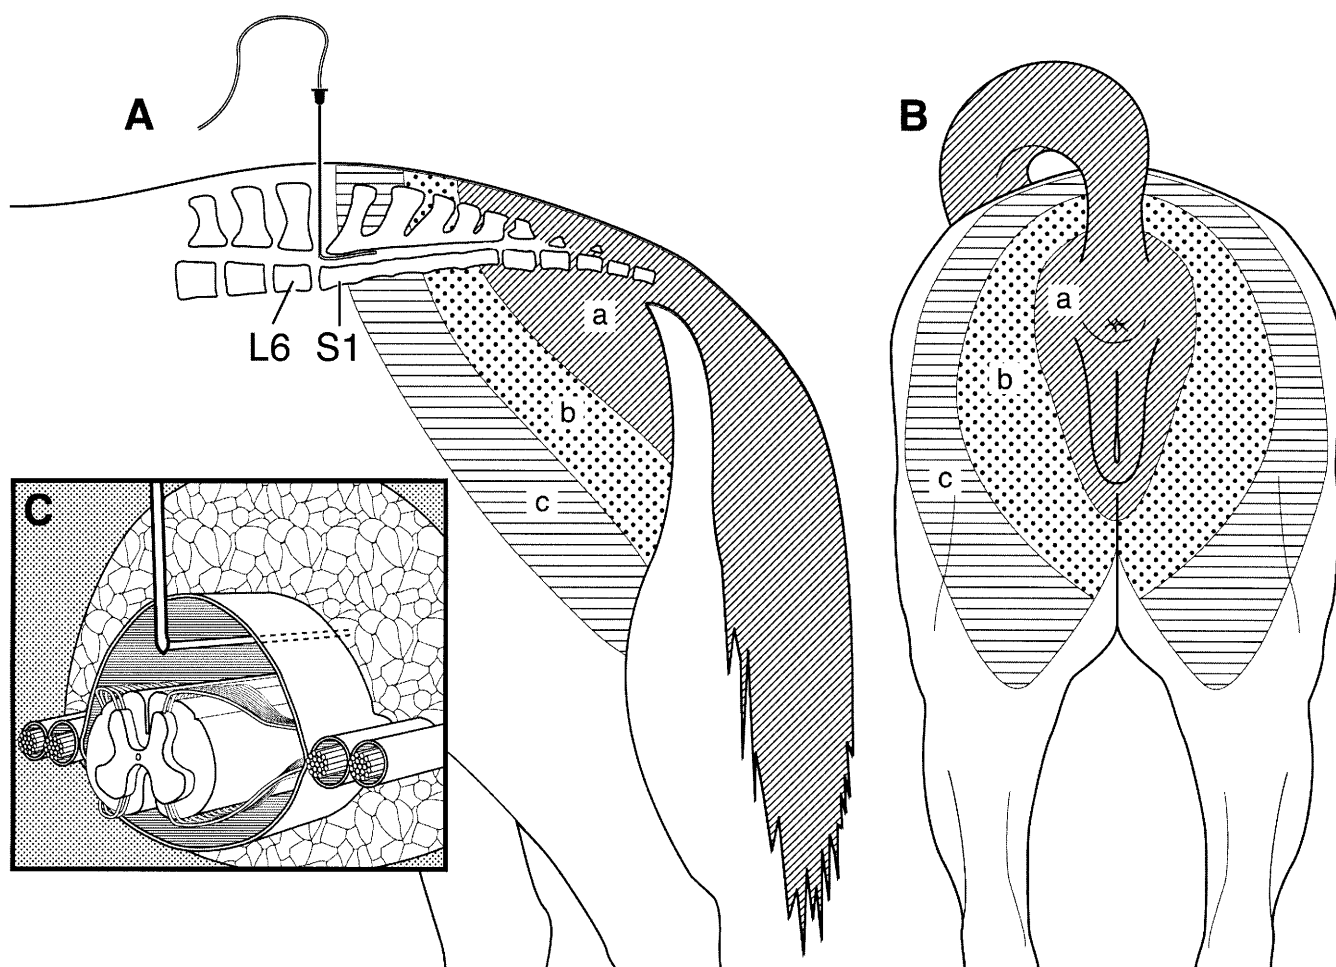

Fig. 22.30. Lateral (**A**) and caudal (**B**) drawings of the lumbosacral, sacral, and sacrococcygeal area of a standing mare with marked loss of skin sensation from coccyx to S4 (a), coccyx to S2 (b), and coccyx to S1, respectively, 30 min after midsacral subarachnoid administration of ropivacaine hydrochloride (0.2% solution, 5 mL/500 kg body weight). **C (inset):** A cranial-left lateral aspect of a transection of the first sacral vertebra at the location of the intervertebral foramen and its associated intraspinal structures with the tip of Huber-point (Tuohy) needle, catheter, and steel spring guide in the subarachnoid space. From Skarda and Muir.¹¹⁰

S5-Co1) and subarachnoid (S2-3) administration of mepivacaine HCl in aqueous solution (2%).⁹² The venous plasma concentrations of mepivacaine determined during caudal epidural and subarachnoid analgesia did not produce measurable direct effects on heart rate, arterial blood pressure, arterial pH, and hematocrit.⁹²

The analgesic, hemodynamic, respiratory, and behavioral alterations of horses after midsacral (S-2 to S-3) subarachnoid administration of ropivacaine (0.2%, 5 mL) HCl solution have been assessed.¹³⁰ Numerical scores of sedation, change in pelvic limb position, sweating in analgesic zones, urination, behavior, response to noise, and compliance with restraint were determined before and during a 5-h testing period (Fig. 22.30). Subarachnoidly administered ropivacaine induced variable analgesia extending bilaterally from coccyx to S1, with minimal sedation and change in pelvic limb position in standing mares. Perineal analgesia was attained in 7 min and lasted for over 3 h. Subarachnoid ropivacaine significantly reduced respiratory rates, but did not change heart rates, rectal temperature, arterial blood pressure,

packed cell volume, arterial gas tensions (PO_2 and PCO_2), pH, standard bicarbonate, and base excess from baseline values. These results demonstrate that ropivacaine (0.2% solution, 5 mL/500 kg BW) can be administered subarachnoidly at the midsacrum (S2 to S3) to produce prolonged (>3 h) bilateral perineal analgesia with minimal changes in behavior and cardiopulmonary function in adult horses.

Similar to local anesthetic administration, detomidine HCl (1% solution), when administered at a dose of 30 $\mu\text{g}/\text{kg}$ into the midsacral subarachnoid space, induces analgesia that extends from dermatome T15 to the coccyx within 10 to 15 min after injection (Fig. 22.31). Analgesia persists for over 2 h, with minimal ataxia, cardiopulmonary depression, and marked sedation in standing horses.¹¹² Yohimbine (50 $\mu\text{g}/\text{kg}$ BW IV) or atipamezole (40 $\mu\text{g}/\text{kg}$ BW IV) can be used to effectively reverse subarachnoidly administered detomidine-induced sedation with partial antagonism of detomidine-induced analgesia, ataxia, and cardiopulmonary depression (Fig. 22.32).⁹⁵⁻⁹⁸

Fig. 22.31. Desensitized skin area between T16 and coccyx in a horse (460 kg) at 30 min after administration of 1.4 mL of 1% detomidine hydrochloride solution into the subarachnoid space of the midsacral (S2-S3) intervertebral space. The subarachnoid catheter (white arrow) is butterfly taped and sutured to the skin at the lumbosacral junction. Sedation was reversed 5 min after intravenous administration of 40 μ g of atipamezole/kg.

There is likely to be further interest in the advantages obtained by the intrathecal use of combinations of local anesthetics with adrenoceptor agonists or opioids. An important component of analgesia produced by opiates and α_2 -adrenoceptor agonists may be due to the inhibition of the release of neurotransmitters in the dorsal spinal cord from primary afferent terminals, thus preventing further propagation of nociceptive signals. Only preservative-free solutions should be administered into the subarachnoid space. Precise dosage (milligrams, milliliters, and specific gravity), catheter positioning, and aseptic technique are necessary to avoid serious complications such as meningitis, sciatic nerve dysfunction, rear-limb ataxia or motor blockade, recumbency, and cardiopulmonary depression or excitement in conscious horses.¹³¹⁻¹³³

Epidural Opioid Analgesia

Numerous studies evaluating the epidural administration of opioids—including morphine, butorphanol, methadone, meperidine, tramadol, alfentanil, and U50488H—have been published in the veterinary literature in recent years.¹³⁴⁻¹⁴⁴ Opioids can provide variable long-lasting analgesia when used alone or in combination with local anesthetics, α_2 -adrenoceptor agonists, and/or ketamine. They have been used for both acute and chronic pain and have proven effective when administered preemptively, intraoperatively, or postoperatively.

Epidural Opioids

Morphine

Caudal epidural morphine administration has been considered a reasonable alternative for the relief of pain that does not respond to standard medication protocols.¹³⁴ In one of the earliest reports,

pain originating from an open luxation of the fetlock joint and comminuted fracture of the first phalanx in a 10-month-pregnant thoroughbred mare was relieved approximately 30 min after injection of 50 mg of morphine, diluted in 30 mL of 0.9% NaCl solution, into the epidural space at the sacrococcygeal interspace. It was judged that analgesia lasted 8 to 16 h, based on the mare's normal behavior (i.e., prolonged period of standing, no sweating, a normal appetite, and a normal heart rate). Analgesia was continued for 3 days by injecting additional morphine (0.2 mg/kg) into an epidural catheter (91.4 cm, 20 gauge) placed into the sacral epidural space by using an 8-cm, 16-gauge Tuohy needle.¹³⁴ In a second study, 50 to 100 μ g of morphine/kg BW in 10 mL of 0.9% NaCl solution, injected into the epidural space at the first coccygeal interspace (Co1-Co2), produced analgesia lasting 17 to 19 h. Indirect arterial blood pressure, heart rate, respiratory rate, and rectal temperature did not change. Although the occurrence of pruritus (evident perineal wheals) in horses may be low, the author has observed this adverse side effect after the epidural use of morphine in horses (Fig. 22.33). Reportedly, epidural morphine (0.05 to 0.1 mg/kg BW) can produce segmental analgesia that preferentially affects the dorsal nerve branches of the lumbosacral plexus.¹³⁶ With higher doses (e.g., 100 μ g/kg), epidural morphine may be accompanied by sedation and head drooping, while producing a more rapid onset, cranial spread, and longer duration. These effects are not typically observed with lower dose (e.g., 50 μ g/kg) administration.¹³⁵

Morphine (0.1 mg/kg BW) diluted in a volume of 20 mL of sterile water and administered into the epidural space at the first coccygeal (Co1-Co2) intervertebral space induces variable segmental analgesia extending from the coccyx to the thoracic dermatomes.¹³⁷⁻¹³⁹ Analgesic action is greatest at the dermatomes closest to the epidural injection site. Analgesia (avoidance response, >40 V) in the perineal and sacral areas lasted for 5 h after the morphine injection. Head ptosis was observed within the first hour after administration of morphine, but no morphine-related changes in motor activity or behavior were observed.¹⁴⁰

Butorphanol

This drug is often described as a κ opioid partial agonist and μ -antagonist and has been widely used as a systemic analgesic in many species, including horses. When butorphanol (0.08 mg/kg BW, in a total volume of 20 mL of sterile water) is injected into the first intercoccygeal epidural space in horses, no changes are observed in avoidance thresholds to noxious electrical stimulation of the dermatomes of the perineal, sacral, lumbar, and thoracic regions.¹³⁷⁻¹³⁹ Changes are not evident in heart and respiratory rates, arterial blood pressure, rectal temperature, and motor activity. Further evidence of the minimal direct epidural analgesic effect of this opioid in horses includes its lack of effect, following caudal (Co1-Co2) epidural administration (0.05 mg/kg BW), on the minimum alveolar concentration (MAC) requirement of halothane.¹⁴³

Methadone

This is a synthetic diphenylpropylamine opioid. A racemic mixture of levorotatory (L) and dextrorotatory (D) methadone is

Fig. 22.32. Recording (10 mm/s) of lead II electrocardiogram (ECG), pulmonary artery pressure (PAP), carotid arterial blood pressure (CAP), and cardiac output (Q) (thermodilution curve) before (control) (A), at 10 min after sacral (S1-S2) subarachnoid administration of 30 μ g of detomidine hydrochloride solution/kg (B), and at 10 min after intravenous administration of 50 μ g of yohimbine/kg (C).

Fig. 22.33. Standardbred mare (470 kg) with multiple wheals over a body area extending from the coccyx to midthoracic region 20 min after caudal (Co1-Co2) epidural administration of morphine sulfate (0.15 mg/kg body weight) in 15 mL of 0.9% sodium chloride solution. Urticaria spontaneously cleared up 18 h later.

available in Europe for clinical use as an aqueous preservative-free solution (Heptadon, 10-mg ampullae; Ebewe Arzneimittel [BASF Pharma], Unterach, Austria). Olbrich and Mosing¹⁴⁴ have compared the effects of caudal epidural administration of methadone (0.1 mg/kg BW) and lidocaine (0.35 mg/kg BW), each diluted with sterile 0.9% NaCl solution to a total volume of 20 mL, on tolerance to thermal stimulation (62°C) of perineal, sacral, lumbar, and thoracic dermatomes. With both drugs, analgesia progressed from the coccyx to cranial in a time-related manner. Perineal analgesia was evident within 15 min of completing methadone or lidocaine injection. Analgesia of the flank region and 13th rib was observed 2 h after the methadone administration, and lasted for 2 and 3 h at the rib and flank, respectively. Perineal analgesia lasted 5 h after methadone injection, compared with 3 h following lidocaine. Analgesia was not produced at the lateral aspect of the crus and the coronary band of the pelvic limbs after methadone or lidocaine administration. Methadone-treated horses defecated and urinated normally, and

demonstrated no excitement, sedation, or ataxia. In contrast, epidural lidocaine caused moderate to severe hind-limb ataxia. Sweating occurred at the injection site and on the medial aspect of the hind limbs as early as 5 min after lidocaine injection in some horses.

Meperidine

This is a synthetic phenylpiperidine-derivative opioid and exerts the strongest local anesthetic effect among the clinically used opioids. Epidural injection of meperidine (Demerol 5%; Abbott Laboratories, North Chicago, IL) may be useful for inducing caudal epidural analgesia in standing conscious horses undergoing prolonged diagnostic, obstetric, or surgical procedures in the anal and perineal region. Meperidine (5%, 0.8 mg/kg BW) administered via epidural injection at vertebral levels extending from the sacrococcygeal intervertebral space to the fifth sacral vertebra induces bilateral analgesia extending from the coccygeal to first sacral dermatomes. The degree of sedation and ataxia induced is minimal (Fig. 22.34).^{145,146} The mean onset of perineal analgesia in response to noxious electrical (<80 mA), thermal (<48°C), and skin-prick stimulation was 12 min after meperidine administration, with the analgesia lasting from 240 to over 300 min.¹⁴⁶ These results are supported by a second study, in which meperidine (5%, 0.6 mg/kg BW), administered epidurally between the first and second coccygeal vertebrae, induced bilateral perineal analgesia in less than 10 min. The analgesic effect lasted, on average, 4 h, with minimal cardiovascular effects, sedation, and motor blockade.⁹³

Tramadol

This drug is a centrally acting synthetic analgesic drug with both an opioid and nonopioid mechanism of action. Tramadol (Silador or Sanofi; Tramadol Caraco Pharmaceutical Laboratories, Detroit, MI) is available as an injectable formulation for clinical use as an analgesic that does not cause the typical opioid side effects of respiratory depression, constipation, and sedation.¹⁴⁷ When administered epidurally in humans, tramadol is one-thirtieth as potent as morphine.¹⁴⁸ Tramadol (1.0 mg/kg BW) has been diluted in a total volume of 20 mL of sterile water and injected epidurally at the first intercoccygeal epidural space in adult horses. Analgesia (avoidance threshold, >40 V) is produced in the perineal and sacral areas within 30 min and provides analgesia for up to 4 h.^{137–139} In comparison, complete perineal and sacral analgesia is present for 6 h after epidural injection of morphine (0.1 mg/kg BW) in an equal volume of sterile water (20 mL). Epidural morphine analgesia will typically last up to 5 h, indicating that at these doses epidural tramadol induces analgesia of faster onset but shorter duration than does epidural morphine.¹³⁹

Alfentanil

Alfentanil (Alfenta; Janssen Pharmaceutical, Piscataway, NJ) is considered to be a highly lipid soluble and potent μ opioid analgesic. When injected into the caudal (Co1-Co2) epidural space of horses at a dosage of 0.02 mg/kg BW diluted to 20 mL of sterile water, alfentanil produced rapid (20 min), but minimal, perineal

Fig. 22.34. Photograph of a healthy thoroughbred mare (615 kg) with marked area of loss of skin sensation between S1 and coccyx on the right side and sedation at 30 min after injection via needle of meperidine hydrochloride solution (5%; 0.8 mg/kg body weight) into the epidural space at the fifth sacral vertebra. The epidural needle with syringe attached is still in place. The ME indicates the epidural injection of meperidine.

and sacral analgesia without signs of CNS excitation.^{137–139} The perineal and sacral analgesic effects induced by epidural alfentanil were considered minimal by the investigators.

Epidural Drug Combinations

Morphine and Detomidine

The combination of morphine (0.2 mg/kg) and detomidine (30 µg/kg) injected via a catheter inserted into the epidural space at the first intercoccygeal space and advanced to the lumbosacral region produces significant analgesia in experimentally induced hind-limb lameness (noticeable both at walk and at trot).^{149,150} Results indicate that the epidural combination of morphine and detomidine can provide profound analgesia for equine hind-limb pain. The preoperative caudal epidural administration of morphine (0.2 mg/kg) and detomidine (30 µg/kg) has also been effective in decreasing lameness after painful bilateral stifle arthroscopy.¹⁵¹ The systemic and local effects associated with long-term epidural catheterization and repeated morphine (0.2 mg/kg) and detomidine (0.03 mg/kg) administration (every 12 h) for 14 days revealed no difference in CSF values or spinal tissue inflammation or fibrosis in the control versus treatment horses.^{152,153} Gross and histological examination of spinal tissue segments from the cervicothoracic, thoracolumbar, lumbosacral, and sacral spinal cord, and the catheter entry point itself, did not reveal evidence of adverse systemic effects of long-term epidural morphine-detomidine administration. However, a degree of lumbosacral and sacral spinal tissue inflammation and fibrosis was evident in catheterized horses, indicating that localized inflammation and fibrosis were likely catheter related and not drug related.¹⁵³

Butorphanol and Lidocaine

Butorphanol (0.04 mg/kg) has been added to lidocaine (0.25 mg/kg) for injection into the caudal epidural space of adult mares.¹⁴² When compared with the effects of epidural lidocaine (0.25 mg/kg BW) alone, the addition of butorphanol in non-sedated horses prolonged both cutaneous (fivefold longer) and visceral (eightfold longer) analgesia. A cranial extension of the cutaneous analgesia was also observed. However, horses demonstrated an unusual way of walking (high steps with pointed hoof) in their hind limbs (hyperkinesias), even though ataxia and weakness were not evident.¹⁵⁴

Morphine and Romifidine

The analgesic, hemodynamic, and behavioral effects of caudal epidurally administered romifidine (30 or 60 µg/kg BW) combined with morphine (0.1 mg/kg BW) have also been evaluated in adult horses.¹⁵⁵ The analgesic effect induced was judged to be moderate. The duration of analgesia was dose dependent, with the 30-µg/kg dose providing 60 min of analgesia and the 60-µg/kg dose providing 90 min of analgesia when combined with 0.1 mg/kg of morphine. Intense sedation and moderate ataxia of the hind limbs were observed during the 4-h observation period. Heart and respiratory rates were decreased.¹⁵⁵

Tiletamine and Zolazepam

Tiletamine is a phencyclidine derivative similar to ketamine, although more potent. Zolazepam is a benzodiazepine derivative licensed for use exclusively in combination with tiletamine in animals. The proprietary tiletamine-zolazepam combination (100 mg/mL [Telazol; Fort Dodge Laboratories, Fort Dodge, IA]) has been injected into the epidural space of horses at a dose of 0.5 and 1.0 mg/kg BW, diluted up to 5 mL in sterile water. Only a mild analgesic effect in response to threshold-to-pressure stimulation of the perineal area was observed.^{156–158} Sedation was not observed and, although all horses remained standing, they were ataxic, demonstrating poor coordination of the hind limbs and fetlock flexion when they were walked out of the stocks. Muscle fasciculation and vigorous head-and-neck movements and dilated nares were observed in one mare 15 min after injecting the 1.0-mg dose of tiletamine-zolazepam/kg epidurally.

Tramadol and Fentanyl

A single caudal (Co1-Co2) epidural injection of a mixture of tramadol (1 mg/kg BW) and fentanyl (5 µg/kg BW) in 20 mL of sterile water reportedly induced analgesia in the perineal and sacral structures within 60 min of injection. Analgesia persisted for 12 to 18 h, with mild sedation and ataxia present in some horses.¹⁵⁹

Although the pharmacological, pharmacokinetic, and clinical effects of epidurally coadministered local anesthetics, opioids, α₂-adrenoceptor agonists, and ketamine have not been fully characterized in horses, these drugs are increasingly being used by this route in an attempt to better manage equine pain. Further studies are necessary to determine the effectiveness of combining these drugs in the treatment of various soft tissue (e.g., perineal injury, lacerations, and septic arthritis) and orthopedic pain syn-

Fig. 22.35. Needle placement for right intratesticular injection in a standing horse.

dromes (e.g., fracture repair). When drug mixtures are used, the severity of pain should be assessed daily and the response to treatment recorded in the medical record.¹²⁸

Anesthesia for Castration

One of the most commonly performed surgical procedures in general equine practice is castration. Regional anesthesia can be accomplished by injecting local anesthetic drug into the scrotum, testicle,^{160,161} and spermatic cord.^{162,163} Standing castrations are generally restricted to tractable yearlings and 2-year-olds. Proper restraint of the horse's head and sedation (e.g., tranquilizer-narcotic or sedative-narcotic combination) are required. The horse may be placed with its side against a wall and a twitch applied to its upper lip. The person holding the twitch should stand on the same side as the operator. The skin of the scrotum and prepuce is surgically prepared, and one of three techniques is used. In one technique, a 7.5-cm, 20-gauge needle is quickly inserted perpendicularly through the tensed skin of the scrotum, and 20 to 30 mL of local anesthetic is injected into the center of each testicle (Fig. 22.35). The local anesthetic should make the testicle firm and reach the inguinal canal within 90 s via lymph vessels for the blockade to begin.¹⁶⁰ Castration can usually be performed painlessly 10 min after the injection with no further use of the twitch. In a second method, percutaneous anesthesia of the spermatic cord is accomplished by inserting a 2.5-cm, 20-gauge needle into the cord as close to the external inguinal ring as possible, where 20 to 30 mL of local anesthetic is injected in a fan-shaped manner without perforating the skin, spermatic artery, and vein. The proposed incision line of the scrotal skin must also be infiltrated subcutaneously with 5 to 10 mL of the anesthetic because the scrotal skin is not desensitized by the deposition of anesthetic into the dartos or the substance of the testicle itself. The proce-

dures are repeated to desensitize the opposite spermatic cord and scrotum. Infiltration of the spermatic cord is less effective than intratesticular infiltration for producing local anesthesia for castration. In a third method, a 15-cm, 18-gauge needle is inserted into the testicle and directed into the spermatic cord while 30 mL of the anesthetic is being injected. The incision sites of the scrotal skin are also infiltrated. Since the testes are to be removed, damage to them is unimportant. More refractory horses are castrated under general anesthesia.¹⁶⁴

Anesthesia of the Perineum

Regional anesthesia of the perineum enables perineal surgery, including urethrostomy, in standing horses. Perineal anesthesia is accomplished by desensitizing the superficial and deep (subfascial) branches of the perineal nerves. These branches arise on both sides of the anus and pass ventrally over the ischial arch to the scrotum. A 2.5-cm, 22-gauge needle is inserted approximately 2.5 cm dorsal to the ischial arch and 2.5 cm lateral to the anus in order to inject 5 mL of local anesthetic subcutaneously. A deeper subfascial injection of 5 to 7 mL of the anesthetic is then performed after the needle is directed dorsally 0.5 to 1.0 cm. The procedure is repeated at the opposite site.¹⁶⁵

Anesthesia of the Penis or Vulva

The penis or vulva is anesthetized by desensitizing the ventral branches of the pudendal nerve. First the perineal nerves are desensitized as described above, and then a 5-cm, 20-gauge needle is inserted at the same site as for perineal nerve anesthesia and is advanced toward the midline to strike the ischiatic arch. Approximately 10 to 20 mL of local anesthetic is injected (Fig. 22.36).¹⁶⁶ The procedure is repeated at the opposite site.

Therapeutic Local Analgesia

Infiltration of sympathetic nerves by local anesthetic solution effectively interrupts reflex spasm of local vasculature and pain. The two common sites where the equine sympathetic nervous system is desensitized most effectively are the cervicothoracic (stellate) ganglion and the paralumbar sympathetic ganglia. Sensory and motor interruption does not result unless the thoracic or lumbar somatic nerves have been desensitized by faulty technique.

Cervicothoracic (Stellate) Ganglion Block

Infiltration of the cervicothoracic ganglion (CTG) in horses with local anesthetic solution is effective and therapeutically recommended for relief of vasoconstriction and pain in the head, neck, and front leg (Fig. 22.37). It can be successfully accomplished in horses with a variety of skin, muscle, nerve, and joint and tendon sheath diseases.^{167,168} A single CTG blockade is effective in acute disorders, whereas two or three blockades are required for good results in chronic conditions of idiopathic shoulder lameness, radial nerve paralysis, and eczema of the head and neck.

The CTG is best reached from a cranial and paratracheal approach in a horse bearing equal weight with both thoracic limbs. The skin-puncture site is 12 to 17 cm dorsal to the intermediate

Fig. 22.36. Topographic anatomy for perineal and pudendal nerve block. The palpable ischiatic arch (a) and ischiatic tuberosity (b) are marked. Infiltration of the left pudendal nerve with local anesthetic is shown. From Skarda.³

tubercle of the humerus in the jugular furrow dorsal to the jugular vein and carotid artery. This area is aseptically prepared and infiltrated with 2 to 3 mL of local anesthetic solution. A 25-cm, 16-gauge needle is inserted through the desensitized skin and advanced horizontally or 5° dorsomedially until it impinges on the transverse process or body of the seventh cervical vertebra, and 2 to 3 mL of the anesthetic is injected (A in Fig. 22.38). The depth of needle penetration ranges from 10 to 15 cm, depending on the size of the musculus longus colli. The needle is first partially withdrawn and then reinserted more laterally and ventrally, thereby bypassing the seventh cervical vertebra and reaching the articulations of the first and second ribs (B in Fig. 22.38). The needle is then 15 to 20 cm from the surface of the skin.¹⁶⁹ After aspiration to be sure that the needle point has not entered a blood vessel, the pleural cavity, or subarachnoid space, approximately 50 mL of 1% lidocaine HCl in aqueous solution is injected with minimal resistance. This amount of anesthetic diffuses throughout the tissues surrounding the CTG. An additional 50 mL of lidocaine is injected during withdrawal of the needle for 5 to 10 cm to desensitize the sympathetic fibers between the CTG and the eighth cervical spinal nerve. Adequate sympathetic blockade is indicated by ipsilateral, increased subcutaneous temperature (up to 3°C) and profuse sweating of the head, neck, and thoracic limb; ipsilateral Horner's syndrome (e.g., ptosis, miosis, and enophthalmos) (Fig. 22.39A); and ipsilateral paresis. These signs are present 10 to 15 min after injection and last more than 75 min. The appearance of Horner's syndrome with no increase in subcutaneous temperature of the thoracic limb indicates that the CTG blockade has not been effective and sympathetic nerve supply to the thoracic limb has not been interrupted for therapeutic purposes.

Increased skin temperature is related to increased blood flow to muscle and cutaneous vascular beds and develops despite the

Fig. 22.37. Restraint of a thoroughbred mare (520 kg, 7 years old) during infiltration of the right-side cervicothoracic ganglion (CTG) with 1 g (100 mL of a 1% lidocaine hydrochloride solution) of lidocaine. Plasma lidocaine concentrations were 0.5 and 0.35 µg/mL at 30 and 60 min after injection. Pain relief from fetlock arthrodiesis after comminuted P1 fracture and secondary osteomyelitis was evident by more weight bearing and food uptake for at least 3 days after CTG blockade.

cooling effect of profuse sweating. Factors responsible for sweating include blood supply and, hence, increased heat in the area, higher metabolism in sweat glands, and central stimulation caused by the horse's excitement. Horner's syndrome is caused by the interruption of the oculosympathetic pathway at the site of the CTG block and/or at the site of the ventral sympathetic roots between the eighth cervical and second thoracic spinal nerves.

Unilateral CTG blockade minimally changes heart rate, cardiac output, aortic blood pressure, and total peripheral resistance in conscious horses.¹⁷⁰ Maximal plasma concentrations of lidocaine after unilateral CTG blockade in adult horses have been reported, indicating that a toxic blood concentration was not present.¹⁷⁰ Ipsilateral laryngeal paralysis, decreased respiratory rates, and increased arterial carbon dioxide partial pressure (PaCO₂) are indicative of vagal inhibition. However, hypoventilation in resting horses is not severe enough to induce significant respiratory acidosis or hypoxemia. Potential serious complications are transitory brachial plexus and recurrent laryngeal nerve paralysis and pneumothorax. Bilateral CTG blockade is contraindicated in horses.

Fig. 22.38. Needle placement to seventh cervical vertebra (A) and cervicothoracic (stellate) ganglion (B) (left side).

Paravertebral Lumbar Sympathetic Ganglion Block

Infiltration of the lumbar sympathetic ganglia in horses with local anesthetic solution has been demonstrated as a therapeutic measure for myositis, periostitis, coxitis, and paralysis of the fibular and penile nerves.^{167,168} Although any of the interspaces between the 18th thoracic and fourth lumbar vertebrae may be used as possible sites to reach the lumbar sympathetic ganglia, the ideal puncture site is between the transverse processes of the second and third lumbar (L2 and L3) vertebrae, about 10 to 15 cm lateral to their spinous processes. This area is aseptically prepared and infiltrated with 2 to 3 mL of local anesthetic. A 25-cm, 18-gauge needle with a marker on the needle shaft is inserted through the desensitized skin and advanced until its tip contacts the transverse process of L2 or L3. The marker is used to note the depth of penetration (A in Fig. 22.40). The needle is partially withdrawn to the subcutaneous area and reinserted at approximately 45° from vertical for a calculated distance, which equals the distance between the marker (skin puncture) and the needle point plus an additional 5 to 8 cm (B in Fig. 22.40). The needle is correctly placed if there is no air from the peritoneal cavity or blood from a blood vessel upon needle aspiration and no resistance to the injection of local anesthetic results. Approximately 100 mL of 1% lidocaine HCl solution is slowly injected. This amount of anesthetic diffuses throughout the tissues surrounding the sympathetic trunk and two segments rostrally and caudally.

Adequate sympathetic blockade is recognized by profuse sweating and increased (up to 2.5°C) subcutaneous temperature of the ipsilateral pelvic limb within 10 min after injection. Nonsedated horses tolerate unilateral lumbar sympathetic ganglionic (ULSG) blockade well. Hemodynamic and respiratory alterations induced by unilateral ULSG blockade in horses are usually minor.¹⁷¹ Potential complications include hematoma caused by puncture of blood vessels, intravascular injection, abdominocentesis, and needle breakage.

Novel Regional Analgesic Techniques

Intra-articular injection with morphine, abaxial nerve block with ketamine, and local application of 5% lidocaine patches are considered novel techniques to produce local and regional analgesia in horses.

Intra-articular Morphine

Intra-articular morphine might be a useful technique for pain relief after arthroscopic surgery. In a recent study, morphine sulfate (15 mg in 5 mL of 0.9% NaCl solution) containing 0.1% wt/vol sodium metabisulfite or 5 mL of 0.9% NaCl solution was injected into the left tibiotarsal joint of eight ponies, weighing 270 to 340 kg, to investigate whether intra-articular morphine inflames the joint and to determine the systemic absorption of morphine and its persistence intra-articularly after 24 h.¹⁷² The peak

Fig. 22.39. Horner's syndrome as evidence of sympathetic blockade to the head 15 min after infiltration of the right cervicothoracic ganglion with 100 mL 1% lidocaine. **A:** Right eye with ptosis, miosis, and enophthalmos. **B:** Unaffected left eye.

mean plasma morphine concentration (7.1 $\mu\text{g/L}$) was determined 30 min after intra-articular morphine administration. Neither morphine nor its metabolites (morphine 3-glucuronide and morphine 6-glucuronide) were detected in plasma at 6 h while morphine was still detectable in the synovial fluid of each pony at 24 h after injection. There was no correlation between the concentration of morphine in plasma and in synovial fluid.¹⁷²

Abaxial Nerve Block with Ketamine

The local analgesic effect of 5 mL of ketamine (1%, 2%, and 3% solution) injected as an abaxial sesamoid block has been assessed using a noxious thermal stimulus.¹⁷³ All horses injected with either 2% or 3% ketamine developed a rapid abaxial sesamoid block with a duration of action of 15 min. In horses injected with 1% ketamine, the failure rate was nearly 50%. Higher doses of ketamine may possess some local anesthetic properties by blocking sodium-ion and potassium-ion channels,

thereby stabilizing cellular membranes and obstructing nerve transmission.

Local Application of a 5% Lidocaine Patch

Lidocaine patch placement has been assessed for lameness localized to the carpus, fetlock, or distal limb. One or two patches of 5% lidocaine (Lidoderm; Endo Pharmaceuticals, Chadds Ford, PA) can be placed on the affected joints.¹⁷⁴ The area for patch placement should be clipped and then covered by the patch (10 \times 14 cm). Patches contain 700 mg of lidocaine (50 mg/g adhesive) in an aqueous base with methylparaben and propylparaben as preservatives. Once the patch is applied, the joint should be bandaged. Transdermal lidocaine application appears to reduce pain in some horses. Mass spectrometry and enzyme-linked immunosorbent assays have not detected lidocaine in venous blood samples taken at 2, 4, 8, and 12 h after patch application, indicating that the systemic uptake of lidocaine is likely quite minimal.

Intra-articular Anesthesia

Anesthesia for Castration

Intratesticular Injection

Conclusion

Introduction

Local or regional analgesia is a preferred method in food animals because of accepted practice and economic necessity. Many surgical procedures are performed safely and humanely using a combination of physical restraint, mild sedation or tranquilization, and local or regional anesthesia. The techniques should provide reversible loss of pain to a limited body area with minimal effects on homeostasis. The standing position is optimal for a number of surgical procedures of ruminants, because it reduces the problems associated with bloat, salivation, recumbency-related regurgitation, and nerve or muscle damage.¹⁻⁴

Local or infiltration analgesia is achieved by injecting a local anesthetic solution into the tissues at a surgical site, whereas regional analgesia is induced after perineural injection near major nerves. The most commonly used techniques in ruminants are surface (topical) anesthesia, infiltration anesthesia, nerve-block (conduction) anesthesia, epidural anesthesia, and intravenous regional anesthesia. Although local anesthetic drugs are routinely used, none has presently been approved by the Food and Drug Administration (FDA) for use in lactating dairy cows. Epidural morphine is safe and effective, and provides an alternative approach for treatment of pain after hind-limb orthopedic surgery.

Infiltration anesthesia, lumbosacral epidural anesthesia, and intratesticular injection are the most popular local anesthetic techniques in properly tranquilized pigs. The advantages of regional analgesia over general anesthesia include the need for minimal apparatus (e.g., syringe, needles, and drug) and little risk of toxic side effects. Several factors must be considered in the choice of a technique:⁵

1. The site, nature, and expected duration of surgery
2. The species, temperament, and health of the patient
3. Special requirements (such as minimum fetal depression during cesarean section)
4. The skill and experience of the veterinarian
5. The economics of time and materials

Local Anesthetics

A variety of local or regional anesthetic drugs can penetrate peripheral nerve barriers and provide reversible anesthesia with acceptable onset times and predictable duration.⁵⁻⁹ The drugs vary as to the potency, toxicity, and cost, and none has been approved by the FDA for use in lactating dairy cows, although such agents are commonly used (Table 23.1). Lidocaine hydrochloride solu-

Table 23.1. Local analgesics

Agent (Generic Name)	Trade Name	Chemical Name	(Procaine = 1)	Potency (Procaine = 1)	Toxicity Dosage	Stability	Comments
Procaine	Novocaine (Winthrop Sterns, New York)	Para-aminobenzoic acid ester of diethylamino ethanol	1:1	1:1	1%–2% for infiltration and nerve block	Aqueous solutions are heat resistant; decomposed by bacteria	Hydrolyzed by liver and plasma esterase
Chlorprocaine	Nesacaine (Astra Pharmaceutical Products, Westboro, MA)	Para-amino-2-chlorobenzoic acid ester of B-diethylamino ethanol	2.4:1	0.5:1	1%–2% for infiltration and nerve block	Multiple autoclaving accelerates hydrolysis and impairs potency	Immediate onset of action; 2-h duration with epinephrine
Lidocaine	Xylocaine (Astra Pharmaceutical Products, Westboro, MA)	Diethylaminoacet-2,6-xylidide	2:1	0.5%, 1:1; 1%, 1.4:1; 2%, 1.5:1	0.5%–2.0% for infiltration and nerve block; topically, 2%–4%	Aqueous solutions are thermostable; multiple autoclaving possible	Excellent penetrability; rate of onset twice as fast as procaine; 2-h duration with epinephrine
Mepivacaine	Carbocaine (Winthrop Laboratories, New York)	1-Methyl-2',6' piperidylidene monohydrochloride	2.5:1	Less toxic than lidocaine	1%–2% for infiltration and nerve block	Resistant to acid and alkaline hydrolysis; multiple autoclaving possible	Absence of vasodilator effect makes addition of a vasoconstrictor unnecessary
Tetracaine	Pontocaine (Winthrop Laboratories, New York)	Parabutyl amino benzoyl dimethylaminoethanol-HCl	12:1	10:1	0.1% for infiltration and nerve block; topically, 0.2%	Crystals and solutions should not be autoclaved	Slow onset of analgesia (5–10 min); 2-h duration; for eye installation
Hexylcaine	Cyclaine (Merck, Sharpe and Dohme, West Point, PA)	1-Cyclo-hexamino 2-propylbenzoate	1–2:1	2–4:1	0.5%–1.0% for infiltration; 2% for nerve block; 5% topically	Crystals and solutions are thermostable	Recommended for epidural and topical analgesia
Dibucaine	Nupercaine (CIBA Pharmaceutical Products, Summit, NJ)	α -Butyl-oxycinchoninic acid of diethylethylene-diamide	20:1	15:1	Topically, 0.1%	Thermostable but precipitation by alkalis	Slowly detoxified
Bupivacaine	Marcaine (Breon Laboratories, New York)	1-Butyl-2',6' piperidylidene-HCl	8:1	Greater margin of safety than lidocaine	0.25% for infiltration; 0.5% for nerve block; 0.75% for epidural block	Stable compound	Intermediate onset, lasting 4–6 h
Ropivacaine	Naropin (AstraZeneca LP, Wilmington, DE)	S-(–)-1-Propyl 2', 6'-piperidylidene HCl monohydrate	8:1	Greater margin of safety than bupivacaine	0.2% for infiltration; 0.5% for nerve block; 0.75% and 1.0% for epidural block	Stable compound	Intermediate onset, lasting 4–6 h

tion has become the single agent of choice because of its intermediate anesthetic duration of 1½ to 3 h and the cost restrictions and limited space in a mobile-practice vehicle. The maximal dose of injected lidocaine should be limited to approximately 4 mg/kg of body weight (0.2 mL/kg of body weight without epinephrine) to avoid toxicity.

Patches of 5% lidocaine (Lidoderm; Endo Pharmaceuticals, Chadds Ford, PA) for transdermal delivery of lidocaine are available. Each patch (10 × 14 cm) contains 700 mg of lidocaine (50 mg per gram of adhesive) in aqueous base and methylparaben and propylparaben as preservatives. Although studies about the analgesic efficacy, pharmacology, and pharmacokinetics of trans-

dermal lidocaine in cattle have not been reported, two patches of 5% lidocaine applied around the fetlock joint have reduced local pain in cows (personal observation) (Fig. 23.1).

The addition of a vasoconstrictor, such as epinephrine at concentrations of 5 to 20 µg/mL (1:200,000 to 1:50,000), is occasionally incorporated or can be added to the commercial local anesthetic solution to increase intensity, prolong anesthetic activity, and reduce the potential for toxicity.¹⁰ These concentrations may be obtained by adding 0.1 mL of 1:1000 (0.1 mg) epinephrine to 5 mL (1:50,000) and 20 mL (1:200,000) of local anesthetic solution. The use of local anesthetic drugs containing a vasoconstrictor often causes tissue necrosis along wound edges,

Fig. 23.1. Black-and-white Holstein cow, 4 years old, with sole abscess of the lateral claws and comminuted fracture of the lateral planar process of digit IV of the right rear foot (**A**). Radiograph of the distal phalanx (P3) confirms the fracture with articular involvement (*arrow*) and possible osteomyelitis and septic arthritis of the distal interphalangeal joint of digit IV, and pedal osteitis of the distal phalanx of digit IV (**B**). A ring block, using 15 mL of 2% lidocaine, was performed at the midmetatarsal level, and the fractured planar process of P3 was removed. An incision was made above the coronary band on the cranial aspect of the foot and connected to the opening of the abscess on the sole. Two gauze patches soaked in betadine solution were used to create a drain for the incision through the opening in the sole of the foot. Two 5% Lidoderm patches were placed over the metatarsals, one medially and one laterally (**C**), and then the leg was wrapped with a bandage. Because the cow appeared more comfortable, was getting up easier without much encouragement, and was standing for longer periods after the transdermal lidocaine application, the Lidoderm patches were reapplied once a day for 3 additional days.

especially in thin-skinned animals, and it should be avoided for anesthesia of the teat and intravenous regional analgesia.

Adding hyaluronidase to lidocaine at a rate of 150 turbidity-reducing units per 25 mL will hasten the time of onset of infiltration anesthesia and shorten anesthesia, owing to increased permeability of the tissues.¹⁰ The necessity for its use, other than in combination with procaine hydrochloride solution (1%), has been questioned with the introduction of newer local anesthetics with improved infiltration power. The enzyme enables smaller volumes of local anesthetic solution to be used. The combination of local anesthetics, epinephrine, and hyaluronidase produces prolonged anesthesia because of reduced uptake while maintaining the spreading action of hyaluronidase upon local anesthetics.¹¹ Accuracy in technique is still necessary because tissue fascial planes act as barriers. The greatest use of hyaluronidase is in ophthalmology (retrobulbar blocks) and local anesthetic nerve blocks for postoperative pain relief.

Regional Anesthesia of the Head

The most frequently desensitized nerves of the head are the auriculopalpebral, supraorbital, zygomaticotemporal (lacrimal), infraorbital, oculomotor, abducens, and trochlear. Many of these nerves are maxillary and ophthalmic branches of the trigeminal (fifth) cranial nerve.

Anesthesia of the Eye and Relaxation of the Globe

The neuroanatomy of ocular structures is complex. The globe, conjunctiva, nictitans, and most of the eyelids are supplied by sensory fibers of the ophthalmic division of the trigeminal nerve. The extraocular muscles are supplied by motor fibers of the trochlear nerve (superficial oblique muscle), the abducens nerve (lateralis rectus and retractor oculi muscles), and the oculomotor nerve. The oculomotor, trochlear, ophthalmic, and maxillary branches of the trigeminal and abducens nerves emerge from the foramen rotundum orbitale.

At present, topical and regional anesthetics are used to facilitate surgery of the eye and its associated structures. The eyelids (without anesthesia) are selectively paralyzed by desensitizing the auriculopalpebral branch of the facial nerve (akinesia). Anesthesia of the eye and orbit and immobilization of the globe are commonly achieved by retrobulbar injection of a local anesthetic or by using the Petersen technique (or its modification).¹²

For topical anesthesia, one or two drops of proparacaine hydrochloride (0.5%) solution are instilled in the eye. Pain associated with corneal disease is relieved in 30 s and for as long as 10 to 15 min.¹³ In addition, blepharospasm caused by superficial irritation of the cornea is relieved, so examination of the eye or minor surgery is greatly facilitated. The FDA has approved the use of proparacaine in food animals to induce topical anesthesia for cauterization of corneal ulcers, removal of foreign bodies and suture from the cornea, and measurements of intraocular pressure (tonometry) when glaucoma is suspected. Other ophthalmic anesthetic solutions, such as Xylocaine [lidocaine] hydrochloride (4%) or tetracaine hydrochloride, are toxic to the corneal epithe-

lium, suppressing mitosis and reducing protective blink reflexes, and should not be used for treatment of the eye.¹⁴

Anesthesia and Akinesia of the Eyelids

The site for producing a linear subcutaneous infiltration (line block) is about 0.5 cm from the margin of the dorsal and ventral eyelids in adult cattle. Approximately 10 mL of a 2% lidocaine hydrochloride solution is administered at multiple sites, 0.5 cm apart, using a 2.5-cm, 22- or 25-gauge needle (Fig. 23.2A).

Paralysis of the eyelids (without analgesia) is commonly performed in cattle by selectively desensitizing the auriculopalpebral branch of the facial nerve (akinesia).¹³ The nerve is sometimes palpable in a notch on the zygomatic arch, anterior to the base of the auricular muscles, where a 2.5-cm, 18- or 20-gauge needle is placed subcutaneously, and 5 to 10 mL of the anesthetic is deposited (Fig. 23.2B). The combination of topical anesthesia and auriculopalpebral akinesia is useful for removing foreign bodies from the cornea and conjunctival sac and for injecting medication into the bulbar subconjunctiva.

Anesthesia for Enucleation

In doing a retrobulbar block for enucleation or to facilitate surgery and radiation therapy in cattle with squamous cell carcinoma at the cornea, a 15-cm, 18-gauge needle with a fairly large bend (approximately 25-cm diameter) is used in adult cattle. Head restraint with a halter or nose grip is necessary. In small ruminants, a 3.75-cm, 22-gauge needle may be used.

The sites for lid penetration are at the superior, inferior, medial, or lateral orbital rim. The surgeon's index finger is used to deflect the globe and protect it from the needle point (Fig. 23.3A). When using the medial canthus approach, the medial wall of the bony orbit is felt. The needle is then inserted in the fornix of the conjunctiva cranial to the nictitans dorsomedial to the operator's finger until the orbital apex is encountered (Fig. 23.3B). Approximately 15 mL of a 2% lidocaine hydrochloride solution or equivalent is injected in small increments as the needle is advanced, thereby pushing initial structures from the needle point. The needle must not be fully inserted into the orbit to avoid penetration of the optic nerve sheath. Once the entire block is completed, the structures that will be desensitized include the optic nerve; the elevator palpebral muscles; the medial rectus, the dorsal rectus, the ventral rectus, and the inferior oblique muscles (all innervated by the oculomotor nerve); the superior oblique muscle (innervated by the fourth cranial nerve); the sensory part of the eye and adnexa (innervated by the fifth cranial nerve); the retractor oculi muscles; the lateral rectus muscle (innervated by the sixth cranial nerve); and the orbicularis oculi muscle (innervated by the seventh cranial nerve). A satisfactory retrobulbar nerve block should then accomplish anesthesia for whatever procedure would be desired for the eye and eyelids and will enable the proptosing of the eye for surgery on the cornea or enucleation.

Adverse effects that may result from retrobulbar injections include apnea,¹⁵ orbital hemorrhages, direct pressure on the globe, penetration of the globe, damage to the optic nerve, initiation of the oculocardiac reflex, and injection into the optic nerve men-

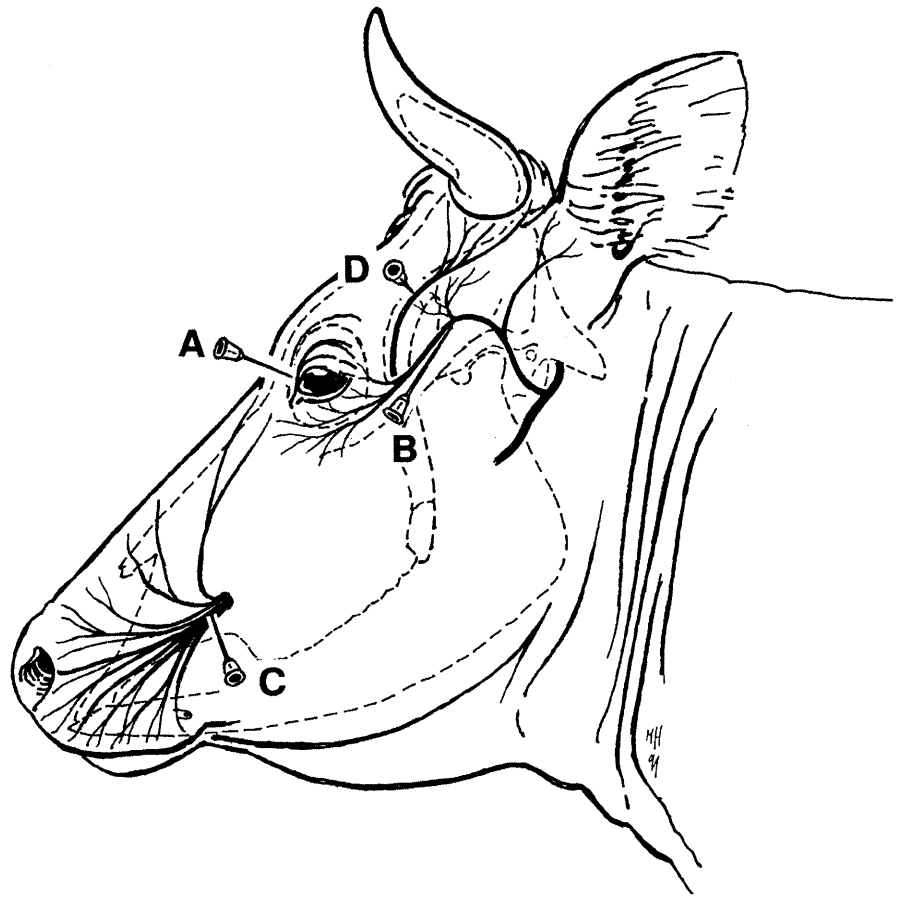

Fig. 23.2. Needle placement for infiltration of the eyelids (A) and nerve blocks on the head in cattle: auriculopalpebral (B), infraorbital (C), and cornual (D) branches of the zygomaticotemporal nerve.

Fig. 23.3. Retrobulbar needle placement through the medial canthus (A) to the orbital apex (B) in cattle.

inges. Damage to the globe may be serious for procedures other than enucleation. If the optic nerve or optic foramen is penetrated and local anesthetic is injected beneath the meningeal covering, epidural or subarachnoid anesthesia of the brain may result, which can be fatal. Risk of subarachnoid (cerebrospinal fluid [CSF]) injection is minimized by aspiration check.

In performing the Peterson block,¹⁶ the notch formed by the supraorbital process cranially, the zygomatic arch ventrally, and the coronoid process of the mandible caudally, is identified. A 2.5-cm, 22-gauge needle is inserted at this notch, and approximately 5 mL of a 2% lidocaine hydrochloride solution is injected subcutaneously. A 2.5-cm, 14-gauge needle (to serve as a cannula) is placed through the desensitized skin as far anterior and ventral as possible in the notch. A straight or slightly curved 10- to 12-cm, 18-gauge needle is inserted into the cannula in a horizontal and slightly posterior direction until it encounters the coronoid process of the mandible at approximately 2.5 cm through the skin. The cow's head is fully extended with frontal and nasal bones parallel to the ground. The needle with no syringe attached (to feel the bony landmarks) is gently manipulated anteriorly until its point passes medially in front of the coronoid process. The needle is then advanced to the pterygopalatine fossa rostral to the solid bony plate that is in close proximity to the orbitrotundum foramen at a depth of 7.5 to 10 cm (Fig. 23.4A). Penetration of the turbinates and nasopharynx must be avoided. Approximately 15 mL of the local anesthetic is injected under control of aspiration to ensure that the needle point has not entered the ventral maxillary artery. All of the important nerves (oculomotor, trochlear, and abducens) and the three branches of the trigeminal nerve (ophthalmic, maxillary, and mandibular) that emerge from the foramen orbitrotundum are desensitized 10 to 15 min after completion of the injection (Fig. 23.5).¹⁷ A proper technique anesthetizes all the structures for sensory and motor function of the eye, except for the eyelid. The lid block is accomplished by desensitizing the auriculopalpebral branch of

the facial nerve by withdrawing the needle to the subcutaneous tissue and reinserting it posteriorly for 5 to 7.5 cm lateral to the zygomatic arch, as an additional 5 to 10 mL of the anesthetic is injected (Fig. 23.4B). If the upper lid is involved in the surgical procedure, a line of infiltration with 10 mL of the local anesthetic should be made subcutaneously approximately 2.5 cm from the margin of the lid (Fig. 23.2A). The anesthetic is laid along its path while the needle is being advanced. Several different planes of anesthetic infiltration along the frontal crest are performed, so no matter where the nerve is coursing through that region, it should be desensitized by this fanning procedure.

As might be expected, some experience is required to strike a foramen that small at such great depth from the surface. To facilitate the Peterson procedure, a curved needle similar to that used for the retrobulbar block may be used. The concavity of the needle is kept caudal to facilitate the passage of the needle point rostral to the mandibular coronoid process. The needle is moved slightly back and forth, fanning across this area until some motor reaction and flinch of the animal's eye is determined.

When comparing the Peterson eye block and retrobulbar injection, it is apparent that the Peterson technique requires more skill to perform correctly, but is safer and more effective if done properly. There is less edema and inflammation than when eyelids and orbit are infiltrated. In addition, the risk of orbital hemorrhage, direct pressure on the globe, penetration of the globe, damage to the optic nerve, or injection into the optic nerve meninges is minimized with Peterson's technique.¹⁸⁻²¹ Comparison of retrobulbar and Peterson nerve-block techniques via magnetic resonance imaging in bovine cadavers also indicates that the retrobulbar injection technique provides a greater distribution of a lipid contrast medium around the periorbital structures, the optic nerve, and in the ethmoid turbinates and nasopharynx, compared with the Peterson nerve-block technique, which primarily distributes the contrast medium in the pterygopalatine fossa and only minimally in the surrounding structures.²²

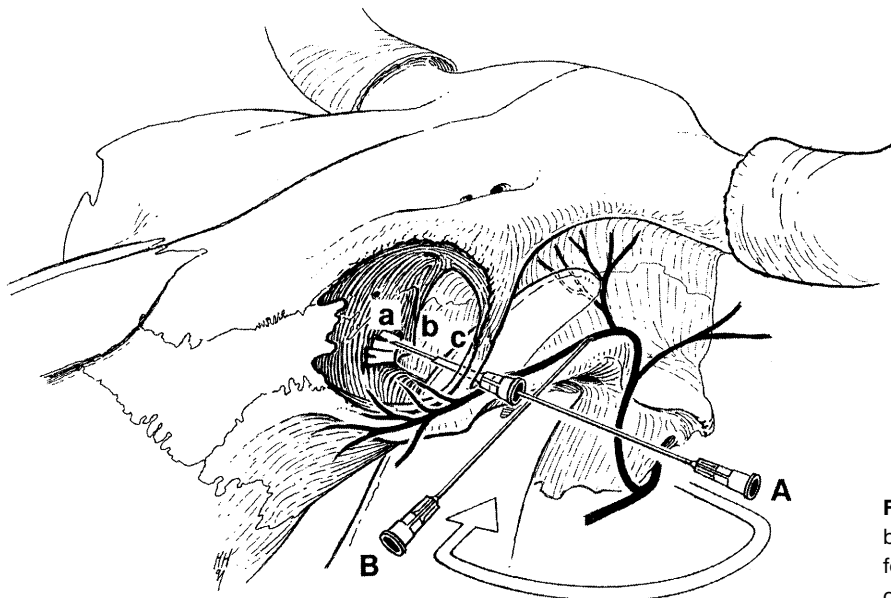

Fig. 23.4. Needle placement for Peterson eye block (A) and auriculopalpebral nerve block (B): a, foramen orbitrotundum; b, pterygoid crest; and c, coronoid process.

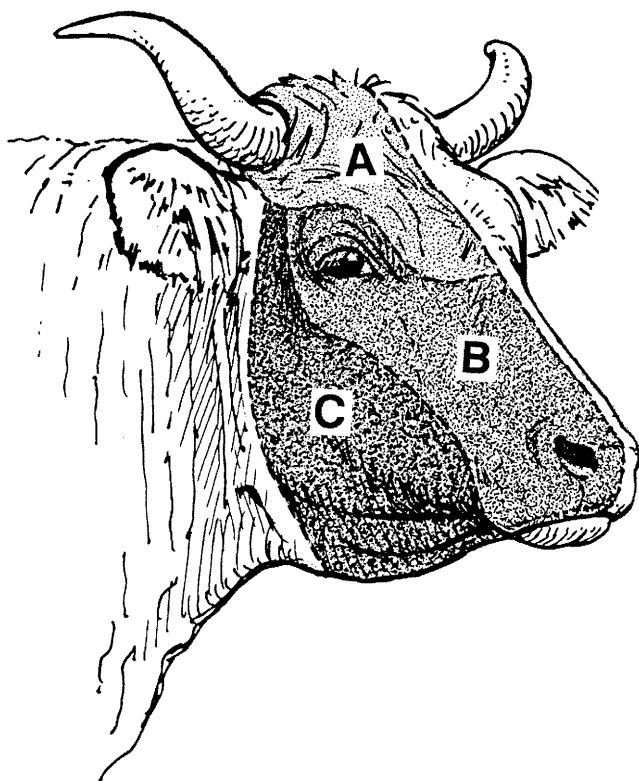

Fig. 23.5. Cutaneous areas of the bovine head supplied by sensory fibers from the ophthalmic (A), maxillary (B), and mandibular (C) nerves.

Both retrobulbar block and Peterson's technique prevent blinking for several hours. Antibiotic eye ointments of sterile saline solution should be applied to the cornea frequently during surgery and after orbital replacement of the globe to keep the cornea moist. Sunlight, dust, and wind in the eye must be avoided to prevent keratoconjunctivitis. Alternatively, the lids may be sutured together until motor activity of the lids returns. Local anesthetics in conventional concentrations should not produce nerve damage of clinical importance. Severe central nervous system (CNS) toxicity in both procedures, however, may arise from penetration of the turbinates and injection of local anesthetic solution into the optic nerve meninges and nasopharynx. The clinical signs of local anesthetic CNS toxicity include hyperexcitability, lateral recumbency, opisthotonus, tonic-clonic convulsions, respiratory arrest, and cardiac arrest.

Nasal Anesthesia

For repair of nasal lacerations in cattle and insertion of a nose ring in mature, ill-tempered bulls, nasal analgesia is required.^{23,24} Bulls must be thoroughly restrained during the procedure and, if unruly, should be tranquilized before nasal analgesia is attempted. A 3.75-cm, 18-gauge needle is used for perineural injection of the infraorbital nerve at its point of emergence from the infraorbital canal. Difficult to palpate, the foramen is located rostral to the facial tuberosity on a line extending from the nasomax-

illary notch to the second upper molar (P2), which in adult animals is approximately 5 cm dorsal to P2. Approximately 20 to 30 mL of a 2% lidocaine hydrochloride solution is injected along a line rostral to the infraorbital foramen and superficial to the maxilla (Fig. 23.2C).

Anesthesia of the Horn

Anesthetic techniques for dehorning cattle and goats and for disbudding young kids have been described.^{24–32} Considerable controversy exists over the ideal method for horn removal, quantification of dehorning-related pain, and consequently the necessity for regional analgesia for dehorning young calves. As early as the 1960s, behavioral, endocrine, and cardiac responses in young Friesian calves during and after dehorning with an electrical cauterizing dehorner either with or without sedation and analgesia (xylazine and butorphanol, intramuscularly [IM]), indicated that routine field use of local analgesia (corneal nerve block) improved the welfare of calves subjected to dehorning with a hot iron.³²

Analgesia of the horn and base of the horn in cattle is achieved by desensitizing the cornual branch of the zygomaticotemporal (lacrimal) nerve, which is a portion of the ophthalmic division of the trigeminal nerve.^{33,34} The zygomaticotemporal nerve leaves the lacrimal nerve within the orbit and passes through the temporal fossa dorsal to the zygomatic process of the squamous temporal bone and around the lateral edge of the frontal bone dorsal to the temporal muscle. At first it lies deep, but on the upper third of the lateral temporal ridge it lies relatively superficial, 7 to 10 mm deep. The zygomaticotemporal nerve supplies sensory fibers to the horn and surrounding skin, particularly on its caudal aspect, and the skin of the ear. The nerve can usually be palpated halfway between the lateral canthus and the horn (bud) between the thin frontalis muscle and temporal muscle. A 2.5-cm, 20-gauge needle is inserted ventromedially close to the frontal bone approximately 2 to 3 cm in front of the base of the horn, and 5 to 10 mL of a 2% lidocaine hydrochloride solution, depending on size, is injected (Fig. 23.2D). Needle penetration is from 1 cm in small cattle to 2.5 cm in large bulls. The cornual artery and vein are close to the site of block; thus, aspiration ensures that the needle point is not inadvertently intravascular. Cornual anesthesia should result unless anesthetic has been injected too deeply in the aponeurosis of the temporal muscle. With an adequately performed cornual nerve block, there is a blink response during infiltration and an ipsilateral lid droop because of the blockade of some branches of the auriculopalpebral nerve. In exceptional cases and in a fractured horn involving the frontal bone and sinuses,³⁴ a large posterior branch of the sinuum frontalis nerve maintains sensitivity of the cornual process. This nerve can be desensitized by using the Peterson eye-block technique.¹⁶ Adult cattle and bulls with well-developed horns require extensive subcutaneous infiltration of the caudal aspect of the horn base to desensitize the cutaneous branches of the second cervical nerve.^{16,25} Regional analgesia dissipates 3 to 4 h after use of a long-lasting local anesthetic (e.g., bupivacaine).³⁵ Thereafter, blood cortisol spikes may develop, and painful behavioral traits become evident.³⁶ In one study, combining corneal nerve block

with wound cauterization substantially reduced the cortisol response for 1 day after dehorning, whereas dehorning alone caused marked cortisol response for nearly 7 h.³⁷ Intravenous administration of a nonsteroidal anti-inflammatory analgesic may also be useful in preventing acute postsurgical pain in dehorned calves. Systemic analgesia can be combined with regional analgesia to reduce the stress associated with dehorning.^{38–40} In a study assessing the efficacy of the nonsteroidal anti-inflammatory drugs (NSAIDs), ketoprofen and adrenocorticotropic hormone, but not phenylbutazone, significantly reduced cortisol levels after local anesthetic administration and dehorning.⁴¹ Pain was best mitigated after hot-iron dehorning in 4 to 8 week calves, with the combined effects of a local anesthetic (lidocaine) and an NSAID (ketoprofen) before dehorning, and an anti-inflammatory drug (ketoprofen) again 2 and 7 h after the procedure.⁴¹ Similarly, the use of a corneal nerve block and intramuscular injection of ketoprofen at least 10 min prior to dehorning, combined with either the use of a butane burner or an electrical Rhinehart dehorning device, has proven efficacious in reducing pain-associated behavior.⁴² Dairymen should be encouraged to dehorn calves at a young age to minimize the pain response. Based on elevated cortisol levels, scoop dehorning has been deemed unacceptable by some investigators.^{43,44} Likewise, the dehorning of cattle while they are restrained with an electroimmobilizer may be painful on application and should not be relied on to produce appropriate analgesia for such an invasive procedure.⁴⁵

The horns and bases of the horns in goats are supplied by the cornual branches of the zygomaticotemporal (lacrimal) and infratrochlear nerves. Goats are typically sedated with intramuscular xylazine (0.1 mg/kg) administration before regional analgesia is initiated. The cornual branch of the zygomaticotemporal (lacrimal) nerve is desensitized by inserting a 2.5-cm, 22-gauge needle halfway between the lateral canthus of the eye and lateral base of the horn as close as possible to the caudal ridge of the supraorbital process and 1.0 to 1.5 cm deep, with 2 to 3 mL of a 2% lidocaine hydrochloride solution in adult goats (Fig. 23.6A). A second injection is made halfway between the medial canthus of the eye and medial base of the horn to desensitize the cornual branch of the infratrochlear nerve. The needle is inserted dorsal and parallel to the dorsomedial margin of the orbit. The anesthetic is administered in a line, because this nerve is frequently branched (Fig. 23.6B).

Early disbudding of small horns (<1 cm in diameter at the base) in the first few days of life uses thermal cautery, whereas larger horns (>2 cm in diameter at the base) are removed by surgery. Hemorrhage should be controlled by ligating the cornual artery. Dehorning of goats that are 8 months of age or older opens the frontal sinus, which should be protected by a snug, but not too tight, sterile bandage for as long as 1 month. The bandage should not produce edema and postoperative pain over the dehorning site. An elliptical ring block around the base of the entire horn of mature goats should be laid for a cosmetic dehorning procedure. This technique produces excellent cosmetic appearance with minimal postoperative care.^{46,47} Anesthesia of the nerve to the sinus mucosa and periosteum of the frontal sinus is impractical, because the nerve arises deep within the orbit and enters the

Fig. 23.6. Needle placement for desensitizing the cornual branches of the zygomaticotemporal (A) and infratrochlear nerve (B) in goats.

frontal bone without appearing superficial.³³ Sedation of the animal is required if the frontal sinus will be entered during horn removal.²⁸ General anesthesia should be used in mature goats with large horns. Owners should be advised that dehorning mature female goats late in gestation can induce abortion and that dehorning male goats used for breeding can temporarily alter their social status within a herd.³⁰

Additional postoperative analgesia can be given by a single intravenous injection of flunixin meglumine (1 mg/kg of body weight). To alleviate pain during disbudding of young kids between 7 and 14 days of age, 0.5 mL of a 2% lidocaine hydrochloride solution is injected subcutaneously around the horn base (ring block). Toxic doses are more likely to administered accidentally after large areas of tissue have been infiltrated with 2% solutions of lidocaine, mepivacaine, procaine, and prilocaine or 0.5% bupivacaine. A total dose of 10 mg/kg (0.5 mL of a 2% solution/kg or 1 mL of a 1% solution/kg) of lidocaine should not be exceeded to prevent overdose. Inadvertent rapid intravenous infusions produce the most dramatic and rapid onset of symptoms. Apparent signs of toxicity include excitation, lateral recumbency, extensor rigidity, muscular twitching, dullness, generalized tonic-clonic convulsions, opisthotonus, and odontoprisis.^{48,49} Coma, blindness, respiratory arrest, and cardiac arrest can occur with high plasma concentrations (>15 µg/mL) of lidocaine.

Anesthesia for Laparotomy

At least six techniques for inducing anesthesia of the paralumbar fossa and abdominal wall in standing ruminants have been described: (a) infiltration, (b) proximal paravertebral thoracolumbar, (c) distal paravertebral thoracolumbar, (d) segmental dor-

solumbar epidural, (e) continuous lumbar segmental epidural, and (f) thoracolumbar subarachnoid anesthesia. Any of these techniques may be used for surgeries such as rumenotomy, cecotomy, correction of gastrointestinal displacement, intestinal obstruction and volvulus, cesarean section, ovariectomy, and liver or kidney biopsy, among others.^{50,51}

Infiltration Anesthesia

Line Block

Simple infiltration of the incision line (line block) is the easiest and probably the most commonly used technique for producing analgesia of the flank in food animals. Multiple subcutaneous injections of 0.5 to 1.0 mL of a 2% lidocaine hydrochloride solution, 1 to 2 cm apart, are administered using a 2.5-cm, 20-gauge or smaller needle. Successive injections of 10 to 15 mL of the anesthetic are made slowly and continuously as the needle is inserted at the edge of the desensitized skin for the skin and subcutaneous line block. This is followed by inserting a 7.5- to 10-cm, 18-gauge needle through the desensitized skin and infiltrating the muscle layers and parietal peritoneum using 10 to 100 mL of the anesthetic, depending on the area to be desensitized (Fig. 23.7). Adult cattle (weighing 450 kg) safely tolerate 250 mL of a 2% lidocaine hydrochloride solution (5 g) for the line block, whereas in adult goats 10 mL of a 2% lidocaine hydrochloride solution (200 mg) should not be exceeded. It is common practice to dilute a 2% solution of the anesthetic with equal parts of sterile saline to make a 1% solution and decrease the total amount of drug by 50%.^{49,50}

Inverted-7 or L Block

The inverted-7 or L block is a nonspecific regional analgesic technique in which up to 100 mL of a 2% lidocaine hydrochloride solution in adult cattle is injected into the tissues bordering the dorsocaudal aspect of the last rib and ventrolateral aspect of the lumbar transverse processes (Fig. 23.8). All nerves entering the surgical field are desensitized 10 to 15 min after administra-

Fig. 23.7. Restraint of a 5-year-old Holstein cow, weighing 600 kg, in dorsolateral recumbency for right ventral abomasopexis. Approximately 25 mL of a 2% lidocaine hydrochloride solution desensitized a 15-cm abdominal incision line. From Skarda,⁵ p. 630.

Fig. 23.8. Regional analgesia of the bovine flank by using the inverted-L infiltration pattern. T13 and L1 to L4 are ventral branches of 13th thoracic and first to fourth lumbar vertebral nerves.

tion of the anesthetic. Deposition of the anesthetic away from the incision site minimizes edema, hematoma, and possible interference with healing. The disadvantages of the inverted-7 or L block are similar to those of local infiltration anesthesia (line block) and include incomplete analgesia and muscle relaxation of the deep layers of the abdominal wall (particularly of the peritoneum), toxicity after injecting significant amounts of the anesthetic solution into the peritoneal cavity, and increased cost owing to larger doses of anesthetic and longer time required.

Proximal Paravertebral Thoracolumbar Anesthesia

The proximal paravertebral anesthesia is a good alternative to the inverted-7 or line block. The dorsal and ventral branches of the last thoracic (T13) and first and second lumbar (L1 and L2) spinal nerves are desensitized as they emerge from the intervertebral foramina (Fig. 23.9). The technique is also called the *Farquharson*,⁵² *Hall*, or *Cambridge technique*.⁵³ In addition, the third and fourth (L3 and L4) lumbar spinal nerves can be desensitized if analgesia of the caudal most part of the paralumbar fossa for cesarean section or ipsilateral foreteat and mammary gland is desired.⁵⁴ However, weakness of the pelvic limb may be caused by desensitizing the L3 and L4 nerves, which carry motor fibers to the femoral and ischial nerves.

Fig. 23.9. Needle placement for proximal paravertebral nerve block in cattle. **A:** Left lateral aspect of thoracolumbar vertebrae T13 to L4 with needle tip placed at spinal nerves T13, L1, and L2. **B:** Cranial view of a transection of the first lumbar vertebra at the location of the intervertebral foramen: *a*, dorsal branch; and *b*, ventral branch of L1 vertebral nerve. From Skarda,⁵ p. 631.

In cattle, the skin overlying the spinal column on the side to be desensitized is clipped, surgically scrubbed, and disinfected. The skin at the most obvious parts of the transverse processes of L1, L2, and L3 at a point 2.5 to 5.0 cm from the dorsal midline is identified and desensitized by injecting 2 to 3 mL of a 2% lidocaine hydrochloride solution, using a short and comparatively fine needle (2.5-cm, 20-gauge). If the T13 and L1 transverse processes cannot be palpated, the distance between the more prominent transverse processes of L2 and L3 is measured to mark the anterior sites at which the needle is to be introduced to desensitize nerves L1 and T13, respectively. The cranial aspect of the transverse processes will usually be on a same cross-sectional plane with the intervertebral foramina, so palpation of the most cranial border of the transverse process of L2 is of value in locating the L1-L2 intervertebral foramen, from which the first lumbar (L1) spinal nerve emerges.

A 1.25-cm, 14-gauge needle (to serve as a cannula) is first inserted into the desensitized skin to minimize skin resistance during insertion of a stout 4.25- to 15-cm, 18-gauge spinal needle. The needle is passed ventrally until its point encounters the transverse process of L2 or the intertransverse (L1-L2) ligament. Small amounts (2 to 3 mL) of the anesthetic are injected as the needle is advanced to counteract spasm of the longissimus dorsi muscle and prevent bending of the long needle. When contact is made with bone, the needle is walked off the cranial edge of the transverse process of L2 and advanced approximately 1 cm to pass through the intertransverse fascia. The penetration of the in-

tertransverse fascia can usually be felt. Approximately 10 to 15 mL of a 2% lidocaine hydrochloride solution is injected with little resistance to desensitize the ventral branch of L1. The needle is withdrawn 1 to 2.5 cm to above the fascia and dorsal surface of the transverse process. An additional 5 mL of the anesthetic is injected with slight resistance to desensitize the dorsal branch of L1. To desensitize T13 and L2, the needle is inserted cranial to the transverse processes of L1 and L3, its tip walked off the cranial edges of the transverse processes to a depth comparable to the previous injection site, and the nerves desensitized similarly to L1.

In sheep and goats, T13, L1, and L2 are desensitized similarly to the cattle method, but 2.5 to 3.0 cm off the midline and with less anesthetic (2 to 3 mL/site). Full anesthesia develops in approximately 10 min and lasts 1½ h. Signs of successful nerve blockade include anesthesia of the skin, increased skin temperature because of hyperemia after paralysis of cutaneous vasomotor nerves, and scoliosis toward the desensitized side caused by paralysis of paravertebral muscles.

When compared with infiltration analgesia, proximal thoracolumbar paravertebral block offers a wide and uniform area of analgesia and muscle relaxation. Analgesia is developed from the 13th rib caudal to the tuber coxae and ventrally to the fold of the flank. The incision site is not disrupted. Disruption occurs with an infiltration block when excessive amount of anesthetic is injected into the tissues and multiple skin punctures by the needle produce hemorrhage and trauma. With an infiltration block, a considerable amount of time is required to desensitize an area of approximately 45 cm, as would be required in a cesarean section. If an incision this long is necessary, a paravertebral nerve block could be done much more quickly and in a more professional and impressive manner. The technique relies on finding landmarks, but it is not at all difficult in thin, bony cows with easily palpable transverse processes. The four major disadvantages of the thoracolumbar paravertebral nerve block are (a) its technical difficulty, particularly in fat cattle and some beef cattle in which the lumbar transverse processes are not easily palpated; (b) arching of the spine due to paralysis of back muscles, which bow out toward the area of incision after unilateral blockade, making the closure of the incision more difficult; (3) the risk of penetrating vital structures such as the aorta and thoracic longitudinal vein on the left side and the caudal vena cava on the right side; and (4) loss of motor control of the pelvic limb caused by caudal migration of local anesthetic to the femoral nerves.

Distal Paravertebral Thoracolumbar Anesthesia

A lateral approach to the dorsal and ventral rami of spinal nerves T13, L1, and L2 in cattle has been used. The technique is also called the *Magda*, *Cakala*, or *Cornell technique*.⁵⁵ The skin is clipped and disinfected at the distal ends of the first lumbar (L1), second lumbar (L2), and fourth lumbar (L4) transverse processes, and 10 to 20 mL of a 2% lidocaine hydrochloride solution is injected in a fan-shaped infiltration pattern ventral to each transverse process, using a 7.5-cm, 18-gauge needle (Fig. 23.10). The needle is withdrawn a short distance and reinserted slightly

Fig. 23.10. **A:** Left lateral aspect of needle placement for distal paravertebral nerve block in cattle to block dorsal (a) and ventral (b) rami of spinal nerves T13, L1, and L2. **B:** Cranial view of the transverse of the first lumbar vertebra at the location of the intervertebral foramen. From Skarda,⁵ p. 633.

dorsal and caudal to the transverse process to inject additional 5 mL of the anesthetic and desensitize the cutaneous branch of the dorsolateral branches. The procedure is repeated for the second and fourth lumbar transverse processes.

Distal paravertebral anesthesia as compared with proximal paravertebral anesthesia offers the advantages of using more routinely sized needles, lack of scoliosis, lack of risk of penetrating a major blood vessel (e.g., the aorta or the posterior vena cava), minimal weakness in the pelvic limb, and minimal ataxia. On the other hand, disadvantages of the technique are the larger doses of the anesthetic needed and variations in efficiency, particularly if the nerves follow a variable anatomical pathway.

Segmental Dorsolumbar Epidural Anesthesia

Although not an easy technique to perform, injection of local anesthetic into the epidural space either between the first and second lumbar (L1 and L2) vertebrae or, less commonly, between the last thoracic (T13) and first lumbar (L1) vertebrae in cattle has been employed to desensitize a number of nerve roots as they emerge from the dura covering the spinal cord and produce a belt of anesthesia around the animal's trunk while maintaining control of the limbs (Fig. 23.11). This type of spinal block may be referred to as *segmental dorsolumbar epidural anesthesia* or *Arthur block*.⁵⁶ The technique was first described in 1948;⁵⁶ subsequently, many have reported its use.⁵⁷⁻⁶¹ Cattle must be thoroughly restrained during the procedure.

In the standard technique, the skin area caudal to the T13 or L1 spinous process and contralateral to the flank region to be desensitized is aseptically prepared, and 2 to 4 mL of a 2% lidocaine hydrochloride solution is injected subcutaneously and adjacent to the interspinous (T13-L1 or L1-L2) ligaments to minimize pain during the puncture procedure. The first lumbar (L1-L2) interver-

tebral space in cattle is located 1.5 to 2.0 cm caudal to an imaginary line drawn across the back from the cranial edge of the transverse process of the second lumbar (L2) vertebrae. The dorsal lumbar processes and the depression between them can occasionally be palpated. A 1.25-cm, 14-gauge needle to facilitate penetration of an 11.25-cm, 18-gauge spinal needle with stylet is inserted at that site. The needle is advanced through the interosseous canal, which is formed by the arches of spinous processes T13 and L1, cranially and caudally, and the intervertebral articular processes laterally, until an abrupt reduction in needle passage is noted, indicating piercing through the interarcuate ligament and entry into the vertebral canal (Fig. 23.12). The spinal needle is inserted for a distance of 8 to 12 cm while being directed ventrally and medially at an angle of 10° to 15° with the vertical, at which point the needle has reached the epidural space. The spinal needle can be inserted through the muscle with relative ease, but encounters a slight increase in resistance during the insertion process at the interspinous and interarcuate ligaments.

Withdrawal and redirection of the needle are necessary if the needle point impinges against the bony arches of T13 and L1 or L1 and L2, respectively. The needle is properly placed into the epidural space if no blood or CSF flows from the needle hub or is obtained upon aspiration. Because of the negative pressure in the epidural space, a sucking sound is heard as air enters the needle immediately after penetration of the interarcuate ligament. This negative epidural pressure may vary between heifers (−10 mm Hg) and lactating (−17 to −20 mm Hg) or pregnant (−15 mm Hg) cows, but the epidural pressure will be negative in all cattle.⁶² Most often, the epidural space is identified by the loss-of-resistance method.³⁹ This means that first a marked resistance to injection of saline or air is encountered when the point of the needle enters the interarcuate ligament, and resistance completely

Fig. 23.11. Needle placement for segmental dorsolumbar epidural analgesia in cattle. **A:** Cranial and left lateral aspect of the thoracolumbar vertebrae and their associated spinal nerves T13 to L3 with needle tip placed at the L1 to L2 intervertebral space. **B:** Cranial view of a transection of the first lumbar vertebra at the location of the intervertebral foramen, showing the relation of the structures inside the spinal canal: *a*, articular process; *b*, interarcuate ligament; *c*, epidural space with fat and connective tissue; *d*, dura mater; *e*, arachnoid membrane; *f*, dorsal branch; *g*, ventral branch of first lumbar [L1] spinal nerve; and *h*, ramus communicans. From Skarda,⁵ p. 634.

Fig. 23.12. The 11.25-cm, 18-gauge spinal needle is directed ventrally and medially of approximately 10° from vertical to enter the neural canal via intervertebral space, which is surrounded by the bases of the spinous processes cranially and caudally and by the intervertebral articular processes laterally (T13, thirteenth thoracic; and L1, first lumbar vertebra).

disappears after the point of the needle has passed through the ligament. An alternative method is to place a few drops of saline or local anesthetic solution in the hub of the needle and observe the drops being aspirated into the needle by the subatmospheric pressure of the epidural space (hanging-drop method).^{63,64} If bleeding occurs, the stylet is placed into the needle, and the needle is withdrawn after 2 to 3 min. If the dura is inadvertently punctured and CSF is obtained, segmental thoracolumbar subarachnoid anesthe-

sia may be performed or the procedure terminated. After piercing through the interarcuate ligament, approximately 8 mL of either a 2% lidocaine hydrochloride solution or a 5% procaine hydrochloride solution can be injected in an average 500-kg cow. This amount of anesthetic is sufficient to desensitize the T13, L1, and L2 dermatomes within 7 to 20 min with a duration of 45 min to 2 h.⁵⁹ The needle must not be manipulated further, but should be removed immediately after injection in order to avoid damage to the spinal cord and meninges (Fig. 23.13).

Factors that influence epidural spread and duration of anesthesia include age, extradural fat, pregnancy, venous circulation, and variables that are under the direct control of the anesthetist, such as positioning of the patient, choosing the site for epidural puncture, orientation of the needle bevel, and determining the volume. Although there is considerable disagreement among authors about the ultimate mode of action of epidural anesthetics, spread of the anesthetic solution within the epidural space is the first event after injection. The epidural space at the thoracolumbar (T13-L1) or first lumbar (L1-L2) intervertebral space in cattle cannot be reached by the spinal needle if the interarcuate ligament is ossified because of old age (>8 years).⁶⁵

The typical effects of segmental blockade in young ruminants reflect a predominantly paravertebral site of action, whereas the widespread anesthesia produced by injection of small volumes in elderly cattle indicates a more intense action within the subarachnoid space itself. The dura becomes more permeable to local anesthetics with age because of a progressive increase in the size and number of arachnoid villi, thereby providing a larger area through which local anesthetic can diffuse into the subarachnoid space. The epidural local anesthetic dose needs to be reduced

Fig. 23.13. Cranial view of a transection of the first lumbar (L1) vertebra at the location of the intervertebral foramen of an adult cow, with needle tip placed for unilateral (right side) segmental dorsolumbar epidural anesthesia. ES, epidural space with fat and connective tissue; SC, spinal cord; and L1, first lumbar vertebra.

slightly in old patients. Similarly, migration of epidural anesthetics is enhanced by distension (engorgement) of epidural veins in full-term pregnancy and increased quantities of fat in obesity. Selective anesthesia on one side of the spinal column is achieved by placing the needle tip within the epidural space across the midline and injecting small volumes of the anesthetic to the nerve roots on the contralateral side (Fig. 23.13). Bilateral anesthesia is achieved by administering either a larger volume of the anesthetic or a regular dose through a needle with its tip placed within the epidural space in the median plane dorsal to the spinal cord, and desensitizing the nerve roots on both sides. The bevel of the spinal needle is directed cranially to limit the caudal flow of the anesthetic, thereby minimizing the risk of loss of motor control of the pelvic limbs.

The area of segmental anesthesia is a function of total mass (volume \times concentration) of drug injected. Increasing the volume or concentration will increase the area desensitized. In general, a single injection of a 2% or 3% lidocaine hydrochloride solution (10 mL), 4% or 5% procaine hydrochloride solution (10 mL), or a 2% tubocaine hydrochloride (10 to 15 mL) into the epidural space at the T13-L1 intervertebral space induced satisfactory anesthesia and relaxation of the abdominal wall and flank for operations such as rumenotomy and cesarean section, with the animal standing. Anesthesia develops approximately 10 min after injection and lasts approximately 2 h. Onset and duration of anesthesia vary widely between local anesthetic drugs and are influenced by several factors. (Table 23.1).

Segmental spread of anesthesia is improved by increasing the volume of the solution injected, whereas a more rapid onset of analgesia and motor blockade, greater frequency of adequate analgesia, greater depth of motor blockade, and longer periods of analgesia are better achieved by increasing the concentration of the anesthetic. The extent of cranial and caudal migration of dye (0.12% new methylene blue in 0.9% saline), rather than diffusion through meninges to CSF, after injection into the first interlum-

bar epidural space has been evaluated in cattle.⁶⁶ As can be expected, the number of stained vertebrae and amount of epidural fat and dura mater were greater in cows administered 10 mL compared with 5 mL of solution. However, the number of stained vertebrae in the 5-mL group was comparable to the number of dermatomes with bilateral analgesia after administration of the larger volume (10 mL) of local anesthetic (procaine), suggesting a wider distribution in the epidural space than provision of actual dermatomal analgesia.

Extradural fat content and venous circulation have also been shown to influence the spread and the pharmacokinetics of 5 mL of xylazine in 0.9% sodium chloride (NaCl) solution when injected into the dorsolumbar (L1-L2) epidural space.^{67,68} A wider area of segmental analgesia with faster onset and longer analgesia was obtained with xylazine when injection was made deeper under the epidural fat. In comparison, the more superficial administration of xylazine between the periosteum and epidural fat produced uneven distribution of analgesia in the right and left flanks with a slower onset and shorter period of analgesia and sedation.⁶⁸

Various flank surgeries, including cecotomy, cesarean section, laparoscopy, omentopexy, rumenotomy, duodenotomy, and fistulization, have been performed during dorsolumbar (L1-L2) epidural anesthesia achieved with either lidocaine, xylazine, or a combination of both drugs.^{60,61} The injection depth used was about 9 mm deeper than the epidural entrance depth (8 cm). The number of analgesic dermatomes increased after injection of epidural xylazine (0.05 mg/kg) when compared with the epidural injection of lidocaine (0.2 mg/kg) alone.⁶⁰ The combination of 0.025 mg/kg of xylazine and 0.1 mg/kg of lidocaine was very effective in producing regional analgesia of the flank when performing standing laparotomy in conscious cattle.^{60,61}

The antagonistic efficacy of atipamezole (0.025 mg/kg in 0.9% NaCl) given by either the intravenous or epidural route, 30 min after the onset of segmental thoracolumbar analgesia induced by the epidural injection of xylazine at the first lumbar intervertebral space, has been documented.⁶⁹ The wide range of segmental analgesia and slower-developing ataxia was considered evidence of xylazine diffusion into the CSF. Atipamezole given by either route (intravenous or epidural) reversed analgesia at the flank, as well as sedation. However, the flank area became desensitized again after intravenous atipamezole administration and remained so for nearly 2 h. Ataxia was more rapidly reversed by epidural atipamezole administration than by intravenous injection.⁶⁹ Although the mechanism by which epidurally administered xylazine produces analgesia remains controversial, the results of this study support an analgesic action being mediated by α_2 -adrenergic receptors, not by a local anesthetic effect. Analgesia at the flank was completely reversed by atipamezole (0.025 mg/kg intravenously [IV] or epidurally), a specific and potent α_2 -adrenergic receptor antagonist. Furthermore, α_2 -adrenergic receptors and α_2 -adrenergic receptor mRNAs have been identified on the dorsal and ventral root fibers and spinal cord of calves.⁷⁰

As for knowing exactly where the local anesthetic block occurs following epidural administration, the critical CSF concentration of local anesthetic required to eliminate response to deep

needle-prick stimulation at the thoracolumbar T13 to L1 dermatomes has been assessed.^{71,72} The subarachnoid threshold concentration of procaine was reached after repeated epidural injections, but not after a single administration, indicating that segmental lumbar epidural anesthesia in cattle may be primarily due to analgesia of dura-covered roots outside the epidural space (paravertebral site), and to be minimally, if at all, dependent on desensitization of nerves within the subarachnoid space.

Finally, segmental spread of anesthesia is improved by a fast injection, but the advantage of a larger segmental area of analgesia is offset by a shorter duration, increased occurrence of incomplete analgesia, and high frequency of the patient's discomfort upon injection, which is probably attributable to transient elevation of CSF pressure. The rate of injection should be slow—a volume of 10 mL given over approximately 10 s.

Selective unilateral segmental (T13-L3) epidural anesthesia in cattle has been associated with decreases in arterial blood pressure and total peripheral resistance, with no changes in stroke volume, left ventricular stroke work, and left ventricular minute work. Increases in heart rate and cardiac output are typical.⁷³ Increases in cardiac output are believed to be caused by an increase in heart rate secondary to the decreased vascular resistance. Respiratory rate; arterial and mixed-venous pH, oxygen, and carbon dioxide tensions; oxyhemoglobin saturation; oxygen content; oxygen transport; and oxygen uptake remain unaltered, indicating that the sympathetic blockade caused by thoracolumbar epidural injection is well tolerated in nonsedated healthy cattle.⁷³

The advantages of segmental dorsolumbar epidural anesthesia as compared with proximal and distal paravertebral anesthesia include the use of a single injection of a small quantity of anesthetic and uniform analgesia and relaxation of the skin, musculature, and parietal peritoneum. The disadvantages include difficulty in performing the technique, potential for trauma to the spinal cord or venous sinuses, and loss of motor control of the pelvic limbs; also, there is the potential for a more profound physiological disturbance owing to overdose or subarachnoid injection.

Continuous Lumbar Segmental Epidural Anesthesia

Continuous lumbar epidural anesthesia in cattle can be achieved by aseptically placing a catheter into the epidural space (Fig. 23.14). A 10.2-cm, 18-gauge thin-walled Tuohy needle with stylet is inserted into the epidural space at the thoracolumbar (T13-L1) interspace as previously described. This space is identified with reference to the last rib (T13) and the cranial edge of the transverse process of the first lumbar (L1) vertebra.⁷⁴ A small quantity of local anesthetic solution (2 to 3 mL) is injected along the track of the needle. The distance from the skin to the thoracolumbar (T13-L1) epidural space may vary between 8 and 12 cm, depending on size. Injection of 5 mL of air should not encounter resistance. If no CSF or blood flows from the needle, 1 mL of a 2% lidocaine hydrochloride solution is injected into the thoracolumbar epidural space during a 10-s period to avoid pain caused by impingement of the catheter and stylet at the spinal cord. After the bevel in the epidural space is directed caudally, a

Fig. 23.14. Paramedian sagittal section of the thoracolumbar area of an adult cow with needle placement for catheterization of the lumbar epidural space (T13, thirteenth thoracic; and L1, first lumbar vertebra). IAL, interarcuate ligament.

commercially available 91.8-cm, 20-gauge Teflon epidural catheter with graduated markings and stylet is introduced into the needle and advanced caudally 3 to 5 cm beyond the tip of the needle. The needle is removed from the catheter while the catheter is left in position and sutured to the skin at the site of emergence from the skin.

Injection of approximately 6 mL of a 2% lidocaine hydrochloride solution or a 5% procaine hydrochloride solution at the anterior portion of the lumbar (L1 to L2) area should produce unilateral or bilateral anesthesia extending from spinal cord segments T12 to L4 of adult cows. Analgesia is achieved 10 to 20 min after completion of the injection and lasts 1 h to 1 h 40 min.⁷⁴ A more caudal spread of epidural block can be expected with an injection of local anesthetic more caudal than L2. An overdose of local anesthetic (>6 mL) to the L2 area or a regular dose of anesthetic at a more caudal level than L2 should be avoided to prevent anesthesia of the femoral and sciatic nerves and thus loss of pelvic limb function.⁷⁴ The reason for unilateral analgesia could be attributable to placement of the epidural catheter at the nerve roots on one side, minimal circumferential

Fig. 23.15. Needle and catheter placement for thoracolumbar subarachnoid analgesia in cattle. **A:** Cranial and left lateral aspect of the bovine thoracolumbar and sacral vertebrae and their associated spinal nerves T13 to L3, with needle tip placed at the lumbosacral intervertebral space. **B:** Cranial view of a transection of the first sacral vertebra at the location of the intervertebral foramen, showing the relation of the structures inside the spinal canal: *a*, articular process; *b*, interarcuate ligament; *c*, epidural space with fat and connective tissue; *d*, dura mater; *e*, arachnoid membrane; *f*, subarachnoid space with cerebral spinal fluid and needle tip; and *g*, pia mater. From Skarda,⁵ p. 635.

dissipation (overflow) of local anesthetic around the dura mater spinalis, and lateral escape of the local anesthetic from the epidural space through patent intervertebral foramina.

In comparison to segmental epidural anesthesia, produced by injection of local anesthetic through a spinal needle, continuous segmental epidural anesthesia offers the advantages of providing a route for repeated small fractional maintenance doses of local anesthetic drug, making the extent of anesthesia more readily controlled and producing a lower frequency of accidental subarachnoid administration of local anesthetic. The reported disadvantages of the catheter technique include higher frequency of postanesthetic myositis, caused by the larger bore and blunter needle, higher frequency of unilateral blockade, unpredictability of whether ipsilateral or contralateral anesthesia develops, and lack of analgesia after passage of the catheter tip into the paravertebral space.

Thoracolumbar Subarachnoid Anesthesia

In cattle, this is performed by aseptically introducing a catheter into the subarachnoid space at the lumbosacral (L6-S1) intervertebral space and advancing it to the thoracolumbar (T13-L1) intervertebral space (Fig. 23.15).⁷⁴⁻⁷⁷ Although the dorsal subarachnoid space in cattle can be penetrated at the thoracolumbar (T13-L1) and first lumbar (L1-L2) intervertebral spaces, dura puncture at these sites is not recommended because of potential trauma to the spinal cord. Cattle must be well restrained in a stock to facilitate the catheterization procedure. The skin at the lumbosacral (L6-S1) intervertebral space and lumbosacral fascia adjacent to the interspinous (L6-S1) ligaments are injected with approximately 5 mL of a 2% lidocaine hydrochloride solution, using a 15-cm, 18-gauge spinal needle. The space is located 1 to 2 cm caudal of a line drawn between the cranial edge of each tuber sacrale and the dorsal midline.

Fig. 23.16. The tip of a 17-gauge Huber-point Tuohy needle with Formocath polyethylene catheter (0.095-cm outside diameter), reinforced with a stainless-steel spring guide (0.05-cm outside diameter).

A larger-bore (17.5-cm, 17-gauge) Huber-point Tuohy needle with stylet is inserted at the desensitized L6-S1 site and is advanced along the median plane perpendicular to the spinal cord until the needle enters the subarachnoid space. The bevel of the needle is directed cranially, the stylet is removed, and 2 to 3 mL of CSF is aspirated. Occasionally, it is necessary to make several minor adjustments before the needle is satisfactorily positioned into the subarachnoid space. Redirection of the needle is required if CSF cannot be obtained, and should be accomplished after almost complete withdrawal of the needle to prevent bending it. Upon CSF aspiration, a Formocath polyethylene catheter 80 to 100 cm long with a 0.095-cm outside diameter, reinforced with a stainless-steel spring guide (0.05-cm outside diameter), is passed through the needle (Fig. 23.16) and advanced approximately 60 cm to the midthoracic area. Minimal resistance to catheter advancement and no movement of the patient indicate proper technique, without kinking and curling of the catheter and no trauma to the spinal nerve roots within the subarachnoid space. The nee-

dle is withdrawn over the catheter; then the spring guide is removed and a catheter adapter or a 23-gauge needle with a three-way stopcock is attached to the catheter. The catheter is then gently withdrawn a calculated distance to place its tip at T13-L1.

The catheter must never be withdrawn after advancing it through the spinal needle because withdrawal may shear off the catheter within the subarachnoid space.^{75,78} The following measurements are made to place the catheter tip at the T13-L1 intervertebral space: (a) the total length of the catheter (T), (b) the distance BC between the skin surface (B) and the subarachnoid puncture site (C), and (c) the distance CD between the lumbosacral (C) and thoracolumbar (D) intervertebral space: ($T = AB + BC + CD$). The length of the free end of the external catheter and the skin surface (AB) equals the total length of the catheter minus the distance from entering the skin to the tip of the subarachnoidally placed catheter: $AB = T - (BC + CD)$. The average distance between the palpable lumbosacral (L6-S1) and thoracolumbar (T13-L1) intervertebral spaces was approximately 45 cm in adult cows.⁷⁵ Proper subarachnoid positioning of the catheter can be radiographically confirmed if the guidewire is left in position (Fig. 23.17).

A small dose (1.5 to 2.0 mL) of a 2% lidocaine hydrochloride solution or a 5% procaine hydrochloride solution is injected at a rate of approximately 0.5 mL/min. Surgical anesthesia extending from spinal cord segment T9 to L3 on one or both sides is maximal 5 to 10 min after injection and lasts for 20 min to 1 h 20 min.⁷⁵ The absorption of drug into the systemic circulation determines the decline of subarachnoid anesthetic concentration and thus the duration of subarachnoid analgesia. The spinal fluid concentration necessary for analgesia is approximately 200- μ g procaine/mL in calves and adult cows,^{65,71} and is easily maintained by fractional bolus administration of 0.5 mL of the anesthetic at 30-min intervals or as needed. In vitro measurements of the rate of hydrolysis of procaine in spinal fluid taken from adult cows did not detect changes in the spinal fluid concentration of procaine after a 2-h incubation (37°C).⁷²

When compared with dorsolumbar epidural analgesia, the advantages of thoracolumbar subarachnoid analgesia include simplicity of needle and catheter placements, anesthetic deposition at nerve roots (and thus a minimal dose requirement), minimal physiological disturbance, and small doses for maintenance of analgesia. A disadvantage of the catheter technique is the unpredictability of whether ipsilateral or contralateral analgesia develops. The cause for the one-sided block has not been investigated, but could be attributable to minimal circumferential dissipation (overflow) of local anesthetic around the pia mater spinalis after placement of the catheter at the ventral surface of the spinal cord, where it could be trapped between the trabecula and dorsal longitudinal ligament. Kinking and curling of the catheter are readily determined by lack of CSF aspiration and avoidance responses of cattle. Accidental vascular puncture and faulty catheter positioning make the technique ineffective for producing abdominal analgesia of the flank region. Thoracolumbar subarachnoid anesthesia is not readily applicable for field use because it requires special equipment, precise dosage administration and catheter placement, and maintenance of sterility.

Anesthesia for Obstetric Procedures and Relief of Rectal Tenesmus

At least four techniques are advocated in ruminants for pain relief and muscle relaxation during obstetric manipulations and surgical procedures involving the tail, perineum, anus, rectum, vulva, vagina, prepuce, and skin and scrotum. These techniques include the caudal epidural, continuous caudal epidural, sacral paravertebral, and pudendal nerve blocks. Any of these techniques may be used for a number of surgical procedures, such as suturing tears in the perineum and vulva, reconstruction of the perineum (Gotze's operation), retraction of the uterine cervix, reduction of prolapsed uterus, ovariectomy, and embryotomy. These techniques may also be used as adjunctive treatments for controlling rectal tenesmus associated with irritation of the perineum, anus, rectum, and vagina. Properly performed blocks do not desensitize femoral and ischial nerves, thereby preserving pelvic limb function. These techniques are not applicable to pigs.

Caudal Epidural Anesthesia

Because this technique is simple and inexpensive, and requires no sophisticated equipment, it is routinely used in cows, sheep, and goats. Needle placement is either at the sacrococcygeal (S5-Co1) or more commonly at the first coccygeal (Co1-Co2) interspace, beyond the termination of the spinal cord and meninges (Fig. 23.18).^{79,80} Only the coccygeal nerves, the thin phylum terminale, the vasculature, and epidural fat and connective tissue remain in the spinal canal at the site of needle penetration, and these structures are not easily damaged when using aseptic technique.⁸⁰ The location of the Co1-Co2 interspace is easily identified by elevating and lowering the tail and palpating the depression and movement between the respective vertebrae. The Co1-Co2 interspace is larger and more easily penetrated than the S5-Co1 site. The S5-Co1 interspace may be ossified in older cows and is not so easily detectable in fat cows.⁸¹

The skin over the Co1-Co2 joint space is disinfected and desensitized with small amount (2 to 3 mL) of local anesthetic to ensure minimal movement during insertion of a 3.75- to 5-cm, 18-gauge needle. The epidural needle is inserted in a median

Fig. 23.18. Needle placement for caudal epidural analgesia and catheterization of the sacral epidural space in cattle. Co1, first coccygeal; and Co2, second coccygeal vertebra. The desensitized subcutaneous area after caudal blockade is *stippled*: epidural needle placement (A) and epidural catheter placement (B).

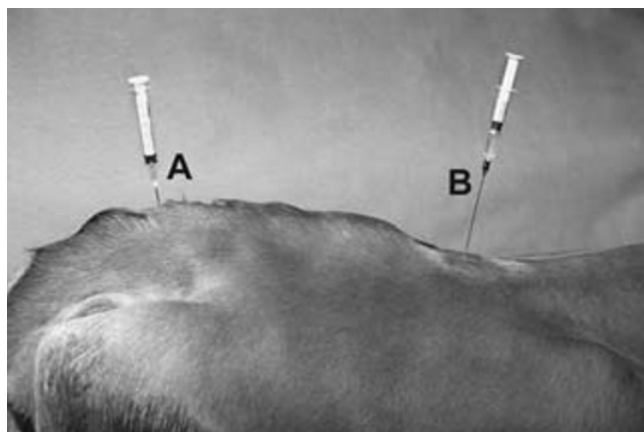

Fig. 23.19. A: A 3.75-cm, 18-gauge needle is placed into the epidural space at the first coccygeal (Co1-Co2) intervertebral space of a Jersey cow (460 kg). B: A 15-cm, 20-gauge spinal needle is placed into the epidural space at the lumbosacral (L6-S1) intervertebral space.

plane until it contacts the floor of the vertebral canal while it is directed either at right angle to the general contour of the croup or ventrocranially at an angle of approximately 10° to vertically (Fig. 23.19A). The needle is then withdrawn approximately 0.5 cm from the ligamentous floor or intervertebral disk to place its tip in the epidural space of the neural canal. Aspiration of a few drops of the anesthetic from the hub into the needle and minimal resistance to injection of the anesthetic indicate that the bevel is placed epidurally.

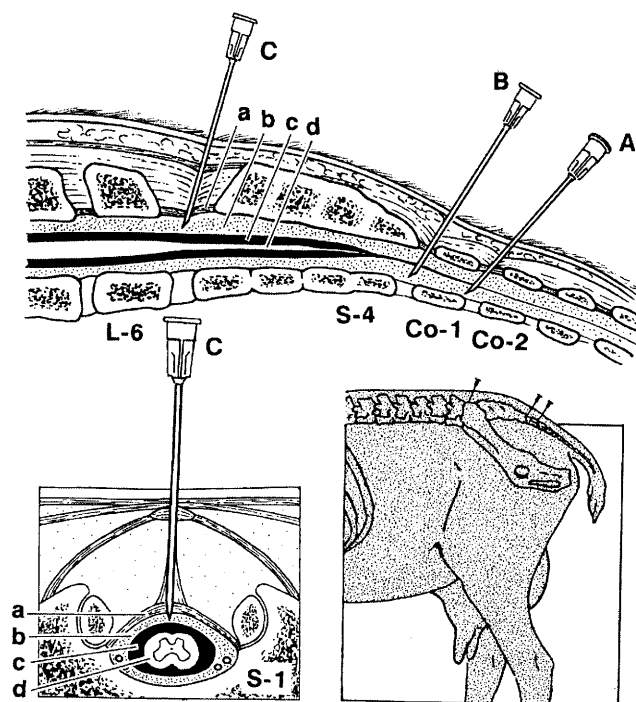

Fig. 23.20. Needle placement for caudal epidural analgesia (A and B) and lumbosacral epidural analgesia (C) in goats: L6, sixth lumbar; S4, fourth sacral; Co1, first coccygeal; and Co2, second coccygeal vertebra. A cranial view of a transection of the first sacral vertebra at the location of the intervertebral foramen is shown in the **bottom left inset**: a, interarcuate ligament; b, epidural space; c, subarachnoid space; and d, spinal cord. The desensitized subcutaneous area after anterior epidural anesthesia is *stippled* and often extends to the umbilicus of the goat and is shown in the **bottom right inset**.

Production of caudal anesthesia depends on the total dose (volume \times concentration) of the anesthetic administered. When 1 mL of a 2% lidocaine hydrochloride solution per 100 kg of body weight is injected at a rate of 1 mL/s, the area of anesthesia extends cranially to the middle of the sacrum and ventrally over the perineum to the inner aspect of the thigh. Proper techniques should desensitize the pelvic viscera and genitalia, and paralyze the tail and abolish abdominal contractions.⁸² However, locomotor function of the hind legs and uterine motility remain unaffected. Maximal anesthesia may require 10 to 20 min and can be expected to last 30 min to 2½ h.

Caudal epidural anesthesia in sheep and goats can be extremely useful for tail docking in lambs and for intravaginal obstetric procedures.^{83,84} A 2.5- to 3.75-cm, 18-gauge needle is inserted epidurally at Co1-Co2 or S5-Co1 (Fig. 23.20), and no more than 1 mL of a 2% lidocaine hydrochloride solution per 50 kg of body weight is injected. Careful aseptic precautions similar to the technique in cattle must be used. Although a 2% lidocaine hydrochloride solution is now almost universally used, the addition of 0.125 mL of 1:80,000 epinephrine per milliliter of anesthetic can suppress the tone and motility of the tail for longer than 1 h.⁸⁵

Adjusting the pH of a 2% lidocaine hydrochloride solution from 6.3 to 6.9 by the addition of 1 mL of 8.4% sodium bicarbonate solution (1 mEq) to 10 mL of lidocaine has little or no effect on the time of onset and duration of caudal epidural anesthesia in cattle.⁸⁶

Caudal Epidural Analgesia with α_2 -Adrenergic Agonists α_2 -Adrenoceptor agonists, such as xylazine, detomidine, medetomidine, and clonidine, have been injected into the caudal epidural space of cattle in an attempt to produce prolonged analgesia (2 to 3 h) of perineal/or flank areas, which is satisfactory for most surgical or obstetric procedures in cattle and llamas.^{87–109}

With the exception of bupivacaine, local anesthetic drugs, such as procaine, lidocaine, and mepivacaine, when administered into the epidural space at the first coccygeal (Co1-Co2) or sacrococcygeal (S3-Co1) intervertebral space, provide perineal analgesia accompanied by muscle paralysis (30 min to 2½ h) and may have to be readministered to enable completion of prolonged surgical procedures. In contrast to the effects of local anesthetics, the α_2 -adrenoceptor agonists produce analgesia with minimal proprioception deficits or motor nerve blockade.

Caudal Epidural Xylazine Perineal analgesia lasts significantly longer (up to 3 h) in cattle after injection of 0.05 mg of xylazine/kg of body weight, diluted to a 5-mL volume with sterile water into the epidural space at the Co1-Co2 intervertebral space, than when lidocaine is injected.^{88–90,97,102,106} However, side effects, such as sedation, mild ataxia, bradycardia, hypotension, respiratory acidosis, hypoxemia, and ruminal amotility, are routinely observed in conscious standing cattle when xylazine is given epidurally.^{93,95,98,102} These side effects can be partially reversed by intravenous administration of tolazoline (0.3 mg/kg), an α_2 -adrenoceptor antagonist, while not diminishing the desirable local (S3 to the coccyx) analgesic effects.⁹⁴ Nonetheless, care must be taken to limit the volume of xylazine and its rostral spread to the femoral and sciatic nerves. Xylazine appears to exhibit some direct local anesthetic sensory and motor nerve-blocking actions in addition to its spinal cord α_2 -adrenoceptor-mediated analgesic effects.

Xylazine hydrochloride (0.05 mg/kg in 5 mL) diffuses from the caudal epidural space into the CSF of adult cattle and can produce a degree of subarachnoid nerve-root anesthesia.^{90,91} Xylazine is not detectable in bovine plasma, however, making it doubtful that its presence within the subarachnoid space after epidural administration is secondary to absorption of xylazine from the bloodstream.⁹¹ Because uterine motility can increase after epidural xylazine administration, this technique is not recommended for providing analgesia during obstetric procedures in pregnant ruminants or fetotomy procedures.⁸⁹

As might be expected, the degree of analgesia, sedation, and ataxia is dose dependent with sacrococcygeal epidural xylazine administration. With increased doses of xylazine (50, 70, 100 μ g/kg), perineal analgesia and marked systemic effects (e.g., sedation, decreased heart and respiratory rates, and decreased rumen motility and bloat) have been prolonged. Further increases of the xylazine dose (120 μ g/kg) extend analgesia to the udder

without affecting the flank, along with marked sedation, sternal decubitus, ptialism, and ptosis.^{96,100}

Irreversible paralysis in three cows and a near fatal apnea in one calf after epidural administration of xylazine have been reported.¹⁰⁶ Although necropsy of the recumbent cows demonstrated marked demyelination of the lumbar spinal cord, it is not clear whether the preservative in the xylazine, or the drug itself, produced the demyelination. Further studies are needed to determine whether analgesia induced by epidurally or subarachnoidally administered xylazine may, in part, be due to demyelination of the spinal cord.

Caudal Epidural Xylazine and Lidocaine By reducing the dose of xylazine to 0.03 mg/kg of body weight and adding a 2% lidocaine hydrochloride solution to a total volume of 5 mL, a more useful epidural anesthetic action may be achieved when performing procedures such as rumenotomy, cesarean section, correction of vaginal or uterine prolapse, repairs of perineal lacerations and rectovestibular fistulae, and removal of vaginal tumors.⁹⁷ The xylazine-lidocaine combination extends analgesia as far cranially as the T13 and L1 spinal segments, thereby covering the tail, perineum, udder, and flank areas. Surgical analgesia is attained in 3 to 4 min after drug administration and lasts for about 1 h 40 min, with a moderate degree of ataxia.⁹⁷ Although the combination of xylazine and lidocaine typically produces sedation and mild ataxia, the analgesia lasts longer than that achieved with either xylazine or lidocaine alone.¹⁰³

Caudal epidural anesthesia has also been used in llamas on occasion. Either 2% lidocaine (0.22 mg/kg), 10% xylazine (0.17 mg/kg) diluted with 2 mL of sterile water, or the combination of 2% lidocaine (0.22 mg/kg) and 10% xylazine (0.17 mg/kg) have been injected into the epidural space at the sacrococcygeal (S5-Co1) junction.^{104,105} Duration of analgesia is extended with the combination of xylazine and lidocaine to nearly 3½ h compared with just over 1 h with lidocaine alone. Mild sedation is often apparent 20 min after epidural xylazine administration, and at this dose lasts approximately 30 min.¹⁰⁵

Caudal Epidural Detomidine Both the epidural administration and the intramuscular administration of detomidine (40 μ g/kg) in cattle appear to induce comparable degrees of analgesia of the perineum and flank, moderate sedation and ataxia, hypertension, cardiopulmonary depression, and ruminal hypermotility.¹⁰⁷ Consequently, the epidural administration of detomidine does not appear to be more or less advantageous or disadvantageous than intramuscular administration.

Caudal Epidural Medetomidine The analgesic, cardiovascular, and respiratory effects of epidural medetomidine (15 μ g/kg diluted in 5 mL of 0.9% NaCl) injection at the first or second coccygeal intervertebral space in adult cattle has been evaluated.¹⁰⁸ Medetomidine induced perineal analgesia within 5 to 10 min, which lasted nearly 7 h, but was accompanied by mild to moderate sedation. The degree of medetomidine-induced analgesia was more pronounced and the duration longer than that achieved with a standard epidural dose of lidocaine. Two of six cows became

recumbent, but were easily coaxed to stand. Salivation was evident, as was the increased frequency of urination after medetomidine. Heart and respiratory rates were decreased, but arterial blood pressure remained unchanged.¹⁰⁸

Caudal Epidural Clonidine Epidural clonidine administration can produce profound antinociception in people, cattle, sheep, goats, pigs, and horses without the sensory or motor blockade of local anesthetics.^{109–119} Although epidurally and intrathecally administered clonidine has been successfully employed as an analgesic in human patients for treatment of acute postoperative pain and in patients tolerant to intrathecally administered opiates, its use has been somewhat limited because of its short-acting analgesic effect and accompanying sedation, hypotension, bradycardia, and respiratory depression.^{120,121}

Caudal Epidural Ketamine

Ketamine alone has been administered into the epidural space at the first intercoccygeal (Co1-Co2) space of cattle. It induces dose-dependent depression (0.5, 1.0, and 2.0 mg/kg) of pain stimulus in the tail, vulva, anus, and perineum, but not in the hind-limb area, and produces minimal sedation, ataxia, cardiopulmonary effects, and changes in rumen function.^{122,123} The 0.5-mg/kg dose produced lack of response to stimulation of the tail only, whereas 1 mg/kg produced variable analgesia, lasting 55 min in the tail and 15 min in the anus and perineum, but having no effect in the vulva. The 2-mg/kg dose of ketamine produced analgesia in all regions tested, lasting 1 h 15 min in the anus and perineum, 1 h 20 min in the vulva, and up to 1 h 40 min in the tail, but this dose was accompanied by moderate sedation and ataxia in two cows. At these doses, ketamine did not induce any analgesia in the hind limbs.¹²²

In a similar study, cattle were injected with 5, 10, and 20 mL of 5% ketamine at the first intercoccygeal (Co1-Co2) space.¹²³ Dose-dependent analgesia without sedation was observed at the tail and perineum 5 min after all three doses. Analgesia lasted from 20 min (low dose) to 1 h (high dose). Moderate ataxia was observed with the 20-mL dose of ketamine. One cow became recumbent after a 20-mL ketamine dose administration. Respiratory rate, mean arterial blood pressure, rumen motility, and rectal temperature were not affected.¹²³

Continuous Caudal Epidural Anesthesia

This is indicated in cattle and sheep with prolapse of the vagina and/or rectum, which can provoke severe continuous straining. The technique in cattle is simply performed by inserting a fine catheter into the epidural space at S5-Co1 or Co1-Co2 through a 7.5-cm, 16- or 17-gauge needle, which is either a thin-walled Huber-point directional needle or a Hustead needle.^{124,125} The skin and the needle track are desensitized. After a stab incision on the midline is made to minimize resistance to the passage of the somewhat blunt needle, the spinal needle with stylet in place and bevel directed cranially is advanced for 5 to 8 cm while being directed at approximately 45° to vertical until resistance to needle passage is abruptly reduced. The stylet from the needle is removed, and a test dose of 2 to 3 mL of anesthetic is injected with

Fig. 23.21. An epidural catheter with adapter in a calf with rectal prolapse.

almost no resistance, assuring proper placement of the needle in the epidural space.

A 30-cm medical-grade vinyl epidural catheter (0.036-cm outside diameter) with gradual markings is introduced into the canal through the needle and advanced cranially 3 to 4 cm beyond the tip of the needle (Fig. 23.18B). The needle is then withdrawn, leaving the catheter in position. Approximately 3 to 5 mL of a 2% lidocaine hydrochloride solution is injected into the catheter at 4- to 6-h intervals or whenever the animal shows signs of straining. The catheter adapter or 23-gauge needle and three-way stopcock are placed on the free end of the catheter. The catheter can be used for many hours of infusion if it is sutured to the skin puncture site with adhesive tape. The sterility of the free end of the catheter is maintained by using protective sterile gauze (Fig. 23.21).

Alcohol epidural injection can be used for long-term demyelination of nerve roots in sheep and goats. First, only 0.5 to 1.0 mL of a 2% lidocaine hydrochloride solution per 50 kg of body weight is injected epidurally at Co1-Co2 or S5-Co1, and the extent of caudal analgesia is noted to ensure that the level of rostral spread does not extend to the sciatic or femoral nerve roots. After full sensation has returned, a mixture of equal volumes of 70% to 95% ethyl or isopropyl alcohol and a 2% lidocaine hydrochloride solution is injected at the same site, using a similar volume and injection rate as the previous injection.

Analgesia of the pelvic and perineal area and paralysis of the tail should result and last from a few days to several months, depending on the time required for remyelination of the nerves.¹²⁶ The alcohol technique is not practical in cattle because the prolonged flaccidity of the tail may lead to buildup of manure and urine in the perineal area, with subsequent dermal excoriation and maggot infestation during fly season. The problems of alcohol epidural anesthesia in sheep and goats with docked tails are similar to, but less serious than, those in cattle. The chronic flaccid tail may possibly become inflamed, necrotic, and purulent, leading to a fly strike in the rectal area. Prolonged rear-limb paralysis from the demyelination of sciatic and femoral nerve roots can result from overdosing on alcohol epidural anesthetic.

Sacral Paravertebral Anesthesia

Sacral paravertebral injection is advocated to relieve rectal tenesmus associated with rectal prolapse without sciatic nerve dysfunction.^{127,128} This technique is associated with minimal risk of the animal's lying down and maintenance of motor function of the tail. Success of the technique depends on blockade of the pelvic splanchnic nerve (medial hemorrhoidal nerve) and caudal rectal nerve (caudal hemorrhoidal nerve), which supply sensory fibers to the anus, vulva, and vagina. The third, fourth, and fifth sacral spinal nerves (S3, S4, and S5) are major components of the pelvic splanchnic and caudal rectal nerves and are desensitized at the emergence from the sacrum on both sides of the spine in cattle and sheep. In males, S3 supplies motor fibers to the retractor penis muscle and, in order to prevent preputial prolapse, must not be desensitized. With the animal in standing restraint and good control of anterior, posterior, and lateral movement, the skin of the dorsal sacral area is cleansed and disinfected. Hair removal is optional. The general anatomical site of sacral foramina S3, S4, and S5 is identified approximately 1.0 to 1.5 cm from the dorsal midline of the vertebral crest or usually just lateral to the border of the crest.

Nerve S5 is at the sacrococcygeal (S5-Co1) junction. Nerves S4 and S3 exit from the S4 and S3 foramina, 3 and 6 cm cranial to the S5 foramen in yearling-to-adult cattle. A 5- to 7.5-cm, 16- or 18-gauge needle, preferably with stylet, is inserted ventrally to a depth just beyond where it enters the foramen (Fig. 23.22). A stab incision through the desensitized skin facilitates the insertion of the needle. A 2% lidocaine hydrochloride solution (5 to 10 mL) is injected into a 1-cm-diameter area within each dorsal foramen to desensitize both the dorsal and ventral rami of that nerve. Anesthesia of the anus, vulva, and vagina can be expected within 10 min after completion of injection and typically lasts for approximately 2 h. No unfavorable sequelae associated with urination and defecation should occur, because urinary bladder sphincter tone and motor function of the tail are maintained, although the motor function of the anal sphincter is slightly reduced. Sensation to the clitoris is unaffected.

Long-term anesthesia (up to 5 weeks) of the sacral area, as determined by observing no avoidance responses to deep needle prick to skin and muscle, may be produced by the administration of 1 to 2 mL of 70% to 95% ethyl or isopropyl alcohol to S3, S4, and S5, without the unfavorable sequelae associated with alcohol epidural anesthesia.^{127,128} Caudal epidural analgesia with a 2% lidocaine hydrochloride solution greatly facilitates the subsequent alcohol paravertebral technique.

Bilateral sacral (S3, S4, and S5) paravertebral analgesia can be produced in sheep and goats similarly to that in cattle by using a 7.5-cm, 18-gauge needle, except that the volume of lidocaine, alcohol, and alcohol-anesthetic mixture is reduced to 1 to 2 mL per injection site.

The advantage of sacral paravertebral anesthesia when compared with epidural anesthesia is relief of straining without sciatic nerve dysfunction, thereby maintaining pelvic limb function and viability of the tail. The disadvantages are technical difficulty and paraphimosis in bulls if S3 is chronically desensitized with alcohol.

Desensitization of the Internal Pudendal (Pudic) Nerves

This technique is used either in standing males for penile analgesia and relaxation distal to the sigmoid flexure and examination of prolapsed penis^{129,130} or in standing females for relief of straining caused by uterine prolapse or chronic vaginal prolapse.^{131,132} The internal pudendal nerve block is useful in the surgical management of a number of surgical procedures, including repair of uterovaginal prolapse; cervicovaginopexy; anorectal prolapse (rectopexy); ablation of anorectal, perianal, and intranal tumors, polyps, and abscesses; and catheterization for dislodging urethral calculi.¹³¹ The technique involves desensitizing the internal pudendal nerve fibers of the ventral branches (S3 and S4) and the anastomotic branch of the middle hemorrhoidal nerve (S3 and S4), using an ischioanal fossa approach. With cattle restrained in a standing position, the lesser sciatic foramen is identified by rectal palpation as a soft circumscribed depres-

Fig. 23.23. Needle placement to the internal pudendal nerve in cattle. The position of the hand palpating the internal pudendal nerve (A) on the right side is shown. Caudal rectal nerve (B), internal pudendal artery (C), sacrosciatic ligament (D), and sciatic nerve (E). From Skarda,⁵ p. 641.

sion in the sacrosciatic ligament. The foramen is less than a hand's breadth (5 cm) cranial to the anus. The pulsation of the internal pudendal artery can be felt a finger's width ventral to the internal pudendal nerve in the fossa.

The skin over the ischioanal fossa on both sides is disinfected and desensitized with 2 to 3 mL of a 2% lidocaine hydrochloride solution. A 1.25-cm, 14-gauge needle to serve as a cannula for an 8.25-cm, 18-gauge spinal needle is inserted through the desensitized skin. The longer needle is then inserted via cannula for a distance of approximately 5 to 7 cm slightly downward until it contacts the internal pudendal nerve at the deepest point of the ischioanal fossa (Fig. 23.23). The position of the needle point is verified by rectal digital palpation. Up to 25 mL of the local anesthetic solution (2% or 3% lidocaine hydrochloride) is injected around the nerve. The needle is then partially withdrawn and directed 2 to 3 cm more caudodorsally, where an additional 10 mL of the anesthetic is deposited at the cranial border of the foramen to desensitize the muscular branches and caudal rectal nerve (middle hemorrhoidal nerve).^{129,133} The position of the hands is reversed, and the procedure is repeated on the opposite side of the pelvis. Pudendal nerve block is effective after 30 min and should last for 2 to 4 h. The addition of hyaluronidase (150 IU) and epinephrine (1:10,000) to the local anesthetic reduces the anesthetic required (20 mL) and increases the duration of anesthesia.¹³⁴ Success with the pudendal nerve block depends on locating pelvic landmarks.

A relatively simple technique for approaching the internal pudendal nerve in sheep from the lateral side has been described.¹³⁵ A finger is placed into the rectum to locate the slitlike sciatic foramen. A 3.75-cm, 18-gauge needle is then inserted through the corresponding skin site, and its point is advanced to the foramen. A 2% lidocaine hydrochloride solution (3 to 5 mL) is de-

posited at the foramen. The needle is withdrawn, and the injection site is massaged. The procedure is repeated on the opposite side while keeping the finger in the rectum.

When compared with caudal epidural anesthesia, the advantages of internal pudendal nerve desensitization are that sciatic nerve function and tail tone are maintained and that the volume of local anesthetic needed to desensitize the nerve supply to the penis by the epidural technique invariably causes posterior paralysis. Ballooning of the vagina may also aid in retention after it is repositioned in cows with prolapse.¹³¹ The disadvantages of internal pudendal nerve block are lack of cervical analgesia and the necessity of identifying the injection sites by rectal palpation. The bull's penis should be protected from injury by replacing it into the prepuce and taping or purse stringing the external preputial orifice.

Desensitization of the Dorsal Nerve of the Penis

The dorsal nerve of the penis as it passes over the ischial arch may be desensitized for penile anesthesia and relaxation as an alternative technique to the internal pudendal nerve block.¹³⁶ The skin adjacent to the penile body approximately 10 cm ventral to the anus and 2.5 cm from the midline is infiltrated with 2 to 3 mL of a 2% lidocaine hydrochloride solution, using a fine needle (22 to 25 gauge). A 4-cm, 20-gauge needle is then inserted through the desensitized skin and advanced for 5 to 7 cm to contact the pelvic floor. Aspiration assures that the needle tip is not placed into the dorsal artery of the penis. While the needle is withdrawn for approximately 1 cm, the region is infiltrated with 20 to 30 mL of a 2% lidocaine hydrochloride solution. The procedure is repeated on the opposite side of the penis. Analgesia and paralysis of the penis are expected within 20 min and should last for 1 to 2 h.

Anterior Epidural Anesthesia

Introduction

Anterior epidural anesthesia is advocated for all procedures caudal to the diaphragm. The anesthetic solution, dosed at 1 mL/4.5 kg of body weight, is injected into the epidural space either at the lumbosacral (L6-S1) junction (lumbosacral epidural anesthesia) or at the sacrococcygeal (S5-Co1) or first intercoccygeal (Co1-Co2) space, using a larger volume of the anesthetic ranging from 40 mL to 150 mL in adult cattle and 5 mL to 25 mL in calves (high caudal epidural anesthesia). The site for needle placement at the lumbosacral site in lighter, immature cattle, sheep, and goats is usually palpable as a depression on the midline caudal to a line joining the anterior border of the ilium on each side (Fig. 23.20C), so injection is made at this site. The lumbosacral space in swine is the only practical injection site for inducing epidural anesthesia, making lumbosacral epidural block the most commonly used form of regional analgesia in swine. The sacrococcygeal or first intercoccygeal space is the injection site of choice in adult cattle and bulls for producing anterior block because the technique is relatively simple and trauma to the spinal cord and meninges are avoided. These structures end cranial to the site of injection, and the risk of injecting the local anesthetic into the subarachnoid space is almost nonexistent.

Proper techniques by either the lumbosacral or coccygeal approach should provide analgesia of the perineal region, the entire inguinal region, the flanks, and the abdominal wall up to the umbilicus. Cranial spread of the anesthetic affects the pelvic limb function by desensitizing the sixth lumbar (L6) and first and second sacral (S1 and S2) spinal nerves (sciatic supply), the fifth and sixth lumbar (L5 and L6) spinal nerves (obturator and femoral supply), and more cranial nerves. Depending on the degree involved, the dysfunction of hind limbs ranges from mild ataxia to complete posterior paralysis. Injury (e.g., hip dislocation) during onset (ataxia) or recovery must be avoided and can be prevented if the animals are restrained in sternal recumbency with their hind legs roped together proximal to the tarsus until recovery is complete, as determined by normal tail function. A major difficulty in producing anterior epidural anesthesia is the uncertainty of the precise extent of paralysis produced. Many factors have been shown to affect the cranial spread of the anesthetic within the epidural space. The major determinants are the size and age of the animal, the presence and size of abdominal mass (pregnancy), and other variables that can be controlled by the anesthetist, namely, positioning the patient, choosing the site of epidural puncture, orientation of the needle bevel, determining the volume and concentration of the anesthetic solution, and speed of injection.⁶⁵

Increasing the dose (volume \times concentration) increases the area desensitized. In general, the cranial extent of sensory blockade associated with epidural administration of lidocaine or mepivacaine in calves, goats, and juvenile pigs is not as far cranial as the dye-solution migration observed immediately after euthanasia.^{137,138}

As stated previously, with the use of local anesthetic drugs, increasing the volume will improve segmental spread, whereas in-

creasing the concentration will provide a more rapid onset of analgesia and motor nerve inhibition, greater frequency of adequate anesthesia, greater intensity of motor blockade, and a longer duration of effects.⁶⁵ A greater area of epidural anesthesia may be achieved by a relatively fast injection. However, the advantage of a large segmental area of anesthesia is offset by the higher frequency of patient discomfort upon injection because of transient elevation of CSF pressure and a relatively fast vascular and lymphatic absorption of the anesthetic, thereby reducing the duration and increasing the occurrence of incomplete block. Gravity has a more definite role in the spread of subarachnoid anesthesia than it does in epidural anesthesia; however, with both techniques, a more rapid onset to maximal segmental analgesia, a longer effect, and a more intensive motor nerve inhibition are achieved on the dependent side. Gravity also allows for unilateral anesthesia in sheep and goats owing to preferential escape of the anesthetic solution toward the paravertebral region. The cephalic spread of anesthesia after epidural or subarachnoid injection of specifically prepared hyperbaric solutions is limited in animals kept in a sitting position. Pregnant animals generally require a reduced dose per kilogram of body weight of the local anesthetic for satisfactory epidural and subarachnoid anesthesia. This may be attributable to decreased volume of the epidural space caused by distension of epidural veins (engorgement), increased sensitivity of neural tissue owing to hormonal changes, and a faulty overestimation of the lean body mass.

Migration of the anesthetic is enhanced by transmission of intra-abdominal pressure (pregnancy) and respiratory-induced intrathoracic pressure. Elderly cattle (over 8 years) with progressively occluded intervertebral foramina may require a smaller volume of the anesthetic than younger cattle with open intervertebral foramina.⁶⁵

Lumbosacral Epidural Anesthesia in Swine

The technique of epidural block is relatively easy to master in well-sedated pigs and is most commonly employed to facilitate cesarean section; repair of rectal, uterine, or vaginal prolapse; repair of umbilical, inguinal, or scrotal hernias; surgery of scirrhous cord; and surgery of the prepuce, penis, or rear limbs.^{139–155} Epidural anesthesia, however, is contraindicated in pigs with known cardiovascular disease, bleeding disorders, and shock or toxemic syndromes, because of sympathetic blockade and consequent depression of blood pressure.^{145,149} The use of sedatives that produce ataxia, partial recumbency, and hypotension should be avoided. Use of a weighing crate, chute, or hog snare is generally necessary to restrain a pig properly. Chemical restraint is required in some instances. A small pig is restrained on its breast or side, whereas a large sow or boar is preferably injected while it is still standing.

The site for the needle placement is on the midline immediately caudal to the spinous process of the last lumbar (L6) vertebra (Fig. 23.24). The injection site is felt as a palpable depression a distance caudal to the transverse line between the cranial prominences of the wing of the ilium (iliac crest) on either side, 0.5 to 1.5 cm in pigs weighing 10 to 50 kg and 1.5 to 2.5 cm in pigs weighing 50 kg or more. In large pigs in which the iliac

wings are not palpable, a vertical line through the patella may be used as a guide to locate the lumbosacral space 2 to 3 cm caudal to the vertical line.^{142,145,146,150} The tissues over the space are thoroughly cleansed, disinfected, and infiltrated with 3 to 5 mL of a 2% lidocaine hydrochloride solution.

A 14-gauge needle can be used to support and guide the spinal needle. The appropriate spinal needles used vary between 6 to 8 cm, 20 gauge for pigs weighing 10 to 20 kg and 10 to 16 cm, 18 gauge for pigs weighing over 100 kg. The needle, preferentially with stylet and the bevel directed cranially, is inserted at the lumbosacral space by using an angle of approximately 20° caudal to the vertical. Penetration depends on the size and condition of the pig, and may be up to 2 to 4 cm in pigs weighing between 10 and 20 kg and 4 to 10 cm in pigs weighing between 20 and 100 kg. For heavy boars and sows, a 10- to 15-cm spinal needle should be selected. The needle passes through a definite area of resistance as it encounters the interarcuate ligament. Penetration of the ligament by the needle tip is often felt as a slight pop and is associated with sudden movements by the animal indicating entrance into the vertebral canal. The lumbosacral aperture in pigs is relatively large (1.5 × 2.5 cm) and allows for some margin of error. The subarachnoid space containing CSF is comparatively small at the lumbosacral-intervertebral space and is not easily penetrated at that site. The spinal cord ends anterior to the sixth lumbar (L6) vertebrae and is unlikely to be traumatized by the needle.

The dose of anesthetic is calculated by either weight or length of the pig. Anesthesia caudal to the umbilicus can be expected

Fig. 23.25. Restraint of a 3-year-old Yorkshire hog, weighing 325 kg, in lateral recumbency. Anesthesia and relaxation distal to the midthoracic region developed after injection of 20 mL of a 2% lidocaine hydrochloride solution into the epidural space at the lumbosacral intervertebral space. From Skarda,⁵ p. 645.

after injecting 1 mL of a 2% lidocaine hydrochloride solution per 4.5 kg of body weight at a rate of approximately 1 mL/2 to 3 s.⁵³ Anesthesia should occur within 10 min, and recovery should be complete at the end of the second hour. Similar results have been achieved by using a smaller dose, such as 1 mL per 7.5 kg for pigs weighing up to 50 kg and an additional 1 mL for every 10-kg increase in weight.^{139,140} Good results have been obtained for laparotomy of pregnant sows by using a 2% lidocaine hydrochloride solution with epinephrine (5 to 12.5 µg/mL) and calculating the dosage as 1 mL for the first 40 cm of back length as measured from the base of the tail to the occipital protuberance, and an additional 1.5 mL of 2% lidocaine for each additional 10 cm.^{141,148} Regardless of the weight or length, the dose should be adjusted to the pig's condition and the surgical procedure (Fig. 23.25). A maximum dose of 20 mL of 2% lidocaine is suggested as the upper limit: 4 mL/100 kg, 6 mL/200 kg, and 8 mL/300 kg of body weight for standing castrations; and 10 mL/100 kg, 15 mL/200 kg, and 20 mL/300 kg of body weight for cesarean sections.¹³⁹

The sedative, analgesic, and immobilizing effects of xylazine and detomidine, when injected into the lumbosacral (L6-S1) epidural space of pigs, were evaluated and compared during a 2-h test period.¹⁵¹ Epidural xylazine (2 mg/kg in 5 mL 0.9% NaCl solution) induces immobilization and bilateral analgesia extending from the anus to the umbilicus within 5 min after completion of injection and persists for at least 2 h. Epidural detomidine (500 µg/kg in 5 mL 0.9% NaCl solution) induces sedation and lateral recumbency, but minimal analgesia caudal to the umbilicus, within 10 min after completion of injection. Atipamezole (200 µg/kg IV) immediately reverses xylazine-induced and detomidine-induced sedation, whereas xylazine-induced analgesia and hind-limb immobilization are not antagonized by atipamezole.

In large sows undergoing elective cesarean sections, 1 mg/kg of 10% xylazine in 10 mL of 2% lidocaine injected at the lumbosacral space induces excellent analgesia extending from the

anus to the umbilicus and produces rear-limb paralysis, as evidenced by a “sitting dog” posture, 5 to 8 min after completion of injection.¹⁵² The intravenous administration of 0.003 mL/kg of a Telazol (tiletamine-zolazepam) mixture (50 mg/mL of tiletamine and zolazepam each) with ketamine (50 mg/mL) and xylazine (50 mg/mL) immobilizes the forequarters. This mixture safely immobilizes sows. Palpebral and corneal reflexes are maintained with only minimal changes in heart rate, respiratory rate, and mean arterial blood pressure. The rear limbs may be affected for as long as 7 to 8 h after epidural injection with the xylazine-lidocaine mixture. Sows are usually able to walk normally 12 h after surgery. Piglets appeared healthy, without signs of sedation or tranquilization.¹⁵²

Epidural anesthesia can be used with general anesthesia to reduce the injectable or inhalation anesthetic requirements. The cardiopulmonary and analgesic effects of epidurally administered lidocaine (5 mg/kg of body weight), alfentanil (5 µg/kg), and xylazine (0.2 mg/kg) in pigs anesthetized with 1% to 1.2% end-tidal isoflurane anesthesia have been compared.^{153–155} Lidocaine provides 45 min to 1 h of analgesia and is associated with decreases in heart rate, respiratory rate, systolic arterial blood pressure, tidal volume, minute volume, core temperature, pH_a , arterial oxygen partial pressure, and total carbon dioxide, and increases in pulmonary capillary wedge pressure, arterial carbon dioxide partial pressure, and bicarbonate-ion concentration. Epidural alfentanil has no analgesic effect. Epidural xylazine provided 1½ h of analgesia and decreased core temperature and tidal volume, offering the most desirable actions in isoflurane-anesthetized pigs.¹⁵⁵

Studies on the effects of epidurally and intrathecally administered drugs on blood flow of the spinal cord have been suggested as a part of their toxicological assessment.¹⁵⁶ To investigate the effect of epidural administration of incremental doses of clonidine (3, 10, and 30 µg/kg, each dose given in a volume of 5 mL) via a lumbar epidural catheter, on regional and central blood flow and hemodynamics, 11 anesthetized pigs, weighing 20 to 23 kg, were studied.¹¹⁸ Lumbar epidural clonidine (3 µg/kg, a dose of clinical interest) did not affect regional blood flow to the spinal cord, brain, and cerebellum. Higher doses (10 and 30 µg/kg) of epidural clonidine produced local vasoconstriction, with a reduction in flow of 25% to 35% in the lumbar and thoracic spinal cord, 61% in the adrenal gland, and 78% in skeletal muscles.

Further interest in pain management is likely to encourage the development of new epidural techniques, emphasizing reduced frequency of injections and localized absorption of drug molecules at the injection site. For example, the effect of 4 mL of poloxamer gel (25%) containing 2% lidocaine hydrochloride or 2% ibuprofen sodium on the duration of analgesia after lumbar (L4 to L6) epidural administration via a catheter has been evaluated.¹⁵⁷ The gel solutions are highly viscous at room temperature, but liquid at refrigeration temperature, enabling injection of a cold-fluid solution that forms a gel in situ at a physiological temperature. In this study, antinociceptive response as assessed by observing the motor function and the nociceptive reflex-withdrawal response to painful pressure stimulation on the feet lasted 1 h longer and was more effective over time in comparison with

routine epidural lidocaine injection. With the lidocaine gel, motor blockade in hind limbs lasted 1½ h longer than with normal lidocaine solution. Epidurally administered ibuprofen in gel or solution prolonged analgesia, almost by 100%, when compared with ibuprofen administered IV. Analgesia was, however, not prolonged after ibuprofen epidural gel injection when compared with the epidural solution. The gel formulation apparently prolonged the systemic absorption of lidocaine and ibuprofen and increased the epidural availability of lidocaine, but not ibuprofen, for epidural analgesia. Only minor inflammatory changes in tissues of the epidural space were observed after epidural poloxamer gel injection in pigs.¹⁵⁷

Epidural anesthesia is a good choice in swine, with low morbidity and mortality, minimal CNS depression, and rapid recovery being its advantages. A rapid recovery is important for sows on a farm if they are to nurse pigs or are to be sold for slaughter before other complications develop. A rapid recovery also enables pathogen-free sows to leave the clinic as soon as the piglets do.¹⁵⁸ Epidural anesthesia can also be used with general anesthesia to reduce inhalant or injectable anesthetic requirements.¹⁴⁴

Lumbosacral epidural anesthesia that extends anterior to the last rib is generally safe in pigs, although complications may arise from overdose. These include cardiovascular and respiratory collapse, transient loss of consciousness, tremors, convulsions, vomiting, and meningitis associated with septic technique.

Anterior Epidural and Subarachnoid Anesthesia in Small Ruminants

Anterior analgesia produced by epidural and subarachnoid spinal nerve blocks provides excellent surgical conditions for cesarean section; intra-abdominal, pelvic, or hind-limb surgery; and udder surgery in small ruminants. The technique may be accomplished by injecting local anesthetic into either the epidural or the subarachnoid space at the lumbosacral intervertebral space.^{159–164}

With full aseptic precautions, in adult sheep and goats, a 6- to 7-cm, 20-gauge spinal needle with a fitted stylet is inserted on the midline halfway between the last lumbar (L6) and first sacral (S1) vertebrae at approximately 90° to the skin (Fig. 23.20C). The site for needle placement is usually palpable as a depression on the midline just caudal to a line joining the anterior border of the ilium on each side. Penetration of the interarcuate ligament is often associated with a sudden movement of the animal owing to pain or the lack of resistance either to further needle passage or to the injection of 5 mL of air, indicating that the vertebral space has been entered.

First, an attempt is made to aspirate CSF into a syringe. If CSF is not withdrawn, it can be assumed that the dura has not been punctured, and epidural injection is made with 1 mL of a 2% lidocaine hydrochloride solution per 4.5 kg of body weight. Posterior paralysis and anterior analgesia extending a fourth of the distance from the pubis to the umbilicus can be expected within 2 to 10 min and last as long as 2 h. The dose of lidocaine recommended for epidural anesthesia in the sheep may vary from a low of 8 to 15 mL of 1.5% lidocaine hydrochloride solution with 1:100,000 epinephrine, depending on the size of the sheep,⁵³ to 1 mL of 2% solution per 5 kg.¹⁶⁴

Anterior Epidural Anesthesia in Small Ruminants

Sedation with xylazine (0.1 mg/kg IM) followed 5 min later by lumbosacral analgesia induced by administration of 2% lidocaine (0.18 to 0.24 mg/kg) and xylazine (0.05 mg/kg) into the lumbosacral epidural space for umbilical surgery in dairy calves has been investigated.¹⁶¹

Supplemental local infiltration of lidocaine cranial to the umbilicus was required in five of six calves in dorsal recumbence to provide adequate analgesia. Calves maintained adequate cardiac output, stroke volume, and oxygen delivery, but were hypotensive throughout the surgery and after placement into sternal recumbency. Reversal of xylazine-induced sedation with tolazoline (1 mg/kg IV) caused transient (30 s) sinus bradycardia and sinus arrest for up to 6 s and second-degree atrioventricular block (Mobitz type 1), accompanied by severe systemic arterial hypotension (20 to 30 mm Hg). The anesthetic protocol may be useful when respiratory compromise or costs are concerns, and the surgical procedure can be completed in less than 1 h. Caution should be exercised when tolazoline (an α_1 -antagonist and α_2 -antagonist) is administered IV to reverse xylazine-induced sedation in neonatal calves, because profound hypotension may occur.

Xylazine and detomidine are α_2 -adrenoceptor agonists commonly used in small ruminants. When the analgesic effects of epidurally and IM administered xylazine (0.3 mg/kg) or detomidine (20 μ g/kg) in healthy sheep (1 to 3 years old) were compared, the epidural administration of either drug produced a greater degree of analgesia in the tail, perineum, hind limbs, and flank region than did similar doses of xylazine or detomidine administered IM.¹⁶⁵ Analgesia was observed within 2 min of each drug administration, with no difference in onset time of analgesia. Epidural xylazine produced complete analgesia of the tail, perineum, hind limbs, flank, thoracic wall, and forelimbs, whereas epidural detomidine produced only mild to moderate analgesia of these regions. Analgesia lasted longer after epidural xylazine (1½ h) than after intramuscular xylazine (30 min), intramuscular detomidine (30 min), or epidural detomidine (30 min). Sedation was evident, and all sheep became recumbent after the epidural injection of xylazine. Ataxia developed after the intramuscular administration of either drug, but was more pronounced after epidural administration. Changes in pulse and respiratory rates, rectal temperature, ruminal motility, and hematologic and biochemical parameters were transient. In a similar study, the cardiovascular and respiratory effects of epidural versus intravenous xylazine (0.2 mg/kg) in sheep were compared.¹⁶⁶ No changes were observed in heart rate, arterial blood pressure, cardiac output, pH_a , arterial carbon dioxide partial pressure, and arterial and mixed-venous oxygen content after epidural xylazine administration, whereas the intravenous route of xylazine produced significant decreases in mean and diastolic arterial blood pressure, arterial oxygen partial pressure, and oxygen saturation.

Analgesic effects have been assessed after the lumbosacral (L6-S1) epidural administration of xylazine (2%, 0.4 mg/kg, diluted with 0.9% NaCl) in rams. Analgesia was evident in the hind limb and perineum in 2 to 3 min and provided analgesia up to the midthoracic (T5 to T6) vertebrae 10 min after drug administra-

tion.¹⁶⁷ Analgesia and motor nerve blockade lasted from 2 h to 2 h 20 min and from 3 h to 4 h 40 min, respectively. Side effects included bradycardia, tachypnea, decreased minute volume, and metabolic alkalosis.¹⁶⁷

In a similar study, the analgesic effects of xylazine (0.07 mg/kg, diluted in 2.5 mL of sterile water) injected into the epidural space at the sacrococcygeal or lumbosacral sites in 22 ewes (body weight range, 60 to 85 kg) suffering from dystocia (vaginal prolapse and emphysematous fetuses) were evaluated.¹⁶⁸ Analgesia of the flank was appropriate for caesarean section 40 to 50 min after xylazine administration at either the sacrococcygeal or the lumbosacral epidural sites. Sedation was not observed in any of the ewes. Neither vaginal nor rectal prolapse recurred. The alleviation of tenesmus was attributed in part to the prolonged analgesic action achieved by epidural xylazine injection.

A combination of 2% xylazine (0.07 mg/kg) mixed with 2% lidocaine (0.5 mg/kg) administered into the sacrococcygeal epidural space has also produced effective caudal analgesia in sheep with preparturient vaginal or cervicovaginal prolapse.¹⁶⁹ This epidural mixture has been used for replacement and retention of rectal, cervical, and uterine prolapse in postpartum ewes.¹⁷⁰ There was no evidence that epidural xylazine-lidocaine caused premature labor.¹⁷¹ The combined epidural injection of xylazine and lidocaine has been considered by some investigators as an improvement over lidocaine epidural injection alone, primarily because of the lack of abdominal straining for at least 1 day after prolapse replacement.

The epidural coadministration of an α_2 -adrenoceptor agonist and opioid appears to shorten the onset time while prolonging the duration of antinociception. For example, in one study, 10 min after completion of injection, xylazine (0.2 mg/kg) administered epidurally alone produced a lack of response to electrical stimulation that lasted for 1½ h, whereas a xylazine-fentanyl combination produced antinociceptive effects in 5 min that lasted 5 h. The cardiopulmonary effects, which were measured after epidural xylazine-fentanyl injection, included decreases in cardiac output, cardiac work, arterial and mixed-venous pH, and bicarbonate values.¹⁷²

Following the acute and chronic lumbar epidural administration of preservative-free and antioxidant-free solutions of morphine (Astramorph/PF [0.5 or 1.0 mg of morphine/mL] and Infumorph 500 [25 mg of preservative-free morphine sulfate sterile solution/mL]) and hydromorphone (Dilaudid-HP [10 mg of hydromorphone hydrochloride/mL]), there was no change in CSF chemistry or hematology, or damage to spinal nerves, arachnoid, pia, or spinal cord tissues. In one portion of the study, three ewes receiving either morphine or hydromorphone developed hind-limb weakness with progressive deterioration of motor and reflex function, hypersensitivity to touch in the flanks, dermatomal flank irritation (scratching and licking, progressing to abrasions), discomfort with injection, catheter-related side effects, and severe neurological damage. Some spinal cord compression was common in all ewes, whereas partial spinal cord necrosis was observed in 50% of ewes after the 30-day epidural use of concentrated morphine and hydromorphone.¹⁷³

Anterior Subarachnoid Anesthesia in Small Ruminants

If spinal fluid is aspirated into the syringe or drips from the hub after needle placement, it is obvious that the dorsal epidural space, the dura, and arachnoid meninges have all been punctured and the subarachnoid space has been entered. Under these circumstances, half the epidural dose (0.5 mL/4.5 kg) can be injected at a rate of approximately 1 mL every 2 to 3 s. Posterior paralysis occurs in 1 to 3 min. With the reduced dose, anesthesia may extend to the last rib, similar to epidural administration of 2% lidocaine but lasting 1 to 1½ h (Fig. 23.26).

Gravity, not diffusion of drug in the CSF, determines the spread of anesthesia. For bilateral anesthesia, the animal is placed on its back immediately after administration of the anesthetic and removal of the needle; for unilateral anesthesia, the animal is maintained in lateral decubitus with its affected side dependent. Although epidural anesthesia and subarachnoid anesthesia in small ruminants are useful techniques and easily performed, careful observation of patients after injection and proper positioning must be maintained in order to avoid complications.¹⁷⁴

A few studies have evaluated the actions of α_2 -agonists placed into the subarachnoid space of small ruminants. The analgesic effects of intrathecally (subarachnoid) applied xylazine and clonidine placed into the cervical region of the spinal cord of sheep have been studied.^{175,176} Xylazine and clonidine both produced dose-dependent analgesia of the forelimbs, with slow onset and maximum effect observed after 45 min to 1 h. Clonidine appeared to be twice as potent as xylazine, with doses of 3, 6, and 12 μ g of clonidine being similar to 5, 10, and 25 μ g of xylazine.

The antinociceptive and physiological effects of xylazine (50 μ g/kg) and detomidine (10 μ g/kg) administered subarachnoidally at the lumbosacral space in sheep indicate that xylazine produces a higher threshold rise, faster onset, and longer threshold enhancement than does detomidine.¹⁷⁷ Atipamezole at doses of 5 μ g/kg and 2.5 μ g/kg, when administered IV at maximum threshold effects produced by xylazine and detomidine, did not affect the resulting antinociception as assessed by electrical stimulation.¹⁷⁷

It should be appreciated that serious side effects may result from injecting the full epidural dose into the subarachnoid space, thereby rapidly advancing the anesthetic through lumbar, thoracic, cervical, and cranial subarachnoid spaces. Likewise, it is not safe to withdraw the needle from the subarachnoid space to the epidural space and proceed with an epidural injection. A dura hole may be patent for many hours and, if spinal anesthesia is considered, a deliberate technique of subarachnoid injection using 1.5 to 2.0 mL of Heavy Nupercaine (1:200 dibucaine in 6% glucose) in adult sheep has been recommended.⁵³

CSF morphine concentration at the brain stem can increase when lumbar epidural morphine is administered adjacent to a dural puncture. Following dural puncture at the lumbar vertebrae with either a 25-gauge Whitacre needle or an 18-gauge Tuohy needle, the concentrations of morphine in CSF sampled at the cisterna magna 6 h after epidural morphine administration were 154 ± 32 and 405 ± 53 ng/mL, respectively.¹⁷⁸ These values are 7 and 20 times larger than without dural puncture. These findings highlight the potential for delayed respiratory depression when epidural morphine is injected after a dural puncture.

Fig. 23.26. Restraint of an 8-year-old female Nubian goat, weighing 80 kg, in lateral recumbency during lumbosacral subarachnoid anesthesia (the right hind foot was amputated).

As a general rule, the subarachnoid administration of lipophilic opioids produces CSF distribution different from CSF distributions of hydrophilic opioids. For example, when morphine (2 mg), hydromorphone (1 mg), methadone (2 mg), naloxone (1 mg), and [¹⁴C]sucrose (5 μ Ci), in 100- μ L dosing solution, were coadministered into the lumbar subarachnoid space or right lateral ventricle of sheep, their distribution into the lumbar subarachnoid space or right lateral ventricle varied greatly.¹⁷⁹ Morphine, hydromorphone, and [¹⁴C]sucrose were detected in lumbar CSF at 11½ h to 1 h 45 min after lateral ventricle injection, whereas hydromorphone and [¹⁴C]sucrose were detected in lateral ventricle CSF 50 min after lumbar subarachnoid injection. In contrast, methadone was not detected in ventricle CSF after lumbar subarachnoid injection, nor was it detected in lumbar CSF after ventricle administration. Methadone, being a highly lipophilic opioid, exerts its effect predominantly on tissues near the site of injection.

A number of studies have evaluated the effects of subarachnoid administration of α_2 -agonists, ketamine, and local anesthetics or combinations thereof in small ruminants.^{180–183} The assessment of the analgesic, ataxic, sedative, cardiopulmonary, and systemic effects of ketamine (3 mg/kg), xylazine (0.1 mg/kg), or lidocaine (2.5 mg/kg) after subarachnoid injection (L6-S1) in goats is one such study.¹⁸⁰ Subarachnoidally administered xylazine produced various degrees of analgesia of the tail, perineum, hind limbs, flanks, and caudodorsal rib areas, which were characterized by a slower onset and longer duration than the ef-

fects of ketamine or lidocaine. However, subarachnoid xylazine also caused clinically relevant bradycardia, hypotension, and respiratory depression, whereas ketamine and lidocaine did not significantly affect the cardiovascular and respiratory systems of goats.

The effects of the α_2 -agonist romifidine alone or in combination with ketamine have also been evaluated following subarachnoid injection.¹⁸¹ After the intrathecal administration of the romifidine and ketamine, analgesia of the tail, perineum, and hind limbs reportedly occurred in 35 s and lasted for at least 2 h. These results indicate a possible synergistic analgesic interaction between intrathecally administered α_2 -agonists and ketamine. Goats also demonstrated moderate to complete weakness of the hindquarters after injection of this combination, whereas heart and respiratory rates and arterial blood pressure were decreased and central venous pressure was increased.¹⁸¹ Although postoperative analgesia in food animals is often ignored, the increased interest in the use of local anesthetics, α_2 -adrenoceptor agonists, ketamine, and opioids by the epidural and subarachnoid routes as a means of prolonging perioperative analgesia is encouraging.^{176,181–185}

Complications from Anterior Epidural and Subarachnoid Anesthesia

Complications may arise from faulty anterior epidural and subarachnoid anesthesia and lack of patient management. These complications can include loss of consciousness, convulsions, respiratory paralysis, hypotension, and hypothermia after overdose,^{186,187} and possibly headache after dural puncture (unknown in nonverbal species). Respiratory paralysis is caused by desensitization of motor nerves supplying the intercostal muscle and/or by desensitizing the phrenic nerves supplying the diaphragm. Animals with severe hypotension show signs of distress, collapse, tachycardia or bradycardia, weak pulse, and shallow, rapid respiration. Therapy is comprised of rapid fluid infusion; raising the animal's hindquarters above the level of the heart to prevent pooling of blood in the hindquarters and to improve venous return, cardiac output, and arterial blood pressure; and supporting respiration by intubation, positive-pressure ventilation, and oxygen administration. In addition, the use of α_1 -adrenergic agonists (e.g., methoxamine, metaraminol, ephedrine, and phenylephrine) has been recommended to constrict the epidurally or subarachnoidally induced dilation of vascular beds in splanchnic and pelvic viscera and muscles of the pelvic limbs. The routine use of metaraminol (5 mg IM) during epidural anesthesia in sheep has been advocated, and, if hypotension is severe, 5- to 10-mg of methoxamine can be given IV.⁵³ The use of ephedrine in pregnant ewes is advantageous because it preserves uterine blood flow.¹⁸⁸ Hypothermia is caused by a patient's inability to shiver. Heat lamps and warm blankets are useful in warming patients.

Teat and Udder Anesthesia of Cows

Introduction

The udder is supplied from fibers of the genitofemoral nerves, which have their origin from the third and fourth lumbar spinal

Fig. 23.27. Schematic illustration of the nerve supply to a cow's udder: A, inguinal nerve; B, internal anterior nerve; C, posterior inguinal nerve; D, external inguinal nerve; and E, perineal inguinal nerve. L1 to L4 are ventral branches of the first to fourth lumbar vertebral nerves. S2, S3, and S4 are ventral branches of the second, third, and fourth sacral vertebral nerves.

cord segments.¹⁸⁹ Cranially, the skin and some glandular tissue of the forequarters are supplied by the ilioinguinal (L2) and iliohypogastric (L1) nerves. Caudally, the udder is supplied by the mammary branch of the pudendal nerve and distal branch of the perineal nerve, which originate from the second, third, and fourth sacral spinal cord segments (Fig. 23.27). Milk secretion is under hormonal control, as there are no secretory nerves to the udder.

Teat analgesia is required for repair of teat lacerations and injuries that most commonly affect the orifice. For this reason, local anesthesia (ring block, inverted-V block, teat cistern infusion, and intravenous regional anesthesia of the teat) is adequate for most surgical procedures, using either physical restraint or chemical tranquilization.^{19,190} Xylazine on its own as a sedative and analgesic is very effective for minor procedures, but its use in advanced gestation may be contraindicated. Standing restraint is advantageous because it prevents udder trauma; however, asepsis and safety to the operator must not be compromised. General anesthesia is rarely necessary for udder surgery except perhaps for udder amputation.

Paravertebral block of the first, second, and third lumbar (L1,

L2, and L3) spinal nerves or segmental lumbar epidural block of these nerves may be used for surgical procedures of the foreudder and foreteats. Both techniques have been described as difficult and often result in cows lying down. Using the perineal nerve block in standing ruminants, surgical procedures may be performed on the caudal-most teats and escutcheon areas of the udder. However, most surgical procedures of the caudal teats and body of the udder require high caudal epidural anesthesia or lumbosacral epidural anesthesia. Both techniques have been described, and there is no advantage to using one technique over the other in performing udder surgery. If high caudal epidural anesthesia is the method used for major udder surgery, up to 150 mL of a 2% lidocaine hydrochloride solution may be required to extend the analgesia to L1 in adult cows. Analgesia can be expected within 10 to 15 min and lasts 1 to 1½ h.

Ring Block of the Teat

After thoroughly cleansing the entire teat and teat base, physical restraint is used (e.g., holding the nose or using a flank strap, rope around the legs, or dorsal tail elevation). An elastic band may be applied firmly around the base of the teat to prevent diffusion of local anesthetic up into the udder. The tourniquet is not applied for removal of supernumerary teats. A 1.5-cm, 25-gauge needle is inserted subcutaneously transverse to the direction of the teat to deposit 4 to 6 mL of a 2% lidocaine hydrochloride solution in the form of a peripheral ring block (Fig. 23.28A). The solution is then massaged into the tissues. The technique provides adequate analgesia of the teat distal to the tourniquet within 10 min and lasts for approximately 2 h. Minor procedures, such as laceration repair, perforating fistula, nonperforating laceration, wart removal, teat removal in gangrenous mastitis, teat-obstruction opening, and fistula and supernumerary teat removal, are facilitated when using ring block. The technique is simple and inexpensive, and cows remain standing. Potential complications are prevented by using aseptic technique and safety during infiltration.

Inverted-V Block of the Teat

As an alternative to the ring block, a 1.5-cm, 25-gauge needle and 4 to 6 mL of local anesthetic solution are used to infiltrate the skin and muscularis of the surgical site by using an inverted-V pattern (Fig. 23.28B). Adequate analgesia for repairs of lacerations or fistulas or for removing warts in standing cows is achieved by this technique. Again, physical restraint and tranquilization are required for aseptic technique and safety during infiltration.

Teat-Cistern Infusion

Infusion of the teat cistern with local anesthetic is recommended for procedures that require anesthesia of the mucous membrane lining of the cistern. Although the muscularis, subcutaneous layers, and skin are not desensitized by this technique, procedures such as removal of teat polyps, opening of contracted sphincters, and opening of the spider teats may be facilitated. Combined with adequate physical restraint and chemical tranquilization, the cistern is milked out and the orifice thoroughly cleansed with al-

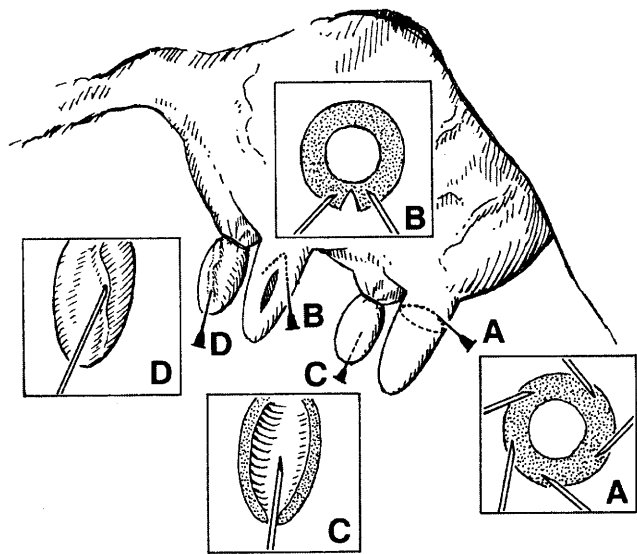

Fig. 23.28. Needle placement for bovine ring block (A), inverted-V block (B), teat-cistern infusion (C), and intravenous regional teat block (D).

cohol. A narrow gauze bandage or suture is placed as high up on the teat as possible to act as a tourniquet, preventing milk from entering the teat and diluting the anesthetic agent. To fill the teat, a teat cannula is introduced and approximately 10 mL of a 2% lidocaine hydrochloride solution is infused (Fig. 23.28C). Anesthesia develops in 5 to 10 min; thereafter, the remaining lidocaine is milked out and the tourniquet is removed.

Intravenous Regional Anesthesia of the Teat

This technique provides anesthesia of the entire teat distal to a preplaced tourniquet. The technique is best accomplished in recumbent cows. A tourniquet is placed around the base of the teat as described for teat cistern infusion. Any superficial teat vein distal to the tourniquet may be used for injection of 5 to 7 mL of a 2% lidocaine hydrochloride solution or its equivalent by using a 2.5-cm, 22- to 25-gauge needle (Fig. 23.28D). Digital pressure and gentle massage are applied to the site of injection to prevent hematoma formation. Analgesia of the teat distal to the tourniquet occurs within 3 to 5 min and persists for the time the tourniquet is applied. Sensation returns to the teat 5 to 10 min after tourniquet removal. Restraint and aseptic technique are critical.

Perineal Nerve Block

Desensitization of the perineal nerve facilitates repair of laceration and removal of supernumerary teats or warts in the caudal-most udder or escutcheon area.¹⁸⁹ The nerve is readily desensitized by injecting 5 to 7 mL of a 2% lidocaine hydrochloride solution into the subcutaneous and subfascial tissues at the ischial arch approximately 2 cm lateral to the midline on both sides.¹⁹¹ The technique does not inhibit wound healing, but it is more difficult technically than local infiltration.

Anesthesia of the Foot

Introduction

Anesthesia of the foot may be induced by (a) infiltrating the tissues around the limb with local anesthetic solution (ring block), (b) injecting local anesthetic solution into an accessible superficial vein in an extremity isolated from circulation by placing a tourniquet on the animal's leg (intravenous regional anesthesia), (c) desensitizing specific nerves (regional analgesia, anesthesia of the brachial plexus, and epidural anesthesia), and (d) using general anesthesia in especially fractious animals or procedures requiring complete immobilization for asepsis and safety during operation.

Ring Block

Many practitioners consider the ring block or infiltration of local anesthetic from skin to bone, encircling the digit at the junction of the proximal and middle of the metatarsus or metacarpus, to be the most reliable way of anesthetizing the digit.¹⁹² A 2.5-cm, 25-gauge needle may be used to inject approximately 15 mL of a 2% lidocaine hydrochloride solution at several sites: deep and superficial to the flexor tendons and in a partial circle around medially and laterally to the extensor tendons. The area between the anterior and posterior injection sites may be divided into thirds; the anesthetic may be injected at one-third to two-thirds of the distance between them. The technique does not require precise anatomical knowledge of the limb. The ring block increases the risk of inducing pyogenic bacteria from multiple injection sites, however, and is often only partially successful.

Intravenous Regional Anesthesia

Intravenous regional anesthesia (IVRA) is a simple and safe method for producing analgesia of the digit in cattle, small ruminants, and pigs, and can be substituted for the cumbersome local infiltration or nerve-block procedures. It is ideal for digital surgery, in which the amount of bleeding at the surgical site must be reduced. In cattle, the technique involves placing either an elastic bandage, a tourniquet of stout rubber tubing, or an inflatable cuff (inflation pressure, >200 mm Hg or 26.7 kPa) proximal^{193,194} or distal to the tarsus,^{194–196} proximal to the elbow,^{197–199} and proximal^{193,200} or distal to the carpus to obstruct the arterial inflow.^{196,201} In the pelvic limb, a rolled bandage is placed in the depression on either side of the limb between the Achilles tendon and the tibia to increase the pressure on the underlying vessels.^{193–195}

IVRA is best performed on the leg of an animal that has been cast and restrained in lateral recumbency with the particular limb uppermost, but alternatively it can be induced in a raised leg of a sedated animal standing.²⁰² In the thoracic limb, the skin over the prominent common dorsal metacarpal vein, plantar metacarpal vein, or radial vein distal to the tourniquet is clipped, shaved, and disinfected (Fig. 23.29A). The cranial branch of the lateral saphenous vein or lateral plantar digital vein is a suitable site for injection in the pelvic limb (Fig. 23.29B). A 2.5-cm to 3.75-cm, 20- or 22-gauge needle with syringe attached is inserted either in proximal or in distal direction as close to the surgical site as possible. In adult cattle, 30 mL of a 2% lidocaine hydrochloride so-

lution (without epinephrine) is injected as rapidly as possible.^{193–195,201,203} Smaller volumes (3 to 10 mL) of lidocaine are adequate for IVRA in small ruminants and pigs.¹⁹⁶

The needle is removed from the vein, and digital pressure and gentle massage are applied to the site of injection to prevent development of subcutaneous hematoma. Anesthesia of the limb distal to the tourniquet develops after 5 min, is optimal in 10 min, and persists for the period the tourniquet is left in place. Analgesia occurs latest in the interdigital region. Ischemic necrosis, severe lameness, and edema are not expected to occur if the tourniquet is applied for less than 2 h.^{193,194} Few surgical procedures require this length of time. Usually, an operation is completed in 10 to 30 min, when the tourniquet may be safely released. Sensation and motor function return to the leg within 10 min after tourniquet release, and no signs of cardiovascular or CNS toxicity are likely.^{193,200,204,205} After tourniquet removal, partial analgesia may persist for an additional 30 min or longer. Evidence of lidocaine toxicity has rarely been reported in cattle if the tourniquet has remained in place for 20 min or more. Maximal venous plasma concentration of lidocaine after tourniquet release was 1.5 µg/mL,¹⁹⁵ which is less than that considered to be toxic.

A measurable concentration of lidocaine in jugular venous blood in buffalo calves (102 ± 9.4 kg) was demonstrated after infusion of a 2% lidocaine hydrochloride solution (4 mg/kg body weight) into the dorsal digital vein, despite tourniquet occlusion.²⁰⁶ The lidocaine concentration progressively rose after injection to 2.9 and 3.67 µg/mL at 30 min and 1 h, and was further increased to 6.9 ± 0.9 µg/mL at 5 min after tourniquet release. Salivation, tremors, and rapid pulse have occurred in cattle after early tourniquet removal (<20 min). Symptoms of lidocaine toxicity—including CNS symptoms and signs such as convulsions and seizures, profuse salivation, and hypotension in cattle—may occur if a large bolus of lidocaine hydrochloride (6 to 8 mg/kg) is injected into the systemic circulation. Toxicity in early tourniquet removal is avoided if the tourniquet is loosened for 10 to 15 s and retightened for 2 to 3 min, and this procedure is repeated several times.²⁰⁷ In cases of local sepsis in the distal limb in cattle, combined use of IVRA and antibiotics has been described.²⁰⁸ It is advised, however, to limit the dose of sodium penicillin to 100,000 IU dissolved in 15 to 20 mL of a 2% lidocaine hydrochloride solution to prevent thrombosis of the veins distal to the tourniquet. Swelling of the forelimb and long-lasting lameness (25 days) in 18% of a group of water buffalo calves (85 to 100 kg of body weight) has been reported after IVRA, when 400,000 IU of benzyl penicillin was diluted in 12 to 15 mL of an 8% to 12% procaine hydrochloride solution and injected into the radial vein distal to a tourniquet.¹⁹⁷ Microthrombosis of digital veins might have been produced in these animals by salt formation of procaine penicillin and benzyl penicillin.²⁰⁹ In any case, animals should be carefully observed for changes in respiratory and pulse rates during the first 10 min after tourniquet release.

Advantages of IVRA when compared with ring block or regional nerve blocks are that it requires no precise anatomical knowledge of the limb and only a single injection is made, thereby reducing tissue trauma, contamination of fascial planes

Fig. 23.29. Tourniquet and needle placement for intravenous regional analgesia of the bovine forelimb (**A**) and rear limb (**B**): a, dorsal metacarpal vein (dorsal view); b, radial vein (medial view); c, plantar metacarpal vein (palmar view); d, cranial branch of lateral saphenous vein; and e, lateral plantar digital vein.

or tendon sheaths, and time required for producing digital analgesia. In addition, the amount of bleeding at the surgical site is reduced during application of the tourniquet. One disadvantage of IVRA is an approximately 7% inexplicable failure rate, with particular lack of analgesia in the interdigital area, even when the technique is performed correctly without hematoma formation at the puncture site.

Regional Anesthesia of the Thoracic Limb

Brachial Plexus Block

Anesthesia of the brachial plexus in cattle can be achieved by desensitizing the ventral roots of the sixth, seventh, and eighth cervical (C6, C7, and C8) and first and second thoracic (T1 and T2) spinal nerves as they pass over the lateral aspect of the middle third of the first rib, thereby inducing loss of sensation distally and including the elbow joint.¹³⁶ The skin-puncture site is 12 to 14 cm cranial to the acromion of the scapula and lymph node. This area is surgically scrubbed and infiltrated with 2 to 3 mL of local anesthetic solution. The animal's head is held away from the side to be

injected. A 16-cm, 18-gauge needle, preferably with stylet, is inserted through the desensitized area and pushed horizontally or 5° ventrocaudally until it impinges at the lateral surface of the first rib, where approximately 10 mL of a 1% or 2% lidocaine hydrochloride solution containing 1:200,000 epinephrine (to delay absorption and diminish the risk of toxicity) or equivalent is injected. The needle is first withdrawn 5 to 10 cm, and then its tip is redirected 1.5 cm more distal to the first injection site, where an additional 10 mL of the anesthetic is deposited. Two to three more injections are made similarly until a band of anesthetic 6 to 8 cm long has been injected along the rib and ventral to the initial site. The needle is correctly placed if there is no air, blood, or CSF upon needle aspiration. Onset of analgesia and loss of motor power are gradual, with maximal effects achieved 15 to 20 min after injection and lasting 1½ to 2 h.

Digital Nerve Block

The nerves in the digits of cattle are not easily located distal to the carpus and tarsus because of tense skin and subcutaneous fibrous tissue. However, individual nerves can be desensitized.

To produce analgesia distal to the carpus, the median nerve,

the ulnar nerve, the medial antebrachial nerve (a cutaneous branch of the musculocutaneous nerve), and the dorsal antebrachial nerve (a cutaneous branch of the radial nerve) must be desensitized.^{8,136,210} Local infiltration of the skin and subcutis can be used effectively where massive extensive muscle mass proximal to the carpus prohibits perineural injection.

The median nerve may be desensitized by injecting 10 to 20 mL of a 2% lidocaine hydrochloride solution beneath the fascia approximately 5 cm distal to the elbow anterior to the flexor carpi radialis muscle on the posterior radius. The nerve lies deep, but it can be palpated and perineurally infiltrated at that site by using a 5-cm, 18- to 20-gauge needle (Fig. 23.30C).

The ulnar nerve can occasionally be palpated approximately 10 cm (a hand's breadth) above the accessory carpal bone at the posterolateral (volar-lateral) surface of the radius. Approximately 5 mL of a 2% lidocaine hydrochloride solution is injected underneath the superficial fascia in a groove between the flexor carpi ulnaris and ulnaris lateralis muscle by using a 5-cm, 20-gauge needle (Fig. 23.30B). The resulting median and ulnar nerve blocks desensitize the medial-posterior aspect of the metacarpus and posterior aspect of the digits.¹³⁶ The medial and dorsal antebrachial nerves supply sensory fibers to the medial and dorsal aspects of the carpus and, in conjunction with the median and ulnar nerves, the limb distal to the carpus. The cutaneous medial and dorsal antebrachial nerves may be desensitized anteriorly approximately 10 cm above the carpus by injection of 20 mL of a 2% lidocaine hydrochloride solution in a band 4 to 6 cm wide adjacent to the dorsal radius just anterior to the cephalic vein (Fig. 23.30A).

Alternatively, anesthesia can be produced from the midmetacarpus distally by desensitizing four nerves at the midmetacarpal area (four-point block): the dorsal metacarpal nerve (a superficial branch of the radial nerve), the medial palmar nerve (a continuation of the median nerve), and the dorsal and palmar branches of the ulnar nerve.²¹¹ A 1.25-cm, 22-gauge needle may be used to inject 5 mL of a 2% lidocaine hydrochloride solution at each site. The needle point is directed proximally to prevent its breaking in the event the animal should kick and pull the leg away. The dorsal metacarpal nerve is desensitized by subfascial injection of the anesthetic medial to the medial digital extensor tendon (Fig. 23.31A). The medial palmar nerve is desensitized at the medial aspect of the superficial flexor tendon in the groove between the superficial flexor tendon and the suspensory ligament (Fig. 23.31B). The dorsal branch and the lateral palmar branch of the ulnar nerve are desensitized by perineural infiltration on the lateral aspect of the limb just anterior and posterior to the suspensory ligament (Fig. 23.31C and D).

Anesthesia of the Interdigital Region

For interdigital anesthesia of the front and hind feet, the branches of the medial dorsal and palmar (plantar) axial digital nerves must be desensitized. Using a 5-cm, 16- or 18-gauge needle, 5 to 10 mL of a 2% lidocaine hydrochloride solution is injected at a depth of 3.5 to 5.0 cm to infiltrate the soft region proximal to the junction of the claws on both the dorsal and the volar aspects of the first phalanx (pastern) (Fig. 23.30D). This method should ad-

Fig. 23.30. Needle placement for desensitizing the musculocutaneous (A), ulnar (B), median (C), and axial digital III and IV (D) nerves of the left forelimb in cattle: a, caudolateral; and b, dorsomedial aspects.

equately desensitize all the dorsal and palmar (plantar) axial digital nerves for removal of interdigital fibromas (corns). Alternatively, a 10-cm, 18-gauge needle can be inserted at a 90° angle to the skin on the dorsum of the pastern, and the middle of the interdigital space can be infiltrated from a single injection site by using 15 to 20 mL of the anesthetic solution.

Regional Anesthesia of the Pelvic Limb

Nerve blocks of the pelvic limb in cattle have seldom been emphasized because IVRA and epidural anesthesia may be conveniently used for anesthesia of the hind legs. Regional anesthesia of the tarsus and distally can be produced by desensitizing the common peroneal nerve and tibial nerve.²¹² Both nerves are continuations of the sciatic nerve. A 3- to 5-cm, 18- to 20-gauge needle with approximately 20 mL of a 2% lidocaine hydrochloride solution are used at each site, inducing anesthesia within 10 to 20

Fig. 23.31. Needle placement for midmetacarpal nerve blocks on the right forefoot in cattle. Dorsal metacarpal nerve (A), medial palmar nerve (B), lateral palmar branch of the ulnar nerve (C), and dorsal branch of the ulnar nerve (D): dorsal aspect (**left**), palmar aspect (**center**), lateral aspect (**right**), and cross-sectional aspect (**inset**). **Inset:** a, extensor tendons; b, interosseous ligament; c, deep digital flexor tendon; and d, superficial digital extensor tendon. From Skarda,⁵ p. 655.

min. The common peroneal nerve is desensitized just caudal to the posterior edge of the lateral condyle of the tibia deep to the aponeurotic sheath of the biceps femoris muscle (Fig. 23.32A). The tibia nerve is desensitized at a point approximately 10 cm above the tuber calcis between the gastrocnemius tendon and the deep digital flexor tendon on the medial aspect of the limb (Fig. 23.32B). Alternatively, anesthesia distal to the tarsus is produced by desensitizing four nerves (four-point block): the lateral and medial plantar metatarsal nerves (both are continuations of the tibial nerve) and the superficial and deep branches of the peroneal nerve.^{136,210,211,213} The superficial peroneal nerve lies superficial to the extensor tendons, and the deep peroneal nerve lies deep on the metatarsus; the lateral and medial plantar metatarsal nerves lie superficial in a fibrous sheath containing artery and vein lateral and medial to the flexor tendons, respectively. A 2.5-cm, 22-gauge needle with approximately 5 mL of a 2% lidocaine hydrochloride solution is used at each site, just above the middle of the junction between the proximal and middle third of the metatarsus.

The superficial peroneal nerve is desensitized subcutaneously on the dorsal surface of the metatarsal bone in the proximal third of the metatarsus (Fig. 23.33A). The deep peroneal nerve is desensitized in the midmetatarsal region beneath the extensor tendons (Fig. 23.33B). Traditionally, the deep peroneal nerve is ap-

Fig. 23.32. Needle placement for desensitizing the common peroneal nerve (A) and tibial nerve (B) in cattle: caudal aspect.

proached by placing a 22-gauge needle under the extensor tendons from the lateral side. Alternatively, a 2.5-cm, 25-gauge needle can be placed through the extensor tendon by using slow injection with considerable pressure. Penetration of the dorsal metatarsal artery must be avoided.

The medial and lateral plantar metatarsal nerves are desensi-

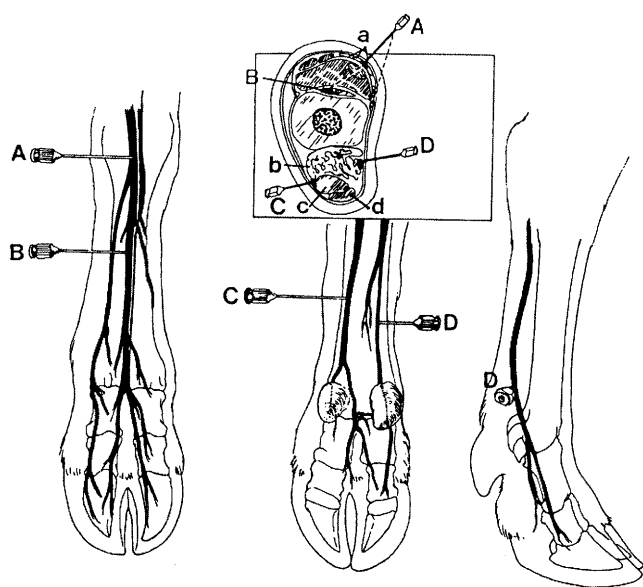

Fig. 23.33. Needle placement for midmetatarsal nerve blocks on the right hind foot in cattle: superficial peroneal nerve (A), deep peroneal nerve (B), medial plantar metatarsal nerve (C), and lateral plantar metatarsal nerve (D): dorsal aspect (**left**), plantar aspect (**center**), lateral aspect (**right**), and cross-sectional aspect (**inset**). **Inset:** a, extensor tendons; b, interosseous ligament; c, deep digital flexor tendon; and d, superficial digital flexor tendon). From Skarda,⁵ p. 657.

tized approximately 5 cm above the fetlock in the groove between the suspensory ligament and flexor tendons on the medial and lateral aspects of the limb (Fig. 23.33C and D). Adequate analgesia for claw amputation can be expected after the four-point block. However, if sensation to the bulb of the heels after injection still remains, it is advisable to repeat the perineural infiltration not only of the lateral and medial plantar metatarsal nerves, but also of the deep peroneal nerve, which supplies sensory fibers to the interdigital area and bulb of the heels.

The advantages of specific nerve blocks in the foot as compared with general anesthesia are fewer complications associated with regional anesthesia and immediate ambulation of the animal after surgery. The most obvious disadvantage of regional anesthesia is that it requires a good knowledge of the anatomy of the region. Multiple injections are required for each region. Analgesia is often incomplete, probably owing to anastomotic, collateral, or recurrent nerve branches.²¹³ The use of general anesthesia may be advantageous in fractious animals that require complete immobilization. In addition, the use of general anesthesia avoids the necessity of injection of the local anesthetic into inflamed tissue, which is often painful and ineffective and can cause the spread of infection or absorption of toxins.

Intra-articular Anesthesia

Arthrocentesis may be considered for diagnostic work in conjunction with examination of joint fluid, but intra-articular analgesia is seldom used, although it is an inexpensive means of providing site-specific analgesia.²¹⁴

In a recent study, 2% lidocaine (40 mg, 2 mL) was chosen for preincisional intra-articular administration, whereas postclosure intra-articular 0.5% bupivacaine (10 mg, 2 mL) was used because of its longer-lasting action in adult sheep undergoing stifle arthrotomy during general anesthesia.^{215,216} Intra-articular lidocaine plus bupivacaine provided analgesia for 3 to 7 h postoperatively.

Anesthesia for Castration

Castration of bulls, sheep, goats, and pigs is one of the most commonly performed surgical procedures in general practice. Optimal methods for pain control during castration are controversial. The operation may be performed by using chemical restraint and regional anesthesia with animals in either the standing or cast position, or by using general anesthesia induced by intravenous or intratesticular injection of a barbiturate or dissociative. The choice of method to be used largely depends on the species and the opportunity to observe the animal after castration. Regional anesthesia can be induced by intratesticular injection of local anesthetic solution in all food animals.

The scrotum should be cleansed with a detergent antiseptic solution, and the proposed line of incision subcutaneously infiltrated with 3 to 5 mL of a 2% lidocaine hydrochloride solution. The anesthetic is injected as the skin is tensed over the testicle and is pulled on the needle.

In bulls and boars, a 3.75- to 7.5-cm, 16- to 18-gauge needle is first inserted through the skin below the tail of the epididymis and then pushed quickly into the center of the testicle by using an angle of approximately 30° from perpendicular without puncturing the side or bottom (Fig. 23.34). The anesthetic (10 to 15 mL per 200 kg of body weight) is injected into the substance of each testicle. The anesthetic is said to enter lymph vessels quickly and to desensitize the sensory fibers in the spermatic cord.²¹⁷

In bull calves, rams, and bucks, a smaller needle (2.5 to 3.75 cm, 20 gauge) is used to enable easy flow between 2 and 10 mL, depending on the size of the animal, of a 2% lidocaine hydrochloride solution to the center of the testicle and to minimize backflow through the needle tract. The bulk of the anesthetic quickly passes from the testes up the spermatic cord via the lymph vessels into the blood, so the administration of an excessive dose must be avoided or intoxication will occur. Intratesticular injection of 3 to 15 mL of a 2% lidocaine hydrochloride solution can be satisfactory for castration in male pigs up to approximately 5 months of age. Additionally, 2 to 5 mL of the anesthetic is injected subcutaneously beneath the scrotum as the needle is withdrawn. General anesthesia, however, is more suitable for older pigs.

Because the distribution and effectiveness of lidocaine into the testicle of piglets have been questioned, the distribution of 0.4 mL of radioactive [¹⁴C]lidocaine with 5 mg of adrenaline/mL injected into each testis and subcutaneously in the scrotum of six male piglets has been evaluated.²¹⁸ Autoradiograms show radioactivity in the testes, distally where the subcutaneous injection was made, and in the entire length of the spermatic cord 10 min after completion of the injection.

Fig. 23.34. Needle placement for right testicular injection in a bull calf. From Skarda,⁵ p. 659.

In another study, to reduce pain associated with ring castration, local anesthetic (2% lidocaine) was injected into three sites around the scrotal neck (1 mL into the anterior-medial surface and 0.5 mL into each lateral surface) of lambs about 6 weeks of age 5 to 10 s before rubber-ring castration.²¹⁹ Injecting lidocaine (1 mL) into each testis through the caudal pole after ring application did not reduce cortisol levels associated with ring castration and docking, however.²²⁰ In two other studies in calves, the intravenous administration of the anti-inflammatory ketoprofen (3 mg/kg of body weight) was considered more effective than the injection of 8 to 9 mL of 2% lidocaine into each testis during castration to alleviate the associated stress response.^{221,222} Systemic analgesia with ketoprofen was considered more effective in reducing inflammatory responses associated with castration than either local or epidural anesthesia.

Intratesticular Injection

A sclerosing agent (Chem-Cast) may be painlessly injected into the testes of bull calves weighing less than 70 kg in order to destroy the testicular tissue within 60 to 90 days without edema, hemorrhage, or unacceptable necrosis.²²³ The recommended dose is 1 mL per testicle in calves weighing up to 45 kg and 1.5 mL per testicle in calves weighing 46 to 68 kg. As compared with surgical castration and mechanically crushing the cord (Burdizzo method), chemical castration is simple and fast; it lacks the high risk of infection associated with surgical castration, and it contributes to improved weight gain. There is no withdrawal time for nontesticular tissues obtained from calves treated with Chem-Cast.²²³

Conclusion

Presently, sufficient clinical work has been done to establish the usefulness, safety, and limitations of local and regional anesthesia techniques in ruminants and swine. Generally speaking, the rational use of a 2% lidocaine hydrochloride solution provides economic and good intraoperative analgesia with rapid recovery and minimal side effects. The systemic administration of an NSAID (e.g., ketoprofen IV) may also be considered for relieving both intraoperative and postoperative pain and stress commonly observed after surgical procedures, such as dehorning and castration.

Introduction

A veterinarian's training often leads to skepticism of Eastern traditional medical practices because of the apparent conflicts with Western scientific methodology and the feeling that Eastern medical practice is somewhat faith based. It is important that novices to *traditional Chinese medicine* (TCM) understand that much of the theory and vocabulary, although similar to Western terminology, have little direct correlation. Much of the practice of TCM developed before the advent of Western medical science and publication of medical textbooks, so a simplified method had to be devised for the practice of TCM based on diagnostic and treatment strategies observable on the external surfaces of the body. Consequently, it is best to think of the description of acupuncture points and TCM diagnostics as metaphors or teaching aids rather than anatomical or pathophysiological correlates to Western medicine.

Treatment strategies have evolved over millennia of trial and error in many species and represent a consensus among TCM practitioners as to what is effective. Current Western medical teaching is that TCM is complementary to Western medicine rather than a replacement for it. Acupuncture is traditionally viewed as one treatment modality among several used by TCM practitioners.

Most Western acupuncture charts show transpositional acupuncture points and meridians on animals, meaning the points are adapted from anatomical correlates on the human body. This creates some interesting adaptations, since animal anatomy (especially horses) varies considerably from humans. Some acupuncturists prefer to use the points described for animals in the early Chinese veterinary texts. These may or may not be aligned with modern points. They are difficult for many Westerners to learn because the names are in Chinese and often describe the anatomy in terms of natural objects (rivers, branches, etc.). Some acupuncturists only use points located on the distal limbs. These are often referred to as *Ting* points and are the ends of the meridians and are usually extremely painful when needed (like sticking needles under fingernails), so they would be expected to produce a pronounced response.

Any patient being treated with acupuncture should be evaluated using the standards of care established for Western-based veterinary medicine. This includes a thorough physical examination, chest auscultation, blood work if necessary, and any other diagnostics that are required. Failure to maintain this standard of care could lead to malpractice. Acupuncture is often used in conjunction with Western treatments such as surgery or pharmacological therapy. It is recommended that written refusal of a Western-based standard of care be obtained from clients who seek to use acupuncture exclusively. Such clients have caused much concern and ethical debate among veterinarians.

History

Acupuncture is an integral part of an ancient Chinese system of medicine that has been used for more than 2500 years to treat diseases and relieve pain. According to tradition, acupuncture is based on a philosophy of balance and unity between the universe, living beings, and energy flow that penetrates everywhere and everything. Any imbalance, disruption, or energy-flow blockage within the body can cause disease or pain. The main concept and philosophy of acupuncture is to return the body to a harmonized, balanced state.

The numerous techniques and approaches to acupuncture reflect a variety of medical traditions and schools from China, Korea, Japan, Vietnam, and other Eastern countries. Some of these approaches focus on points located on traditional acupuncture meridians that crisscross the body surface. Other methods focus on points located on the ear (auricular acupuncture) or

hands or feet (Korean hand acupuncture [*Su-Jok*]). In general, it is believed that the ears, hands, and feet are micromodels of the entire body, with areas that represent the body parts, organs, meridians, and acupuncture points. These micromodels have the same principles of energy flow as the whole body. An explanation that has been offered for this phenomenon is a principle of the fractalization (similarity) of living and nonliving things in which small parts have the same shape as the whole.¹ No matter what method of acupuncture is used, it must be applied to specific points to achieve analgesia or other beneficial regional or systemic effects.

Modern research on the basic mechanisms of acupuncture started in the People's Republic of China in 1949, where Mao Zedong encouraged the practice of acupuncture. Ten years later, acupuncture was introduced in the former Soviet Union, where further research was initiated. The practices and research results remained essentially unknown to most Western scientists and physicians. This typically reflected a failure to publish articles in English, along with a lack of interest in the Western research community.²

Interest in acupuncture surged in the United States in the early 1970s, in part, because James Reston, a *New York Times* reporter covering President Richard Nixon's trip to China, developed acute appendicitis. After his postoperative pain was treated with acupuncture, he described his experience on the front page of the newspaper, igniting an interest in acupuncture in the Western medical community.³ Subsequently, American and European physicians visiting China witnessed surgeries in which the only anesthetic used was acupuncture. A number of articles in newspapers and magazines about the use of acupuncture instead of general anesthesia followed. Basic research on acupuncture's mechanisms in Western societies started in 1976 after the endorphin hypothesis of acupuncture's mechanism of action was introduced. Further advancement of acupuncture research was prompted by introduction of functional magnetic resonance imaging (fMRI) and positron-emission tomographic scanning, which revealed the relation between acupuncture stimulation and activation of certain brain structures.⁴⁻⁸ Interest in the United States led the National Institutes of Health to create the National Center for Complementary and Alternative Medicine (NCCAM), which has funded basic and clinical acupuncture studies.

In 1997, the World Health Organization issued a list of human medical conditions that may benefit from treatment with acupuncture. Applications include prevention and treatment of postoperative and chemotherapy-associated nausea and vomiting, treatment of pain, therapy for alcohol and other drug addiction, treatment of asthma and bronchitis, and rehabilitation from neurological damage such as that caused by stroke.⁹ Scientific information on the effectiveness of acupuncture for veterinary disorders is limited. The effectiveness of treatment is based on a consensus among veterinarians commonly performing acupuncture in specific species.

Skepticism about the effectiveness of acupuncture therapy in humans and animals remains among some Western medical practitioners. Some factors contributing to this skepticism are (a) the scientific basis of acupuncture remains unclear, (b) the philosophical basis of acupuncture is difficult for a modern industrial

society to accept, (c) the operational language is unusual, and (d) the traditional system of acupuncture points does not correspond to Western concepts of anatomy or neurology. Moreover, traditional Chinese acupuncture remains a mix of philosophy and science and teaches that many factors can profoundly influence the outcome of the treatment. In addition to the signs related to the disease, a practitioner might consider a patient's gender and psychological profile, the season, the time of the day, and even the environment in which the treatment is administered.¹⁰⁻¹⁸ Because of these differences, it is believed that the efficacy of interventions may differ substantially among patients with similar symptoms, and thus it is difficult to standardize procedures. Scientific exploration of these factors remains limited. Another problem associated with acupuncture studies is defining an adequate placebo as a control intervention for them. Some trials compare acupuncture with drugs, and others use *sham acupuncture* (acupuncture at random spots on the body surface that are thought to be inactive). There is substantial controversy, however, about the use of sham acupuncture as a control treatment because the procedure itself can provide neurohormonal and clinical effects, though usually of lower effectiveness compared with treatment at defined acupuncture points.¹⁹

Basic Concepts

The theory of TCM, of which acupuncture is one part, is complex and beyond the scope of this review. Unlike Western biomedical science, TCM does not make a distinction between physical, mental, and emotional components of life. Moreover, it considers a being as an integral part of the universe. It is believed that everything within the universe, including animals, obeys the same laws. Therefore, health and disease result from balance or imbalance.

Organs and Meridians

Most modern acupuncture schools teach meridian theory. However, early practitioners (and some modern practitioners) do not recognize meridians or do not agree on their path. Meridians are most useful in remembering locations of points, although they are used in developing treatment protocols. Meridians were identified based on observations in a small percentage of people who are extremely sensitive to acupuncture. A meridian can describe the course of a tingling or burning sensation along a path that roughly corresponds to the meridian. Most of the meridians are not obviously associated anatomically with nerve pathways, although many of the relationships observed seem to be explained by the way peripheral nerves enter the spinal cord and neural pathways converge in the brain. For example, many people that have heart attacks describe a pain across the chest and down the arm. The heart meridian courses down the chest and arm. The pain (origin in the heart muscle) is felt in the arm because some of the afferent fibers enter the spinal cord near the location of afferents from the thoracic limb. Other observations indicate that distant areas of the body have complementary effects because many areas in the somatosensory cortex of the brain colocalize. Associations between internal organs and meridians

(and superficial points) are very common and make sense if the concept of referred pain is understood.

The theory of traditional Chinese acupuncture recognizes 12 main meridians with corresponding organs in the human body. In addition, eight so-called *curious meridians* can be distinguished. Most acupuncture “organs” have names similar to organs of Western medicine but only an approximate correlation with physiological functions and anatomical structures. Organs, as seen in ancient Chinese traditions, are functional systems rather than anatomical structures, with broader and sometimes peculiar physiological functions and anatomical representations. For example, two traditional acupuncture organs, namely, “triple warmer” and “pericardium” (“heart governor”), do not have a distinct anatomical representation at all. All meridians and organs are connected and related to one another directly or indirectly according to various rules and principles:

- Each organ has a corresponding meridian with acupuncture points located along it.
- Meridians travel inside the body and on the body’s surface and are connected to one another and organs by a complex network of accessory collateral connections.
- The function of the meridians is to regulate and modify the corresponding organ or group of related organs. It is believed that meridians can control pain along the areas they traverse.

Points

In Chinese acupuncture, points are called *xue*, which means “cave” or “hole.”^{20,21} In Chinese acupuncture tradition and language, the names of points are important and informative. Western acupuncture practitioners rarely use Chinese names because of unfamiliarity with the Chinese language. Instead, the points are identified by number and capital letter abbreviation of the meridian to which they belong: 365 classic points are located along the meridians and at least the same number of extrameridian points. The exact location of the points is important, because, according to classic theory, even small deviations from the intended location can nullify the response. The distance of acupuncture points to anatomical landmarks is usually described as *cun*.

Investigation into the anatomy and physiology of acupuncture points has resulted in a hypothesis that most recognized acupuncture points coincide with tissues that are capable of eliciting a strong neurohumoral response when irritated. These include nerves, neurovascular complexes, Golgi tendon apparatuses, and other sensitive tissues. Stimulation of these tissues might cause acute and intense irritation that triggers endogenous analgesic, immune, and behavior-adapting systems to be activated, resulting in the clinical effectiveness of acupuncture.

Point Location

Several factors have been associated with precise location of acupuncture points:

- Points are located in a small hollow or depression on the skin surface.
- Acupuncture points are usually tender compared with the surrounding area, and a response (probably associated with

discomfort) can often be elicited with deep palpation. Human patients describe a feeling of slight pain or numbness radiating circumferentially for at least a centimeter when the point is pressed.

- A subjective roughness or stickiness can be appreciated when an acupuncture point is brushed slightly with the finger.²¹
- A specific feeling called the *De-Qi* sensation is usually felt by human patients, and the acupuncturist feels a change in the resistance to needle movement, when a needle stimulates an acupuncture point.

In humans, the *De-Qi* sensation may be described as soreness, numbness, warmth, heaviness, or distension around the area where a needle is inserted. Sometimes this sensation radiates along the pathway of the meridian to which the stimulated point belongs. An experienced practitioner also feels tightness and some heaviness in the fingers when the needle hits the point.²² This change in needle resistance coupled with the animal’s reaction to needle placement is what most veterinary acupuncturists rely on to assess the attainment of *De-Qi* sensation. Most human and veterinary acupuncturists consider *De-Qi* sensation to be crucial in achieving the effect of acupuncture.^{22–24}

The descriptions of the diameter and depth of acupuncture points vary among various species. Traditionally, the size depends on the individual point, the patient’s condition, the time of day, and possibly the season. The depth depends on the amount of hair on the patient, skin thickness (e.g., the thin skin of cats versus the rather thick skin of stallions), location of the point, and duration of the disease.^{21,22} In veterinary acupuncture, most clinically used points in most species are believed to be 3 to 15 mm below the skin surface.

Point Stimulation

Traditional Chinese acupuncture teaches that each point has specific functions and indications for use. For example, stimulation of certain acupuncture points distant from the source of pain can provide analgesia, whereas stimulation of inappropriately selected points in close proximity to the source of pain might be ineffective or even aggravate the symptoms. Stimulation of site-specific acupoints usually induces spatially restricted analgesia. Although this aspect of acupuncture has yet to be studied in detail, Benedetti et al.²⁵ demonstrated that, in people, placebo or treatment expectation provides an analgesic response with a highly spatial presentation, which is completely abolished by systemic naloxone administration. These data indicate that this type of analgesic response is mediated by endogenous opioid release but that the effect is regional rather than systemic. Acupuncture might manifest a similar mechanism of action. Li et al.²⁶ demonstrated that acupuncture stimulation of the ipsilateral Huantiao (GB 30) point, which is traditionally thought to be effective in treating pain in the lower limbs, including sciatica pain, significantly inhibits nociceptive responses of spinal dorsal horn neurons evoked by stimulation of the sural nerve in rats. In contrast, stimulation of the contralateral Huantiao (GB 30) and some other points produce much less, if any, inhibition.

Cho et al.,⁵ using functional MRI, demonstrated a correlation

between activation of specific areas of the brain and corresponding acupoint stimulation predicted by ancient acupuncture literature. In this study, acupuncture points belonging to the bladder meridian and located on the foot were stimulated. These points are traditionally related to the eyes and visual function. The investigators also demonstrated activation or deactivation of signal intensity in the visual cortex. A subsequent study confirmed this finding and demonstrated activation of visual and auditory cortex caused by electroacupuncture stimulation of eye-related points and ear-related points, respectively.⁸ However, electroacupuncture at sham points also elicited activation in the auditory cortical zone, suggesting that acupuncture-induced activation of medial occipital cortex and superior temporal gyrus may not be an acupoint-specific phenomenon.

Point specificity was also questioned in another functional MRI study by Cho et al.,²⁷ where meridian and sham acupuncture were both involved in the transmission and perception of pain. Meridian acupuncture demonstrated more profound pain control than did sham-point stimulation, but the effect may not have been entirely point specific. Point specificity, as stated in traditional acupuncture literature and demonstrated by clinical practice and some experimental studies, is not fully supported by other studies and therefore remains a controversial issue. For any species being treated with acupuncture therapy, only careful systematic research using site-, organ-, and function-specific acupuncture points with carefully selected sham control points can resolve this issue.

Mechanisms of Analgesic Action

Starting in the 1960s, Western-trained Chinese physicians began to study acupuncture analgesia, particularly acupuncture-induced physiological changes in the central nervous system (Fig. 24.1). This, and subsequent research in Western countries, resulted in the discovery of several plausible mechanisms of acupuncture analgesia, receptors, and several endogenous opioids involved in the process; hence, a comprehensive hypothesis of acupuncture analgesia was formed. Experimental studies on animals and clinical studies on humans have since identified numerous clinical and physiological responses to acupuncture stimulation.

Comprehensive Mechanism Theory

Based on a review of hundreds of modern scientific studies on acupuncture analgesia, Pomeranz and Stux² proposed a comprehensive mechanism of action for acupuncture analgesia. The basis for the theory is that three mechanisms contribute to acupuncture analgesia:

1. Acupuncture needles stimulate type I and type II afferent nerves or A- δ fibers in muscles, all of which send impulses to the anterolateral tract of the spinal cord. At the spinal cord, pain is blocked presynaptically by the release of enkephalin and dynorphin, preventing pain messages from ascending in the spinothalamic tract.

2. Acupuncture stimulates midbrain structures by activating cells in the periaqueductal gray matter and the raphe nucleus.

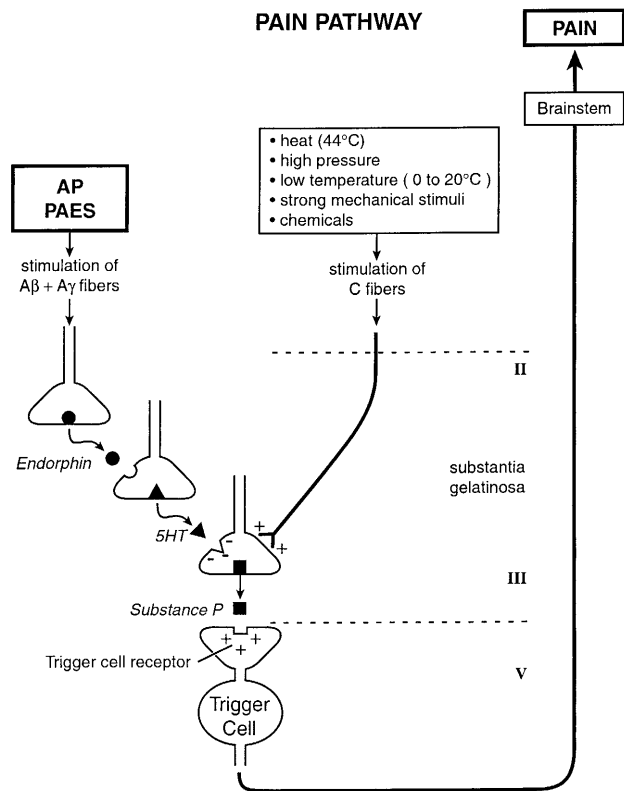

Fig. 24.1. Pain pathway and mechanism of inhibition by acupuncture (AP) and percutaneous acupuncture electrical stimulation (PAES). The release and binding of endorphin and serotonin (5-hydroxytryptamine [5HT]) inhibits substance P release in the substantia gelatinosa that normally mediates pain transmission within the spinal cord.

They in turn send descending signals through the dorsolateral tract, causing the release of the monoamines norepinephrine and serotonin in the spinal cord. These neurotransmitters inhibit pain presynaptically and postsynaptically by reducing transmission of signals through the spinothalamic tract (diffuse noxious inhibitory control).

3. Stimulation in the pituitary-hypothalamic complex provokes systemic release of β -endorphin into the bloodstream from the pituitary gland. Its release is accompanied by the release of adrenocorticotrophic hormone.

The National Institutes of Health and National Commission for Complementary and Alternative Medicine have also suggested three possible mechanisms of action for acupuncture:

1. Conduction of electromagnetic signals that may start the flow of endogenous analgesic compounds and immune system cells to specific areas of the body that are injured.
2. Activation of the opioid systems in central nervous system and peripheral tissues.
3. Changes in brain chemistry, sensation, and involuntary bodily functions.

These mechanisms are supported by the observations that conditions that have the best responses to acupuncture include pain,

Fiber spectra profile of a sensory nerve

Fig. 24.2. Different-diameter nerve fibers have differing characteristics enabling waveform stimulation neuroselectivity. Large-diameter myelinated (A- β) fibers can respond to high, 100-Hz stimulus, whereas small nonmyelinated (C) fibers respond to low-frequency stimulation (2 to 10 Hz).

immune-related dysfunctions, and visceral dysfunctions. Conditions that are not reversible, functional conditions (end-stage disease) often respond poorly to acupuncture, although occasionally symptomatic improvement may be observed.

Nociceptors

A- δ fibers are activated by pinprick, pressure, thermal manipulation, and high-threshold ergo receptors in muscles. A- δ fibers provide rapid, precisely located identification of noxious stimu-

lation without affective response. Some of these fibers terminate on the rostral reticular formation and thalamus. From there, they pass forward to the arcuate nucleus of the hypothalamus and on to the prefrontal cortex.²⁴ Myelinated A- δ fibers are considered the most likely candidates for conveying acupuncture stimuli, but other fibers, including nonmyelinated C fibers and A- β fibers, may contribute (Fig. 24.2). C fibers, which are ontogenetically older, produce pain described as slow, deep, throbbing, and dull. This sort of pain is often accompanied by a strong affective component. Therefore, noxious stimulation by the C-fiber system leads to a perception of pain that is poorly localized but has considerable behavioral and emotional impact. These fibers primarily make synaptic contacts in substantia gelatinosa in lamina II. Different kinds of fibers are involved in different components of the De-Qi sensation.²⁸ Because different modalities of acupuncture stimulation produce different types of De-Qi sensation, they may trigger diverse brain networks, based on their activation of various types of afferent input.⁶

The Brain

Acupuncture influences on regional brain activity were elaborated by Wu et al.,⁷ who reported that acupuncture at two major points, Zusanli (ST 36 [Fig. 24.3]) and Hegu (LI 4 [Fig. 24.3]), activates the hypothalamus and nucleus accumbens on functional MRI and deactivates the rostral part of the anterior cingulate cortex, amygdala, and hippocampal complex. In contrast, control stimulation by superficial needling that did not elicit the De-Qi sensation did not alter regional brain activity. Therefore, acupuncture at major points with strong analgesic properties seems to activate structures of the descending antinociceptive pathway and to deactivate multiple limbic areas subserving pain association.

Fig. 24.3. The anatomical location of various acupuncture points, including the Zusanli (ST-36) and Hegu (LI-4) points, that can produce analgesia in dogs.

Other Potential Mechanisms

Acupuncture not only provokes release of endogenous opioids from central nervous system stores, but may also activate other analgesic mechanisms. For example, acupuncture may relieve pain by modulating the hypothalamic-limbic system.^{4,8} Biella et al.⁴ used positron-emission tomographic scans in healthy volunteers who were not experiencing any pain to evaluate regional cerebral blood flow in response to classic manual acupuncture stimulation of the Zusanli (ST 36) and Qize (LU 5) acupuncture points. The researchers demonstrated activation of the left anterior cingulum, the insulae bilaterally, the cerebellum bilaterally, the left superior frontal gyrus, and the right medial and inferior frontal gyri. Several imaging studies indicate that the same structures are activated by acute and chronic pain.^{29–32} *Placebo acupuncture* (needles inserted superficially into nonacupuncture points 1 cm lateral to each acupoint and then immediately extracted) also produced a degree of cerebral activation, but at areas differing from those activated by traditional acupuncture points. Cho et al.²⁷ had similar results. All the structures that were activated by acupuncture are also involved in nociceptive processing and play a role in the concept of the *neuromatrix* as proposed by Melzack.³³ Biella et al.⁴ proposed that, according to this concept, acupuncture can be thought of as a conflicting message in the pain neuromatrix, unbalancing it and thus modifying the perception of pain.

An interesting theory has been proposed suggesting an important integrative role of connective tissue in the mechanism of action of acupuncture.³⁴ Langevin and Yandow³⁵ found 80% correspondence between acupuncture points and the location of intramuscular connective tissue planes in postmortem tissue sections. According to this theory, needle manipulations lead to the development of coupling between needle and tissue, with subsequent transduction of the mechanical signal to a cellular response that may underlie some of the therapeutic effects of acupuncture both locally and distally.

Acupuncture analgesia leads to development of tolerance when applied continuously or repeatedly over short time intervals. It would be reasonable to speculate that when acupuncture stimulation releases endogenous opioids to exert an analgesic effect, it also provokes the release of antianalgesic substances. Cholecystokinin is a powerful antagonist of the analgesic effect of acupuncture, and cholecystokinin antisense RNA increases the analgesic effect induced by acupuncture.^{36–40}

Many studies have focused on the analgesic effects of acupuncture and the role of endogenous opioids in acupuncture analgesia. However, acupuncture stimulation produces a much broader spectrum of systemic responses, including altering the secretion of neurotransmitters and neurohormones and changing the central and peripheral regulation of blood flow. There are also data suggesting that acupuncture alters immune function and accelerates nerve regeneration.^{24,41,42} The mechanisms of these physiological responses remain unclear.

Types of Acupuncture

Invasive methods include skin penetration with an acupuncture needle with subsequent manual stimulation of needles, elec-

troacupuncture, or chronic intradermal needle insertion. These methods are considered *dry needle* techniques. Drugs can be injected into acupoints, a technique considered *wet needle* acupuncture or *aquapuncture*. Noninvasive methods include acupressure, transcutaneous electrical stimulation, moxibustion, and application of various stimulating patches and pellets.

Because the traditional theory of acupuncture is based on the concept that diseases are caused by an imbalance of Qi, the goal of needle insertion is, in the context of TCM, to disperse excessive Qi or to replenish it. These two goals can be achieved by several means: applying needles of different sizes or lengths, using needles made of different material, changing the direction of needle insertion, selecting different points for stimulation, and so forth. For strong stimulation, a bigger needle, more intense needle manipulation, or directing the needle tip against the hypothetical energy flow along the meridian is believed to disperse the excessive energy, whereas for mild stimulation, a smaller needle, gentle and more superficial needle insertion, or directing the needle toward the energy flow is used to replenish it. Manual stimulation techniques can be altered to provide the desired effect by using strong vertical up-and-down movements, rotational movements, or mild vibrating movements, for example. Some practitioners believe that selecting the proper acupuncture maneuvers and appropriate points is key to producing a satisfactory therapeutic effect. Consistent with this theory, Chen et al.⁴³ demonstrated that different manual needling maneuvers provide different responses on tail-flick latency and vocalization threshold in rats.

Electrical Stimulation

Electrical stimulation of acupuncture points (*electroacupuncture*) was developed as an alternative to manual stimulation of acupuncture points. Electrical stimulation has several advantages in that it (a) is less painful than manual stimulation, (b) requires less practitioner time directly spent with the patient, (c) provides better analgesia, and (d) facilitates standardization.⁴⁴ Transcutaneous and percutaneous electrostimulation are now the most common types of acupuncture analgesia performed in people (Fig. 24.4).⁴⁵

In humans, the De-Qi sensation depends on the type of acupuncture stimulation. Manual stimulation produces mainly soreness, fullness, and distension, whereas electroacupuncture generally produces tingling and numbness. Kong et al.⁶ report that manual acupuncture manipulations decrease fMRI signals, in contrast to electroacupuncture stimulation, which generally increases MRI signal intensity. Both types of stimulation, however, produce analgesia. Therefore, various stimulation modalities seem to trigger different brain networks, depending on how acupoints are stimulated. How various stimulation modalities influence brain networks in companion animal species such as dogs and cats has not been evaluated.

Electroacupuncture with high-frequency stimulation (100 to 200 Hz) provides rapid-onset analgesia that is not cumulative and cannot be blocked by naloxone. This type of analgesia is probably mediated by norepinephrine, serotonin, and dynorphins.⁴⁶ In contrast, low-frequency stimulation (2 to 4 Hz) and medium-

Fig. 24.4. A package of ten sterile acupuncture needles (top left) for single use. Pointer-plus handheld unit for electrically locating and stimulating transcutaneous points (transcutaneous electrical nerve stimulation) (top middle). Acu-Vet unit for stimulating acupuncture points transcutaneously (top right). Electroacupuncture Unit IC 4107 for locating and stimulating acupuncture points percutaneously (percutaneous acupuncture electrical stimulation). There is little standardization of acupuncture equipment because it is manufactured in several different countries.

frequency stimulation (15 to 30 Hz) produce an analgesic effect that is reversed by naloxone (and therefore presumably mediated by enkephalin and endorphins), have a tendency to accumulate, and last at least 1 h after treatment ceases.^{44,46} Reportedly, antinociception induced by low-frequency stimulation is mediated by both μ opioid and δ opioid receptors; high-frequency electroacupuncture stimulation induces antinociception mediated by κ opioid receptors; and medium-frequency stimulation (e.g., 30 Hz) induces antinociception mediated by all three opioid receptor types.⁴⁷

Needles

Most modern acupuncture needles are made of stainless steel, although needles made of gold or silver are also available (Fig. 24.5). Most acupuncture needles are between 1.3 and 12.7 cm long and range from 26 to 36 gauge in diameter. The tips of the needles are rounded and thus separate fibers rather than cutting tissues. For this reason, even capillary bleeding from an acupuncture site is rare unless a needle accidentally penetrates a vessel. In the treatment of human patients, special needles have been developed for intradermal use, auricular acupuncture, and hand and foot acupuncture.

Fig. 24.5. Most good-quality needles are manufactured in China, Japan, or South Korea. They should be sterilized at 120°C for 30 min at 15 pounds of pressure before each use, especially for percutaneous acupuncture electrical stimulation therapy.

Veterinary Acupuncture

Probably the most commonly treated species is the dog, although historically, equine acupuncture was more widely used because horses were important for the daily survival of people (similar to the history for Western veterinary medicine). Dogs tend to be cooperative, and most relax during the treatment. If an animal becomes severely distressed, it is unlikely that the treatment will have the desired effect. The most commonly treated problems are related to the musculoskeletal system. It is important for beginners to recognize that pain and disuse in many musculoskeletal diseases—especially chronic degenerative diseases, including low-grade intervertebral disk disease—often wax and wane. This coupled with the placebo effect would suggest that some of patients treated (whether with acupuncture or nonsteroidal anti-inflammatory drugs [NSAIDs]) should improve, at least for a while. One should be careful to not interpret a positive response as possession of superior TCM skills. However, some scientific evidence supports the use of acupuncture alone or in conjunction with other Western treatments such as NSAIDs.^{48,49} Other common uses for acupuncture in canine patients include treatment of signs associated with chronic diseases such as cancer, nervous system degeneration, and organ failure, such as chronic renal disease. Unless functional tissue is present, reversal of the course of disease is unlikely. Acupuncture cannot miraculously regenerate tissue. Owners should be educated on what the treatment capabilities are of any form of therapy before administering it.⁵⁰

Based on experiences with horses and needles, it would not be expected that they are good patients for acupuncture. However, horses tend to relax with treatment and often do not respond much to needle placement. The veterinary acupuncturist should use common sense, and care is required anytime one is working around a large animal capable of lethal force. For example, al-

though acupuncture points are described all over the equine body, few practitioners routinely use points between or behind the rear legs.

Equine acupuncture is commonly used as a treatment for medical colic, lameness, performance issues, and behavioral problems. One should realize that using acupuncture as the sole treatment for a surgical colic likely constitutes malpractice unless the owners do not consent to surgery. Western therapies should always be used when they are considered the established standard of care. Acupuncture is being increasingly used for the symptomatic treatment of postoperative ileus in horses with little documentation of its efficacy.

Acupuncture has been used in almost all species. Although species-specific diagrams may not be available, an understanding of anatomy will often help veterinary acupuncturists locate the transpositional points. Theory remains the same except that one should realize that there are relative differences in the normal characteristics of different species. Before agreeing to treat any species, acupuncturists must weigh the perceived benefits and the potential distress induced in transport and treatment. Some zoos consult with acupuncturists because the animals are frequently handled and can be safely restrained by keepers in a relatively stress-free manner. On the other hand, animals that never leave their familiar surroundings may be severely stressed by the whole exercise.

Owners should be informed about the complications and contraindications to treatment.⁵⁰ Complications are rare, but include infection, tissue or organ trauma, and needle breakage. Acupuncture needles are extremely flexible and strong, so breakage is rare. It is more common for hypodermic needles to break. An animal's behavior can change after treatments, so owners should be educated on what to expect. Some practitioners have suggested that acupuncture treatment can be problematic in cancer patients. Increased blood flow and needle trauma might spread cancer. However, many people find acupuncture useful for symptomatic treatment of paraneoplastic conditions. Acupuncture-associated stress and physiological responses can cause extremely ill animals to decompensate. It is suggested that very ill animals be treated very conservatively at first until they can tolerate more aggressive treatment. Implants for chronic acupoint stimulation (e.g., gold beads) should not be used when animals are subject to prepurchase examinations (mostly horses). The beads will show up on radiographs and are usually diagnostic for preexisting lameness. Pregnancy can be a contraindication to acupuncture, because it is believed that stimulating points distal to the elbow and knee may induce labor.

Application in a Perioperative Setting

Perioperative acupuncture and related techniques have been advocated for preoperative sedation, to reduce intraoperative opioid use, and to decrease postoperative pain. There is compelling evidence that acupuncture reduces postoperative nausea and vomiting in human patients, and it has been used to decrease vomiting associated with opioid administration to dogs. It may also stabilize cardiac function and ameliorate some consequences of anesthesia and surgery.

Mann⁵¹ proposed the theory that diseased organs have a reduced response threshold to stimuli, whereas a considerable stimulus is needed to alter the function of a healthy organ. Therefore, just the small stimulus of an acupuncture needle may treat severe disease, whereas a comparable stimulus normally produces little or no effect in healthy volunteers.⁵¹ To some extent, then, perioperative acupuncture contradicts a traditional principle of acupuncture philosophy in that its goal is to achieve an abnormal insensitivity to pain and reduced awareness and concern. Perioperative acupuncture can be divided into three components: preoperative preparation, intraoperative acupuncture-assisted anesthesia, and postoperative care.

Preoperative Preparation

The goals of preoperative preparation with acupuncture are to optimize the conditions for patients, reduce preoperative anxiety, and trigger release of endogenous opioids to enhance analgesia. One way that acupuncture might help preoperative preparation is by producing relaxation and sedation. For example, Ekblom et al.⁵² demonstrated that although acupuncture did not produce intraoperative and postoperative analgesia for dental surgery in humans, it caused significant relaxation and drowsiness. Ulett et al.^{44,53} reported that electroacupuncture to classic acupoints is associated with a deep calming effect. In people, postoperative pain intensity and consumption of postoperative analgesics both correlate with the amount of anxiety that patients experience.^{54,55}

Intraoperative Assisted Anesthesia

Reduction in volatile anesthetic or opioid requirement is a clinically important outcome because it can reduce anesthetic toxicity and duration of recovery. Evidence suggests that inadequately treated pain, even during general anesthesia, activates nociceptive pathways.⁵⁶ Subsequent release of local mediators then primes the nociceptive system and aggravates postoperative pain.⁵⁷ To the extent that intraoperative acupuncture inhibits activation of nociceptive pathways and provides analgesia, it may similarly reduce postoperative pain and the requirement for postoperative opioids.

It is important to emphasize that acupuncture does *not* provide true anesthesia or unconsciousness, because it preserves all normal sensory, motor, and proprioception sensations. It does not provide adequate muscle relaxation or suppress autonomic reflexes caused by intra-abdominal visceral pain.⁵⁸ Instead, acupuncture produces analgesia and sedation as long as patients are cooperative.^{59–63} For these reasons, acupuncture cannot be recommended for use as a sole anesthetic technique in veterinary patients.

Acupuncture is relatively safe and, in combination with conventional anesthetic techniques, can reduce the required dose of opioids. It has been suggested that acupuncture facilitates more comfortable postoperative conditions than does anesthesia alone.^{60,64} Questionable results, however, were obtained by Sim et al.⁵⁸ in a blinded, randomized, placebo-controlled study on the effect of electroacupuncture on intraoperative alfentanil and morphine consumption during gynecologic surgery. Patients received true acupuncture or placebo acupuncture (continued throughout

surgery), or they received no preoperative treatment and acupuncture postoperatively (continued for 45 min). Intraoperative alfentanil consumption was similar in the acupuncture and control groups but was significantly greater ($P = 0.024$) in the group that received acupuncture postoperatively. This finding may indicate a treatment-expectation placebo effect accompanied by endogenous opioid release in both control and preoperative acupuncture groups, rather than an acupuncture effect, although endogenous opioid concentrations were not measured. Acupuncture-induced postoperative analgesia in the preoperative acupuncture group was obvious during the first 6 to 12 h postoperatively. However, cumulative 24-h, patient-controlled analgesia consumption of morphine was not significantly less in the acupuncture-treated groups than in the placebo groups. The inability of acupuncture to reduce the 24-h morphine consumption can possibly be explained by the analgesic effect of a single electroacupuncture session lasting only 2 to 3 h.⁶⁵

Acupuncture might decrease volatile anesthetic requirements. In an experimental setting, electroacupuncture produces a small, but statistically significant, reduction in halothane requirement in anesthetized dogs.⁶⁶ Similar results have been recently observed by Culp et al.⁶⁷ when using electroacupuncture during isoflurane anesthesia but not when using manual needle stimulation. Electroacupuncture therapy decreased isoflurane requirement (minimum alveolar concentration) by 10%. An advantage of evaluating acupuncture during general anesthesia is that it enables full blinding without resorting to sham stimulation. In three volunteer studies, anesthetic requirement with and without acupuncture was determined by the Dixon up-and-down method and defined by the average desflurane concentration required to prevent purposeful movement of the extremities in response to noxious electrical stimulation.^{68–70} The first study was a crossover, double-blinded, placebo-controlled study in which Greif et al.⁶⁸ showed that transcutaneous electrical stimulation of the lateralization-control point near the ear tragus reduces anesthetic requirement for acute noxious stimulation by $11\% \pm 7\%$. Acupuncture stimulation was initiated after induction of general anesthesia. In the second study, Taguchi et al.⁷⁰ found that acupuncture initiated after induction of general anesthesia reduced desflurane requirement by $8.5\% \pm 7\%$. Auricular acupuncture was performed after induction of general anesthesia with needles placed at the Shen Men, thalamus, tranquilizer, and master cerebral points on the right ear. In the third volunteer trial, Morioka et al.⁶⁹ tested the hypothesis that electroacupuncture at the Zusanli (ST 36), Yanglingquan (GB 34), and Kunlun (BL 60) acupuncture points on the leg decreased anesthetic requirement during electrical noxious stimulation on the thighs. Desflurane requirement on the acupuncture ($4.6\% \pm 0.6\%$) and control ($4.6\% \pm 0.8\%$) days did not differ. Acupuncture significantly reduced anesthetic requirement in two of these three volunteer trials, but neither reduction was clinically important. This conclusion is consistent with that of a recent clinical study in which patients given acupuncture-assisted anesthesia required even more volatile anesthetic than did patients in the control group.⁷¹ Available data therefore indicate that acupuncture has little, if any, effect on anesthetic requirement. As might be expected, manual stimulation of classic acupuncture points during surgery

did not influence pain scores or change intraoperative or postoperative analgesic requirements.⁷²

Postoperative Pain Control

Acupuncture and related techniques can potentially serve as important adjuvants for pain control and for relieving opioid-related adverse effects during the postoperative period. However, controversial results, dissimilar study designs, and diverse modes of acupuncture-point stimulation make it difficult to evaluate the clinical importance of perioperative acupuncture analgesia across a wide array of species. The results of few randomized, controlled clinical trials on acupuncture-related postoperative pain relief have been published in English. Interpretation of these available studies is complicated by the fact that acupuncture success depends on numerous factors, including adequate patient selection and the acupuncturist's knowledge and skill level.

Christensen et al.⁷³ demonstrated that postoperative analgesic requirement or pain was not reduced in human patients receiving electroacupuncture before and during hysterectomy. However, in this study, patients were also given relatively high doses of meperidine for induction and intraoperative pain control. Opioid-induced analgesia may have masked the putative benefit of electroacupuncture.

In another study, acupuncture increased intraoperative discomfort, postoperative pain, and consumption of analgesic after dental surgery.⁵² In this study, local anesthesia was supplemented by preoperatively or postoperatively administered acupuncture with manual stimulation. Both acupuncture groups had increased consumption of pain medication and greater pain rating postoperatively than did the control group.⁵² In addition, patients from the preoperative acupuncture group needed more local anesthetic than did patients from the other groups and expressed more distress during the surgical procedure. However, patients in both acupuncture groups demonstrated significant mental relaxation. There are several potential explanations for these conflicting results: (a) The relaxing effect of acupuncture might blunt the activation of a natural endogenous pain-inhibiting system. (b) The vasodilatation induced by acupuncture might have caused faster washout of the local anesthetic. (c) The investigators might have used suboptimal acupoint selection and stimulation technique.

In contrast, in a randomized, double-blinded, placebo-controlled trial, Lao et al.⁷⁴ demonstrated the efficacy of acupuncture for reducing pain and postoperative analgesic consumption after a similar oral surgery. The stimulated acupoints and technique selected for this study were similar to those selected for the previous study. An experienced acupuncturist performed the procedure, in contrast to the previous study, where the level of expertise of the person performing acupuncture was not disclosed (it is not uncommon that acupuncture for research purposes is performed by inexperienced personnel). Acupuncture or a noninsertion placebo treatment was administered twice: immediately after the surgical procedure and after the patient reported moderate pain. The results showed that pain-free postoperative time was significantly longer in the acupuncture group (173 min) than in the placebo group (94 min) ($P = 0.01$), and the average

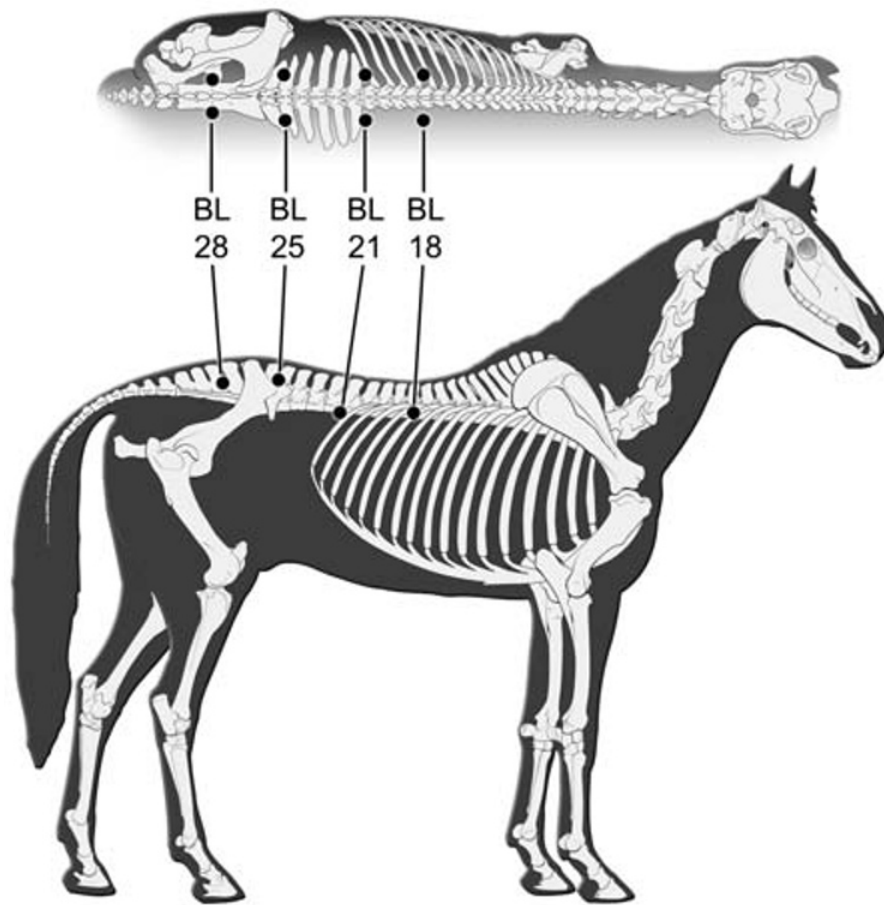

Fig. 24.6. Equine Shu points located bilaterally 3 to 6 cm lateral to the midline can be used to induce visceral analgesia in horses with colic and visceral organ disease or dysfunction. Horses are typically treated at these points with percutaneous acupuncture electrical stimulation for colic pain.

pain medication consumption was significantly less in the acupuncture group.

As previously mentioned, in human patients, point selection and mode of stimulation perform important roles in the outcome of acupuncture for postoperative pain relief. It seems that different components of postoperative pain respond to different combinations of acupuncture points. *Shu* points of the internal organs are located bilaterally 3 cm lateral to the posterior midline. *Shu* points are associated with the viscera and traditionally have been used for treatment of internal organ diseases.²⁰ Stimulation of these points may alleviate pain associated with visceral organ dysfunction (Fig. 24.6).²⁰ For example, consumption of supplemental morphine is reduced by 50% and the incidence of postoperative nausea is reduced by 20% to 30% in acupuncture patients undergoing upper or lower abdominal surgery.⁶⁰ In this controlled, double-blinded study, intradermal needles were inserted paravertebrally in *Shu* points. All needles were inserted while patients were in the preinduction area. In addition to less morphine consumption and postoperative nausea, patients with intradermal acupuncture had better pain relief than did controls ($P < 0.05$). Plasma cortisol and epinephrine concentrations were 30% to 50% less in the acupuncture group during recovery and on the first postoperative day ($P < 0.01$).

Transcutaneous electrical nerve stimulation (TENS) near the incision site significantly reduces postoperative pain.⁷⁵ However, this treatment seems to be most effective for the superficial cuta-

neous component of postoperative pain, leaving the deep visceral pain component largely intact. It seems likely that high-frequency TENS near the incision site mainly stimulates specific afferent nerve fibers instead of triggering endogenous opioid-release mechanisms.^{76,77} Combining TENS and stimulation of viscera-associated *Shu* points in the treatment plan is therefore promising for reducing postoperative superficial and deep visceral pain, respectively.

Both high-frequency and low-frequency electroacupuncture at the Zusanli (ST 36) point performed 20 min immediately before induction of anesthesia reduces morphine consumption after abdominal surgery in human patients.⁶¹ This point is traditionally considered effective for the treatment of abdominal disorders. The high-frequency acupuncture group had a 61% reduction in 24-h patient-controlled analgesia morphine consumption. Pain scores postoperatively did not significantly differ between groups, but cumulative morphine consumption for the first 24 h, number of patient-controlled analgesia demands, and intervals for the first request for analgesic were significantly less in both the high-frequency and low-frequency electroacupuncture groups. The aforementioned parameters were also reduced in the sham-acupuncture group compared with the control group, although they were greater than in the acupuncture groups. This is not surprising because sham acupuncture seems to have an analgesic effect in 40% to 50% of patients compared with 60% to 70% for real acupuncture and 30% to 35% for placebo (con-

tol).⁷⁸ The extrapolation or translation of human clinical trial findings to veterinary patients is controversial, although similar responses and mechanisms of action are plausible.

Acupuncture for the treatment of postoperative nausea and vomiting is one of its most common and investigated uses in human patients. This application has not been adequately assessed for use in animals during the perioperative period to date. Acupuncture may reduce nausea and vomiting through endogenous β -endorphin release into the cerebral spinal fluid or through a change in serotonin transmission via activation of serotonergic and noradrenergic fibers.^{79,80} The exact mechanisms have yet to be established.

Miscellaneous Perioperative Uses

Cardiopulmonary Resuscitation

In a study using 35 dogs anesthetized with halothane, acupuncture reversed cardiovascular depression induced by morphine and halothane. Acupuncture at point Jen Chung (GV 26) significantly increased cardiac output, stroke volume, heart rate, mean arterial pressure, and pulse pressure while simultaneously significantly decreasing total peripheral resistance and central venous pressure. The authors concluded that stimulation of the GV 26 acupoint could be helpful in resuscitating patients whose cardiovascular system is depressed by opioids and volatile anesthetics.⁸¹

GV 26 (also called Renzhong) is in the midline of the nasal philtrum, one-third of the way from the nose to the edge of the upper lip. The point is in the center of the horizontal line joining the lower edge of the nostrils. GV 26 has many clinical uses, the best known being its use in emergencies (coma, shock, apnea, anesthetic emergencies, drowning, etc.).

In human patients, the Neiguan (P 6) point has long been considered a primary point for treatment of various cardiovascular diseases.²¹ It has been shown to be effective as an adjunct therapeutic modality in conservative treatment of severe angina pectoris.⁸² Electroacupuncture at Neiguan (P 6) was effective in maintaining the hemodynamics and cardiac contractility in anesthetized open-chest dogs.⁸³ End-diastolic volume was maintained and even slightly increased in comparison with the control group, in which end-diastolic volume gradually decreased over 11/2 h; stroke volume and cardiac output also slightly increased compared with the control group. The end-systolic pressure and end-systolic elastance increased markedly in the Neiguan (P 6) acupuncture group. No analogous data support acupuncture-induced cardiovascular benefits in human patients, an obvious prerequisite to clinical application of the technique.

Impaired Intestinal Function

A major side effect of general anesthesia and opioid administration for postoperative pain control is the impairment of intestinal function.⁸⁴ To the extent that intraoperative and postoperative acupuncture for pain relief decreases perioperative opioid consumption, it may be beneficial for indirectly speeding postoperative recovery of intestinal function.⁶⁰ Acupuncture treatment has also been shown to promote postoperative recovery of impaired intestinal function after abdominal surgery in people.⁸⁵ Acupuncture for the treatment of ileus in horses is becoming

more common, and practitioner consensus indicates that it may be effective in some horses.

General Principles of Acupuncture Analgesia

Patient Selection

Acupuncture in people is more effective in young adults than in the elderly. Small children are usually poor candidates for acupuncture-assisted anesthesia and analgesia with needles simply because they are rarely willing to cooperate with the acupuncturist. The same can probably be said for veterinary patients. However, choosing patients wisely and having their owner's consent and help will improve the chances for successful therapy. Obviously, acupuncture is not suitable for moribund preoperative patients because acupuncture is less effective in decompensated patients.¹¹

Point Selection

According to traditional Chinese theory, certain rules and principles are generally applied when selecting points for acupuncture treatment. First, appropriate meridians should be selected, and then appropriate points on these meridians should be stimulated. For example, for postoperative pain control, a meridian that passes through the surgical area or close to the surgical area is usually selected. Also, according to the *organ phenomena* concept of TCM, the lung commands the skin. Consequently, stimulation of acupuncture points on the lung meridian can provide analgesia for surgical skin incisions. Similarly, the liver meridian commands the eyes, making the liver meridian ideal for ophthalmologic surgery. Whether these relationships hold true for acupuncture therapy in companion animal species is speculative.

Needling of points that easily produce a strong De-Qi sensation is thought to provide better analgesia. Conversely, analgesia is often poor at needling points that produce weak De-Qi response or in which the sensation is difficult to obtain. When selecting acupuncture points, one must consider convenience as well as the patient's comfort. Points located below the knee or elbow are usually selected during surgery. Points located on the ear are often selected for acupuncture during the perioperative period. After the locus point is identified, auxiliary points may be added.²⁸

Summary

Acupuncture is increasingly being incorporated into veterinary medicine and more specifically pain management.⁸⁶ Acupuncture and related analgesic techniques are being widely used in conventional human medical settings, as well. Accordingly, the number of owners willing to use or specifically request acupuncture techniques for their pets is likely to increase. However, despite more than 30 years of research, the exact mechanisms of action and efficacy of specific acupuncture techniques have yet to be completely established. Consequently, considerable controversy remains about the role of acupuncture in both human and

veterinary clinical medicine. Nevertheless, it should be remembered that the *how* is not as important to the patient as is the *outcome*. Although an exact explanation for the mechanisms may not yet exist, it seems reasonable to continue to explore acupuncture's potential as an adjuvant to proven analgesic and anesthetic techniques in both people and animals.

Introduction

Companion animal rehabilitation is a rapidly growing area aimed at improving supportive care in veterinary patients. In the veterinary setting, rehabilitation is essentially akin to the human-oriented profession of physical therapy. Similar to physical therapy, rehabilitation uses physical and mechanical methods such as light, heat, cold, water, electricity, massage, and exercise to improve function and reduce pain and morbidity in a variety of conditions, including orthopedic and neurological disease. Other terms commonly used to describe rehabilitation are physical rehabilitation, physical therapy, and physiotherapy. Because pain and discomfort may be elicited by some techniques on occasion, therapists should be prepared to administer an appropriate analgesic, if necessary. Advanced training and certification in rehabilitation are available for certified veterinary technicians, physical therapists, and veterinarians. Practice acts vary from state to state, with most requiring that animal rehabilitation be supervised and in some cases implemented by a veterinarian.

Until recently, rehabilitation has not played an important role in the management of a pain in veterinary medicine.¹ Standard postoperative care has focused on basic nursing and support care, confinement, and pharmaceutical intervention. With the incorporation of rehabilitation into overall supportive care and pain management, many patients are recovering sooner and more completely from medical, surgical, and traumatic events. To date, however, the benefits of nondrug therapies in the management of pain, including those of rehabilitation, have been relatively undocumented in the veterinary literature.^{2,3} Similarly, the analgesic effects and overall benefits of therapies such as acupuncture and electroacupuncture, acupressure, and transcutaneous electrical nerve stimulation are relatively undefined. Despite this lack of experimental scientific evidence for their efficacy, clinical experience in veterinary patients suggests that the use of such

therapeutic modalities in conjunction with drug therapy can be beneficial. The desired clinical outcome is better control of discomfort and reduction in the overall pharmacological requirement of patients.

Therapeutic Modalities

Seven therapeutic modalities are used to decrease pain, reduce inflammation, and stimulate normal healing responses in veterinary patients: (1) local hypothermia and hyperthermia, (2) passive range-of-motion activity, (3) massage, (4) therapeutic exercise, (5) hydrotherapy, (6) ultrasound, and (7) electrical stimulation. In this chapter, the indications and contraindications, along with the methods of action and application are discussed for each therapeutic modality commonly used in companion animal rehabilitation.

Local Hypothermia

Local hypothermia therapy, or cryotherapy, entails the application of therapeutic cold to a musculoskeletal tissue. Common forms of therapeutic cold include commercial available reusable ice and gel packs, continuously circulating cold-water blankets, homemade ice packs and towels, ice massage, and cold-water hydrotherapy. The application of local hypothermia is indicated in the acute (<72 h) postinjury period to ameliorate inflammation, irritation, pain, swelling, and edema. The primary purported method of action of cryotherapy is via vasoconstriction, which reduces arterial and capillary blood flow, thereby minimizing fluid leakage and edema. Because cryotherapy also decreases enzyme activity and metabolism in tissues, it is effective against local inflammation in periarticular and articular tissues.⁴ Analgesia is provided by alteration of sensory nerve conduction and skeletal muscle relaxation.^{5,6}

The cooling effects of local hypothermia on deeper tissues are less profound and unpredictable, depending on the application method, the initial temperature of the treated area, and the duration of treatment.⁷ Regardless, application of local hypothermia should be limited to multiple short sessions (5 to 15 min up to four times daily) to prevent reflex vasodilation and edema.⁶⁻⁹ Overzealous cryotherapy causing a 10.0°C (18.0°F) or more decrease in tissue temperature may cause protein degradation, local hyperemia, epithelial and nerve damage, and muscle atrophy and contracture. The use of local hypothermia should be avoided in hypothermic animals. If body core temperature is further dropped, peripheral vasoconstriction and increased blood pres-

sure may ensue. Furthermore, cryotherapy is contraindicated in people and presumably animals that have diabetes mellitus, ischemic injuries, vasculitis, or indolent wounds.

Local Hyperthermia

This technique uses heat to promote capillary dilation and increase capillary hydrostatic pressure, permeability, and filtration. The cellular and vascular changes produced by heat also stimulate inflammation and invigorate wound healing. Tissues treated with local hyperthermia increase in temperature, which causes a local histamine release while simultaneously enhancing cellular metabolism.¹⁰ Heat therapy provides pain relief by increasing blood flow and capillary permeability, decreasing edema, increasing local metabolic rate, increasing extensibility of collagen in articular and ligamentous tissues, and decreasing muscle tension and spasm, as well as providing general relaxation.^{4,11–13}

Common forms of therapeutic heat used in veterinary medicine include the application of hot packs, warm towels, warm-water blankets, therapeutic ultrasound, circulating warm-water baths, and hydrotherapy units. The therapeutic protocol for heat is similar to that for cryotherapy, with application durations varying from 15 to 20 min, two to four times a day. Other types of less frequently used heat therapy include incandescent, infrared, ultraviolet, and microwave radiation, all of which require special equipment and training.

As the primary method of action of heat therapy is inflammatory, local hyperthermia should be used only once acute inflammation has subsided, typically 24 to 72 h after injury or surgery. Heat therapy is indicated to remove the inflammatory mediators and edema present in the peri-injury site tissues. It is important to note that local hyperthermia has a narrow therapeutic temperature window (40° to 45°C [104° to 113°F]) and warrants careful monitoring.^{10,14,15} Care should be taken not to prematurely apply heat too soon after a traumatic injury, because that can induce vascular leakage, exacerbate the inflammatory response, augment edema and seroma formation, and potentiate hemorrhage and pain.^{10,14,15} Local hyperthermia has few indications in the immediate postoperative period and should be combined with other forms of physical therapy (massage or exercise) in the later stages of convalescence (>72 h after surgery). Therapeutic heat is also contraindicated in neurological or vascularly impaired patients.^{10,14,15} Direct nerve injury from local hyperthermia and burns is possible, especially with prolonged application or the use of electric heating pads.

Passive Range of Motion

Passive range of motion (PROM) exercise refers to the controlled movement of the limbs and joints in flexion, extension, adduction, and abduction by the therapist with no effort being exerted by the animal.¹⁶ The goals of PROM are to stretch and manipulate the periarticular structures of the appendicular skeleton to maintain normal joint ROM while preventing soft tissue and muscle contracture.¹⁶ Experimental evidence evaluating the effects of prolonged immobilization and restricted weight bearing on canine cartilage reveals chondrocyte atrophy and deterioration of the supportive matrix, which in many cases is irreversible.¹ In

addition to direct benefits to cartilage, PROM improves blood flow and sensory awareness of the affected joints and limbs. However, PROM is not a replacement for normal weight bearing and the superior affects of voluntary active movement. In comparison to PROM, active exercise produces superior cartilage, better prevents muscle atrophy, and improves muscle strength and endurance.^{1,17}

PROM should be instituted immediately after surgery and continued until the patient begins to ambulate within normal limits. If the animal has decreased ROM, as documented by goniometry, the PROM exercises can be prolonged to improve the function of the limb. Typically, PROM is performed with the animal in relaxed lateral recumbency. The joint or joints are flexed or extended to their nonpainful end point and held for 10 to 30 s and returned to a normal or functional standing position. These cycles are repeated for 10 to 15 complete cycles of flexion and extension. Caution should be taken not to overstretch the periarticular tissues, because overzealous PROM may tear the joint capsule and surrounding tissues and result in pain and unintentional fibrous scar formation. Contraindications to the use of PROM include unstable fractures, luxations, hypermobile joints, or skin grafts.

Therapeutic Massage

This involves the manual or mechanical manipulation of soft tissues and muscle by rubbing, kneading, or tapping. Benefits of massage include increased local circulation, reduced muscle spasm, attenuation of edema, and breakdown of irregular scar tissue formation. The method of action of this therapeutic technique is based on both reflexive and mechanical effects. The reflexive effects are due to stimulation of peripheral receptors, which produces the central effects of relaxation while simultaneously producing muscular relaxation and arteriolar dilation. The mechanical effects are due to increased lymphatic and venous drainage removing edema and metabolic waste, increased arterial circulation enhancing tissue oxygenation and wound healing, and manipulation of restrictive connective tissue enhancing ROM and mobility.

The most common techniques of massage used in veterinary medicine are effleurage, pétrissage, cross fiber, and tapotement. *Effleurage* (Latin, *effluere*, “to flow out”) is a form of superficial or light stroking massage and is generally used in the beginning of all massage sessions to relax and acclimatize the animal. *Pétrissage* is characterized by deep kneading and squeezing of muscle and surrounding soft tissues. *Cross fiber* is also a deep massage that is concentrated along lines of restrictive scar tissue and designed to promote normal ROM.^{9,18} This type of massage has limited use in veterinary medicine because it requires sedation of the animal during therapy and most often temporarily exacerbates lameness because of an inflammatory response to the tissue manipulation. *Tapotement* involves the percussive manipulation of soft tissues with cupped hand or massage equipment and is most commonly used to relax spastic muscle contraction or enhance postural drainage for respiratory conditions. Contraindications to massage therapy include unstable or infected fractures or tissue and the direct manipulation of a malig-

Fig. 25.1. A dog undergoing therapeutic exercise by walking on elevated treadmill.

nancy. In most instances, massage is an indispensable therapy when animals are in intensive care and have restricted mobility.¹⁰

Therapeutic Exercise

The potential for catastrophic failure associated with uncontrolled activity has previously limited the role of therapeutic exercise in the recovery of veterinary patients, particularly in postoperative orthopedic animals. Controlled active therapeutic exercise, however, may be safely performed in most cases, even orthopedic, when closely assisted and attended to by the therapist or the attentive owner. The benefits of therapeutic exercise are abundant. Exercise helps build strength, muscle mass, agility, coordination, and cardiovascular health. In addition, therapeutic exercise may be used as a preventive measure to improve general health, reduce obesity, and increase performance in all veterinary patients.^{1,18} Prior to initiating therapy, all animals must be fully evaluated and assessed, because it is imperative to match the intensity of the activities to the animal's level of function and ability. Included in the repertoire of controlled active exercise are assisted standing; facilitated walking; prolonged, momentary, and repeated sits and downs; stair walking; walking on inclines and hills; and weight shifting (Fig. 25.1).^{1,18} When performed appropriately and in consultation with the primary-care clinician or surgeon, these activities can be performed early in the postoperative recovery period and modified and intensified to promote cardiovascular and musculoskeletal fitness.

Aquatic Based Rehabilitation

Aquatic based therapeutic techniques for veterinary patients include local therapeutic massage with warm or cold water, underwater treadmill exercise, and swimming. Massage in water is particularly beneficial for postoperative animals, because it is an efficacious method for removing lymphedema from extremities. Water-based massage is also relaxing and effective for cleansing surgical incisions. Cold-water hydrotherapy may be employed as soon as a surgical incision has established a fibrin seal, which is generally within 24 h of surgery. This form of hydrotherapy is a

Fig. 25.2. A dog undergoing aquatic based therapeutic rehabilitation to reduce concussion during exercise.

relatively low tech–high yield form of rehabilitation in that it requires little equipment, other than a washtub and a hose.

Increasing the water depth and the temperature to 30°–32°C (86°–90°F) provides a nongravitational environment that is ideal for performing nonconcussive active-assisted exercise such as underwater treadmill and swimming activity (Fig. 25.2).¹⁹ The natural properties of water provide both buoyancy and resistance, which can be manipulated to improve limb mobility, joint ROM, gait, and cadence.⁶ Caution should be used with any water exercise in order to minimize the risk of aspiration or drowning. It is wise to acclimatize animals to water before initiating any therapy regimen.^{1,18}

Therapeutic Ultrasound

The method of action of therapeutic ultrasound is based on the delivery of energy to tissue in the form of acoustic vibrations. Sound waves can produce both physiological heat and cellular inflammation.¹⁸ The net physiological effects of ultrasound may be divided into two categories: thermal and nonthermal.¹⁸ The *thermal* effects of ultrasound increase connective tissue extensibility and vascularity and provide a form of temporary nerve blockage, thus promoting muscular relaxation and pain relief. The *nonthermal* effects of ultrasound include the acceleration and compressing of the inflammatory phase of healing; an in-

Fig. 25.3. Therapeutic ultrasound therapy in a bird to reduce scar tissue and enhance tendon healing.

crease in local circulation; a decrease in edema; an increase in endorphins, enkephalins, and serotonin; and the stimulation of collagen synthesis and bone growth.²⁰ Therapeutic ultrasound is primarily indicated in the treatment of chronic scar tissue and indolent decubital ulcers. It may also be effective for palliation of muscle spasms and for enhanced tendon healing (Fig. 25.3).^{18,20} Contraindications for the use of therapeutic ultrasound include tissue infection or inflammation. Prior to its application, therapeutic ultrasound should be thoroughly investigated because there is a wide variety of continuous-wave or pulsed-wave delivery modes, wave intensities, and therapy regimens to choose from.^{18,20} Complications are associated with operator inexperience and error that can produce excessive heat, free radicals, and subsequent tissue destruction.^{18,20}

Electrical Stimulation

This entails the delivery of electrical current to a selected treatment area.²¹ Common uses for electrical stimulation include muscle reeducation, pain palliation, and edema reduction.²¹ There are a variety of waveforms and devices available, varying in cost and versatility. The nomenclature is quite confusing and does little to improve one's understanding of the fundamentals of electrical stimulation. Essentially, however, there are two forms: neuromuscular electrical stimulation (NMES) and transeletrical nerve stimulation (TENS).

NMES is indicated in animals that are neurological, debilitated, recumbent, or immobile or need prolonged joint immobility. It prevents disuse atrophy and improves limb performance by recruiting contracting fibers and increasing maximum contractile force of affected muscles.¹⁸ The electrical stimulation device consists of a simple pulse generator and electrodes, which are placed over selected weakened or paralyzed muscle groups to create an artificial contraction (Fig. 25.4).¹⁸ Pulse amplitude, rate, and cycle length may be varied to suit the comfort of the patient.¹⁸ Muscular pain and edema may also be reduced because of improved blood flow.¹⁸ Combining neuromuscular stimulation

Fig. 25.4. The use of electrical stimulation for pulse generation over weakened muscle groups to enhance contraction in a dog.

with PROM exercises improves joint ROM and prevents muscle contracture and is particularly indicated in fractures of the distal femur of young dogs.¹⁸ This technique has proven effective in promoting muscle reeducation after prolonged disuse.

TENS has been used widely to identify neural stimulators that modify pain. Electrical stimulation to alter pain sensation involves the application of an electrical current to a sensory nerve. There are various suggestions as to the mechanism(s) responsible for altered pain sensation: the gate control theory, which involves the increased activity of the sensory afferents causing presynaptic inhibition of pain transmission; an endogenous opiate release; the counterirritant theory; and the placebo effect.²² In most patients, altered pain sensation via TENS is probably due, in part, to all of the aforementioned mechanisms. TENS should be considered an adjunctive pain management modality, to be combined with other pain-management techniques rather than as a sole therapy to control pain.

Summary

Implementing rehabilitation as part of a multimodal analgesic regimen will augment pain management and facilitate veterinary patients' recovery and return to function. The nature of any rehabilitation program is influenced by factors such as facilities, equipment, and trained personnel.⁸ It should be appreciated that one does not always need advanced training and equipment to perform physical therapy in animals. Most patients will experience improved recoveries with simple fundamental techniques such as massage, cold packing, PROM, and controlled exercise regimens.

Introduction

The selection of a particular anesthetic regimen is predicated upon the patient's physical status and temperament, the type of procedure for which anesthesia is being considered, anticipation of perioperative pain, the familiarity with anesthetic drugs, the type of facility and available equipment, the personnel available for assistance, and the cost of anesthetic drugs. There is no single best method for anesthetizing dogs or cats, and familiarity with just one anesthetic technique at best limits a veterinarian's ability to perform the myriad of surgical and diagnostic procedures commonly performed in a modern veterinary practice. A debilitated dog or cat undergoing extensive repair of a fractured limb will require a different anesthetic regimen than one undergoing routine neutering, one requiring short-term restraint for radiography, or a geriatric patient requiring extensive dental manipulations.

General anesthesia is characterized by muscle relaxation, unconsciousness, amnesia, and analgesia. Rarely does a single drug provide all of these elements at safe doses. Inhalation anesthetics come closest to satisfying all of these conditions, but even they

are more useful when coadministered with anesthetic adjunctive drugs such as opioids, local anesthetics, or neuromuscular junction–blocking agents. As a general rule, when formulating an anesthetic plan, it is best to consider using relatively low doses of several different drugs rather than a large dose of a single drug. For example, apnea resulting from a large bolus of propofol can be eliminated, or its duration shortened, by prior administration of acepromazine, opioids, or α_2 -adrenergic agonists, which allow administration of a lower propofol dose.¹ The opioid drugs, although important components of modern anesthetic regimens, by themselves do not produce general anesthesia.² Muscle rigidity, salivation, and long recoveries associated with large dosages of ketamine can be lessened when it is combined in reduced doses with opioids, α_2 -adrenergic agonists, and central muscle relaxants such as benzodiazepines.³

Any chemical restraint or general anesthetic plan must include a provision to control pain if it is present or anticipated. A good analgesic regimen should include drugs sufficient to ensure analgesia during and after the procedure. The one thing that should not vary among anesthetic procedures is the degree of vigilance associated with monitoring an anesthetized dog or cat. Early warning of impending anesthetic difficulty is the single most important factor responsible for decreasing anesthetic-related morbidity and mortality.

Preanesthetic Considerations

Recording a thorough history (Table 26.1) and conducting the physical examination are the most important components of a preanesthetic evaluation. Even young, seemingly healthy, animals presented for routine procedures such as neutering require both. These animals may have never been previously examined by a veterinarian, and congenital disorders, severe parasitism, or heartworm disease may be discovered.

Signalment

Anesthesiologists are often queried about “sensitivity to anesthesia” in a variety of dog and cat breeds. Although several breed-associated anesthesia concerns have been documented, all breeds have been successfully anesthetized by using standard anesthetic regimens, and most reports of “sensitivities” are anecdotal. One well-documented breed-associated anesthetic concern is the altered pharmacokinetics of barbiturates and other anesthetic drugs in sight hounds.⁴ Another is brachycephalic breeds and their associated airway anatomical malformations. Since toy breeds have

a greater surface area–body mass ratio and have a relatively greater metabolic rate, they require careful attention to maintenance of body heat and blood glucose concentrations. Additionally, they require a relatively greater dose of drugs on a per-kilogram basis. Generally, there are no gender-related differences in the response to anesthesia. However, a history of the estrous cycle will often identify recent estrus and thus alert the clinician to the concerns associated with an enlarged and vascularized uterus. This would potentially cause concern regarding blood loss during an ovariohysterectomy. Additionally, the owner of an intact female animal should be queried about the possibility of their animal being pregnant because the stress of surgery and anesthesia may adversely affect the fetus(es).

Age is an important anesthetic consideration. Generally, the very young (less than 11 weeks) and the aged (more than 80% of the expected life span) do not biotransform anesthetic drugs as rapidly as do young, healthy patients.⁵ Healthy geriatric patients may only require 25% to 50% of the dose of sedatives, hypnotics, tranquilizers, and opioids given to comparable young healthy animals.

History

In addition to questions concerning organ system function (Table 26.1), the owner should be queried regarding any previous anesthetic episodes, past and present illnesses, and past and current medication history, including history of heartworm prophylaxis.⁶ The time elapsed since the last feeding should be noted.

Physical Examination

The preanesthetic physical examination should be thorough, with all body systems considered (Table 26.2). Any abnormality discovered by physical examination or suggested by the medical history should be followed with appropriate laboratory or other suitable diagnostic testing. The assessment of an animal's temperament is critical. Vicious or aggressive dogs will require a different approach to anesthesia than quiet, relaxed individuals.

Laboratory Evaluation

The minimum preanesthetic laboratory data required for young healthy dogs are hematocrit and plasma protein. These tests are easy, quick, and inexpensive. Hematocrit is an indicator of hemoglobin concentration, which directly relates the ability of the blood to transport oxygen to the tissues. As a general rule, a hematocrit of less than 20% indicates the need for perioperative administration of blood or, if available, a hemoglobin-based oxygen-carrying solution. Hemoglobin concentration (g/dL) can be approximated by dividing the hematocrit by 3.

For elective procedures in middle-aged to older animals, or animals treated chronically with medications that could alter liver

or renal function (e.g., nonsteroidal anti-inflammatory drugs, phenobarbital, or antineoplastic chemotherapeutics), a complete blood count, urinalysis, and biochemistry profile should be performed. Other tests should be performed (e.g., thoracic radiographs and/or echocardiography) if the history or physical examination suggests specific organ system disease. A minimum laboratory database prior to emergency anesthesia should include packed cell volume, total protein, and electrolytes (sodium, potassium, and chloride).

Physical Status

Many factors (e.g., age, breed, concurrent disease, surgical procedure, surgeon skill, and available equipment) contribute to the overall anesthetic risk for a given patient. One risk factor is the physical status of the patient. A convenient system of status classification for veterinary patients has been adapted from the American Society of Anesthesiologists.⁷ In general, physical status I and II patients appear to be at less risk for anesthetic complications. Physical statuses III through V are usually at greater anesthetic risk. However, this is not to imply that category I and II patients are at no risk from unanticipated anesthetic mishaps (Table 26.3).

Patient Preparation

Fasting

Healthy dogs and cats should be fasted for at least 6 h prior to being anesthetized, if possible. Water can be allowed until just prior to anesthesia. Dogs and cats less than 8 weeks old and those weighing less than 2 kg should not be fasted longer than 1 or 2 h, because they are at a greater risk of perianesthetic hypoglycemia. They should receive dextrose-containing intravenous fluids during any prolonged anesthesia (longer than 15 min) and/or serial blood glucose measurements should be performed until fully recovered.

Patient Stabilization

When possible, life-threatening physiological disturbances should be corrected prior to anesthesia (Table 26.4). However, this may not always be possible, and anesthesia should never be delayed if immediate surgical or medical intervention is the only way to save the patient's life.

Venous Access

Advantages to inserting an intravenous catheter into a peripheral vein include the following: Tissue-toxic drugs such as thiopental can be administered without fear of perivascular administration, intravenous fluid administration is facilitated, and the circulation is immediately accessible for administration of emergency drugs. The most common site for catheter insertion in dogs and cats is the cephalic vein. The lateral and medial saphenous veins are also easily accessible and may be preferred if surgery is performed on the head or thoracic limbs. The jugular vein can also be used, especially if longer-term indwelling catheters are being placed. Typically, an over-the-needle style of catheter is most suitable for perianesthetic use. A 20-gauge, 2-inch catheter is

Table 26.3. Physical status classification of veterinary patients

ASA Status Level	Patient Description
I	Normal healthy patient
II	Non-incapacitating systemic disease (e.g., obesity, mild dehydration, and simple fractures)
III	Severe systemic disease not incapacitating (e.g., compensated renal insufficiency, stable congestive heart failure, controlled diabetes mellitus, or cesarean section)
IV	Severe systemic disease that is a constant threat to life (e.g., gastric dilation and volvulus)
V	Moribund, not expected to live 24 h irrespective of intervention (e.g., severe uncompensated systemic disturbance)

ASA, American Society of Anesthesiologists.

Procedures performed under emergency conditions are denoted by placing an *E* behind the physical status number.

Table 26.4. A list of conditions that should be corrected prior to anesthesia

- | |
|---|
| A. Severe dehydration |
| B. Anemia or hypoproteinemia
Packed cell volume < 20 with acute blood loss
Albumin < 2.0 g/dL |
| C. Acid-base and electrolyte disturbances
pH < 7.2
Potassium < 2.5–3.0 or > 6.0 |
| D. Pneumothorax |
| E. Cyanosis |
| F. Oliguria or anuria |
| G. Congestive heart failure |
| H. Severe, life-threatening cardiac arrhythmias |

suitable for most dogs and cats weighing more than 2 kg, and a 22-gauge, 1.25-inch catheter is suitable for those that are smaller. An 18-gauge catheter can be used in medium to large dogs if more rapid fluid administration is anticipated or needed.

Intravenous Fluids

The purpose of perianesthetic administration of intravenous fluids is to maintain vascular volume and adequate cardiac preload, which can be decreased as a result of increased vascular capacitance associated with anesthetic drugs, blood loss, and insensible fluid loss. In healthy patients without metabolic disease, a balanced electrolyte solution such as lactated Ringer's solution is most suitable for routine use since most fluid loss during anesthesia is isotonic. A patient's disease process may warrant the use of other fluids, such as normal saline, those containing dextrose, or a colloid solution, such as whole blood, packed red cells or other hemoglobin-based oxygen carrier, plasma, or a plasma

expander.⁸ The routine crystalloid administration rate for dogs and cats is $10 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$. This rate can be decreased to $5 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$ for the second and subsequent hours of anesthesia if the surgical procedure is associated with minimal blood loss. Preexisting cardiac disease (e.g., mitral valve insufficiency) may warrant reduced fluid administration rates so as to not cause potentially fatal pulmonary edema.

Several styles of fluid administration sets are available. An administration set with a 10-drop/mL calibration is most convenient for patients weighing more than 5 kg. For smaller patients, a calibrated 60-drop/mL drip chamber enables a more precise estimation of proper fluid rate. If very small volumes of fluid are given, or precise volume measurement is desired, a syringe pump may be used. It is convenient to calculate the number of drops per minute necessary to deliver the calculated hourly fluid amount. The following example uses a 10-drop/mL drip set in a 25-kg dog at a rate of $10 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$:

$$\begin{aligned} 25 \text{ kg} \cdot 10 \text{ mL/kg/h} &= 250 \text{ mL/h} \\ 250 \text{ mL/h} \cdot 10 \text{ drops/mL} &= 2500 \text{ drops/h} \\ 2500 \text{ drops/h} \div 60 \text{ min} &= 42 \text{ drops/min} \end{aligned}$$

A danger of perioperative fluid administration to very small animals is inadvertently administering too much fluid by improperly adjusting the drip rate. This can be particularly problematic in cats because they have a relatively small plasma volume relative to their size. A mechanical infusion pump or measured volume administration set will assist with delivery of the correct fluid amount.

The Anesthetic Plan

Several things should be considered when formulating an anesthetic plan (Table 26.5). In general, the anesthetic or chemical restraint technique rely primarily on local anesthesia, injectable anesthesia, or inhalation anesthesia. These techniques frequently overlap. For example, inhalation anesthesia is usually initiated with injectable anesthetics. Local anesthetic nerve blocks are typically accompanied by general anesthesia.

The remainder of the discussion regarding the choice of anesthetic drugs assumes the reader has reviewed and has a familiarity with the pharmacology of the various anesthetic drugs.^{9,10} Although the drug combinations described are suitable for a variety of patients, the reader should refer to the appropriate sections of this text or consult a veterinary anesthesiologist if questions remain about how to anesthetize and monitor specific patients.

Short-Term Anesthesia (Less than 15 Minutes)

Several drugs are available for short-term anesthesia or chemical restraint (Tables 26.6 to 26.9). Immobilization for a short duration not requiring strong analgesia (radiography, suture removal, otoscopic examination, etc.) can be performed most simply with intravenous injectable drugs such as thiopental, propofol, or the ketamine/diazepam combination. These drugs induce rapid and predictable short-term loss of consciousness. Thiopental is relatively inexpensive and is suitable for short-term restraint of most

healthy dogs and cats. A disadvantage to its use as a sole anesthetic is that relatively large doses are required, full recovery can take up to 1 h, and recovery can be associated with ataxia and disorientation. These undesirable characteristics are reduced when its administration is preceded by a tranquilizer such as acepromazine or a sedative such as medetomidine. Another disadvantage is that it must be administered intravenously, a problem with fractious or uncooperative animals. Perivascular thiopental administration is associated with local tissue inflammation, pain, and potential tissue necrosis. Perivascular administration should be attended to by infiltrating the area with a crystalloid fluid (e.g., 0.9% sodium chloride) volume equal to three to five times the volume of perivascularly administered thiopental. Additionally, a local anesthetic such as lidocaine and an anti-inflammatory (e.g., methylprednisolone) may be infiltrated near the site of perivascular injection. Another important side effect of thiopental is the significant respiratory depression that can accompany its use. Alternatives to thiopental include propofol, etomidate, and the combinations of diazepam and ketamine or tiletamine and zolazepam (Telazol). The duration of action following a 1-bolus dose of these drugs is generally less than 15 min. Because of its rapid plasma clearance, multiple boluses of propofol, or a propofol infusion, can be used to prolong the duration of restraint without significantly prolonging the duration of recovery.¹¹

Table 26.6. Sedatives and tranquilizers

Drug	Dosage (mg/kg) ^a	Comments
Acepromazine	0.025–0.2 IV, IM, SC (3–4 mg maximum)	Mild to moderate sedation of 1- to 2-h duration
Xylazine	0.3–2.2 IV, IM	Moderate to deep sedation, analgesia; 20 min to 1 h
Medetomidine	Dogs, 0.005–0.05 IV, IM Cats, 0.05–0.12 IV, IM	Similar effects to xylazine but 1- to 3-h duration
Diazepam	0.2–0.4 IV, IM	Most useful when combined with other sedatives, opioids, or ketamine Avoid IM in cats and small dogs
Midazolam	0.1–0.3 IV, IM, SC	Similar to diazepam but also useful IM or SC

IM, intramuscular; IV, intravenous; and SC, subcutaneous.

^aGenerally the low end of the dosage range is used IV and in sick or debilitated patients.

Table 26.7. Opioids and opioid combinations

Drug(s)	Dosage (mg/kg) ^a	Comments
Oxymorphone	0.05–0.1 IV, IM, SC	Excitement when used alone in young healthy dogs Duration of analgesia is 1–4 h
Morphine	0.2–0.6 IM, SC	Same as for oxymorphone
Hydromorphone	0.1–0.2 IV, IM, SC	Same as for oxymorphone
Butorphanol	0.2–0.4 IV, IM, SC	Opioid agonist/antagonist Minimal sedation when used alone Duration of analgesia is <1 h in dogs and up to 2–3 h in cats
Buprenorphine	0.005–0.01 IV, IM, SC, PO	Partial opioid agonist with approximately 6–8-h duration
Acepromazine-opioid	0.05–0.1 IV, IM Use dosage ranges for opioids listed above	Can be combined in same syringe Sedation lasts 15 min to 1 h
Midazolam-opioid	0.2–0.3 IV, IM Use dosage ranges for opioids listed above	Can be combined in same syringe Sedation lasts 15–40 min Generally produces poor results in young, healthy animals Not recommended for immobilization of vicious or difficult to handle animals Better quality restraint in older or debilitated animals
Xylazine-opioid	0.4–0.6 IV, IM Use dosage ranges for opioids listed above	Both drugs are reversible; sedation lasts 30–40 min Observe for bradycardia Useful for immobilization of difficult to handle or vicious animals
Medetomidine-opioid	Dogs, 0.001–0.002 IM Use dosage ranges for opioids listed above Cats, 0.004–0.006 IM Use lower end of dosage ranges for opioids listed above	Both drugs are reversible; sedation lasts 30 min to 1 h Observe for bradycardia Useful for immobilization of difficult to handle or vicious animals

IM, intramuscular; IV, intravenous; PO, oral; and SC, subcutaneous.

^aUse low end of opioid dosage in cats.

Table 26.8. Cyclohexylamines and cyclohexylamine combinations

Drug(s)	Dosage (mg/kg)	Comments
Ketamine	2.0–10.0 IV, IM	Not useful alone in dogs Useful restraint in cats lasts 5–30 min
Ketamine-diazepam and ketamine-midazolam	5.5/0.20 IV	Diazepam and midazolam are equally effective in this combination Useful restraint lasts 5–10 min Poor muscle relaxation
Ketamine-xylazine	10.0/0.7–1.0 IM	Useful restraint lasts 20–40 min
Ketamine-acepromazine	10.0/0.2 IM	Useful restraint lasts 20–30 min
Tiletamine-zolazepam (Telazol)	2.0–8.0 IV, IM	Limited shelf-life after reconstitution Useful restraint for 20 min to 1 h
Telazol-ketamine-xylazine ^a	Cats 0.022 mL/kg	Long recoveries
Medetomidine-ketamine- opioid	Cats 0.03–0.06/5.0 Use opioid dose listed in previous table Dogs 0.015–0.03/3.0 Use opioid dose listed in previous table	Good immobilization Medetomidine and opioid can be reversed Can be used without opioid for restraint alone

IM, intramuscular; and IV, intravenous.

^aReconstitute Telazol powder with 4 mL ketamine (100 mg/mL) and 1 mL xylazine (100 mg/mL).

Table 26.9. Injectable anesthetic drugs^a

Drug	Dosage (mg/kg)	Comments
Thiopental	8.0–20.0 IV	Use lower dosage after premedication
Methohexital	3.0–8.0 IV	Muscle rigidity Best if preceded by a tranquilizer or sedative Duration 3–5 min
Etomidate	0.5–2.0 IV	Duration 5–10 min Myoclonus, gagging/retching
Propofol	4.0–6.0 IV CRI, ^b 0.2–0.8 mg/kg/min	Duration 5–10 min after single-bolus dose Apnea for several minutes with rapid injection
Alphaxalone	1.0–15.0 IV, IM	Use lower dosages after premedication and for anesthetic induction and larger dosages for longer term immobilization

IM, intramuscular; and IV, intravenous.

^aInjectable combinations using ketamine are listed in Table 26.8.

^bConstant-rate infusion.

Dissociative-anesthetic combinations (ketamine-diazepam or tiletamine-zolazepam) produce less muscle relaxation than thiopental or propofol. They also are associated with increased salivation and dysphoria upon recovery. However, dissociative-anesthetic combinations generally produce less respiratory and cardiovascular depression than other available short-acting in-

jectable anesthetics. Muscle relaxation and recovery quality are improved and salivation lessened when dissociatives are given with or preceded by a tranquilizer or sedative.¹²

Sedative/opioid combinations are suitable for short-term restraint for minimally invasive procedures or those procedures not requiring general anesthesia. An advantage is that one or both of

Table 26.10. Antagonists of various classes of anesthetic drugs

Drug	Dosage (mg/kg)
Alpha ₂	
Yohimbine	0.1 IV, IM
Atipamezole	0.04–0.5 IM ^a
Benzodiazepine	
Flumazenil	0.01–0.2 IV ^b
Opioid	
Naloxone	0.002–0.02 IV, IM ^c

IM, intramuscular; and IV, intravenous.

^aDosage in milligrams is equal to five times the previously administered dosage of medetomidine.

^bBegin with lowest dosage and repeat, if necessary, to effect.

^cUse lowest dosage for “partial” reversal and highest dosage for complete reversal (refer to text for explanation).

these components can be reversed, enabling a rapid return to pre-anesthetic mentation and function (Table 26.10). Propofol or thiopental can be added to the regimen when complete immobilization or general anesthesia is necessary.

Alphaxalone is a neurosteroid anesthetic drug that produces hypnosis and muscle relaxation by enhancing GABA_A receptor ion conduction. Immobilization is characterized by excellent muscle relaxation and hypnosis in dogs and cats. It is solubilized in cyclodextran and thus does not induce histamine release as did the Cremaphor vehicle used in Saffan (alphaxalone and alphadolone). It can be administered intravenously or intramuscularly, and its duration of action is dose dependent. It is compatible for use following commonly used preanesthetic sedatives and tranquilizers.¹³

The relatively cumbersome nature of inhalation anesthesia makes it inconvenient for use in very short procedures. However, the rapid induction and recovery associated with isoflurane and sevoflurane make them suitable for short-term anesthesia, particularly in neonates or those animals with severe organ system compromise. Mask induction with inhalant anesthetics should be preceded by preanesthetic administration whenever possible to reduce the stress and anxiety (and catecholamine release) associated with the initial breathing of high concentrations of inhalant anesthetics.

Intermediate-Term Anesthesia (15 Minutes to 1 Hour)

For procedures of intermediate duration that do not require good analgesia, thiopental, ketamine/diazepam, and propofol can be used and redosed to effect. Typically, one-third to one-half of the induction dose is administered slowly to prolong the anesthetic effect. Thiopental and ketamine/diazepam should not be redosed many times. Their initial duration of action following bolus administration primarily depends on redistribution away from the

brain to other tissues, such as muscle. However, when these tissues are saturated with drug, redistribution greatly slows, and metabolism becomes the rate-limiting factor for awakening. Propofol, because of its relatively rapid clearance and large volume of distribution, can be administered repeatedly to dogs by using small boluses or by constant-rate infusion (Table 26.9).

Invasive surgical procedures such as feline onychectomy or canine and feline gonadectomy typically require 15 min to 1 h of anesthesia, accompanied by good perioperative analgesia. Several options are available (Table 26.8). A combination of Telazol, ketamine, and xylazine is suitable for cats, although its use has been associated with prolonged recoveries.¹⁴ An alternative is the combination of medetomidine, ketamine, and an opioid. Inclusion of an α_2 -adrenergic agonist in the combinations suggests that partial antagonism of the anesthetic and analgesic effects with atipamezole is possible, if required. Inhalation anesthesia is also appropriate for procedures of intermediate duration and may be the most convenient. Inhalant anesthetic delivery of this duration usually requires intubation and careful monitoring, but has the benefit of enabling a rapid adjustment of the depth of anesthesia should anesthetic conditions change unexpectedly (e.g., loss of blood or respiratory arrest).

Long-Term Anesthesia (Longer Than 1 Hour)

Long procedures are best managed with inhalation anesthesia. Awakening from sevoflurane and isoflurane anesthesia is predictably rapid. Even sick and debilitated patients recover from prolonged periods of inhalation anesthesia relatively quickly, and liver or renal impairment does not directly affect drug clearance. Injectable anesthesia using intramuscularly or intravenously administered drugs has been described.^{15–18} Those techniques that involve infusion of propofol and opioid combinations along with reversible tranquilizers or sedatives are most suitable for prolonged anesthesia because of propofol’s predictably rapid clearance. Those techniques involving nonreversible drugs are less suited for prolonged immobilization because of the attendant prolonged recovery. Most anesthetic techniques are associated with some degree of respiratory depression and a loss of the protective swallowing reflex, so tracheal intubation and a means to assist ventilation are essential to reducing anesthetic risk.

Premedication

Inhalation anesthesia can be initiated without premedication; however, administration of a sedative, tranquilizer, opioid, or combination of these drugs is recommended prior to induction (Tables 26.6 and 26.7). Preanesthetic drugs aid in restraint, reduce apprehension, decrease the quantity of potentially more dangerous drugs used to produce general anesthesia, facilitate induction, enhance perioperative analgesia, and reduce arrhythmogenic autonomic reflex activity. Premedications are usually administered intramuscularly or subcutaneously 15 to 20 min before induction. The choice of premedication depends on signalment, temperament, physical status, concurrent disease, the procedure to be performed, and personal preference (Table 26.11). For procedures associated with postoperative pain, premedication should include an

Table 26.11. Suggestions for premedication in dogs and cats^a

Dogs	Premedication
Young normal healthy	Acepromazine Xylazine Medetomidine Any of the above with an opioid agonist if moderate to severe perioperative pain is anticipated; any of the above with butorphanol or buprenorphine if less intense pain is anticipated or for moderate restraint
Aggressive/vicious	Acepromazine–opioid agonist Medetomidine–opioid agonist Xylazine–opioid agonist
Geriatric	Acepromazine (low end of dosage range) Midazolam–opioid
Painful procedures	Acepromazine–opioid agonist Midazolam–opioid agonist
Cats	Acepromazine–opioid (low dosage) Ketamine (low dosage) Ketamine (low dosage–acepromazine) Xylazine or medetomidine (young and healthy) Telazol (low dosage)

^aThese drugs or drug combinations should be administered between 15 and 30 min prior to anesthetic induction.

analgesic such as an opioid or α_2 -adrenergic agonist and possibly a nonsteroidal anti-inflammatory drug. Fewer analgesics are typically needed postoperatively when analgesics are administered preemptively.¹⁹ Repeated patient assessment following surgery is needed to assess the adequacy of analgesia, and additional analgesics should be administered when needed.

Induction

Induction is most easily accomplished in most animals with propofol, etomidate, dissociative anesthetic–benzodiazepine combinations, or thiopental (Table 26.9). Advantages to an intravenous method of induction include rapid loss of consciousness and ability to quickly intubate endotracheally. Alternatives to these rapid intravenous induction protocols include higher-dose intramuscular dissociative anesthetic–benzodiazepine administration, chamber or mask inhalant induction, or high-dose intravenous opioid induction. These techniques can be useful in special circumstances, but for routine use in healthy dogs and cats their disadvantages generally outweigh their advantages.

Chamber/Mask

One disadvantage to chamber and mask induction is the associated waste-gas pollution. Another is the struggling and associated stress during the induction phase.²⁰ Mask induction is most easily accomplished in moribund animals and small tractable dogs. Prior tranquilization or sedation enhances the quality and speed of induction.²¹ Isoflurane and sevoflurane are the most suitable inhalants because they produce a relatively rapid induction.²² Relatively high oxygen flow rates (4 L/min for chamber and 3 L/min for mask) and vaporizer settings (3% to 5% isoflurane and 5% to 7% sevoflurane in healthy animals) are used. The use of nitrous oxide is not necessary during chamber or mask induc-

tion.²³ With chamber induction, once the animal loses its righting reflex and is unresponsive to the chamber being tilted from side to side, the animal is removed from the chamber and induction is continued using an appropriately sized mask and the vaporizer setting used during the chamber phase. Mask induction (not preceded by a chamber) is begun by exposing the animal to the mask and oxygen. The inhalation concentration is slowly increased to 3% to 5% for isoflurane and 5% to 7% for sevoflurane. This is accomplished with a non-rebreathing or rebreathing circuit by gradually increasing the vaporizer setting over 2 to 4 min. Use of a non-rebreathing anesthetic system (e.g., the Bain coaxial system [see Chapter 17]) will facilitate a more rapid induction because the time-consuming exchange of the room air in the reservoir bag, breathing circuit, and carbon dioxide absorber of a circle system with anesthetic-laden gas from the vaporizer is not necessary.

Intravenous High-Dose Opioid Induction

A disadvantage to opioid induction is the attendant relatively slow loss of consciousness. Advantages include good cardiovascular stability (although severe bradycardia may be seen when anticholinergics are not coadministered) and the attenuation of the stress response associated with anesthesia and surgery. Opioid induction works best in debilitated dogs and is not recommended in cats or young healthy dogs that are not well sedated. Incremental doses of an opioid agonist (Table 26.7) are alternated with small incremental doses of diazepam or midazolam (Table 26.6) until the dog can be intubated.

Anesthetic Maintenance

The maintenance phase of anesthesia begins when unconsciousness is induced and ends with discontinuation of anesthetic deliv-

Table 26.12. Vaporizer settings^a

Drug	Induction Phase (%)	Maintenance Phase (%)
Halothane	3	1–2
Isoflurane	3	1.5–2.5
Sevoflurane	4–5	2–4

^aListed vaporizer settings assume a fresh-gas flow of 1 to 2 L/min during the induction phase (first several minutes following induction with injectable drug), and a fresh-gas flow of 10 mL/kg/min during the maintenance phase. Low-flow system vaporizer settings are typically 1 to 2% higher. Refer to text for discussion of mask or chamber induction.

ery. After the loss of consciousness, a properly sized cuffed endotracheal tube or alternative airway is usually inserted to enable assisted ventilation, if necessary, and protect against aspiration of oropharyngeal contents. Adequate cardiovascular function is rapidly verified and the anesthetic vaporizer turned on. The initial and subsequent anesthetic vaporizer settings (percentage concentration of inhalant) vary with the condition of the patient, the type of breathing circuit used, and the fresh-gas flow rate (Table 26.12). The relatively high fresh-gas flow rate and vaporizer setting that are initially used after induction are decreased to maintenance settings when the patient nears the desired anesthetic plane (usually when palpebral reflex disappears and the heart rate begins to decrease). The vaporizer setting is adjusted according to signs of anesthetic depth. The most useful signs of anesthetic depth in dogs and cats include a combination of muscle tone (assessed by opening the mouth its full extent), heart and respiratory rates, and systemic blood pressure. All but systemic blood pressure are easily and inexpensively monitored and should be performed routinely. Other monitors that may be used include a pulse oximeter and a capnometer. Pulse oximetry noninvasively provides an estimate of hemoglobin's oxygen saturation (normal $\geq 95\%$). This information along with packed cell volume or hemoglobin concentration indicates the oxygen content of arterial blood. A capnometer noninvasively assesses ventilation by monitoring respiratory rate and end-tidal expired (related to arterial) carbon dioxide partial pressure. End-tidal CO₂ monitors can also identify problems with the gas delivery system such as malfunctioning one-way valves and exhausted CO₂ absorbent, especially

when graphic display of the CO₂-time profile is provided (i.e., capnogram).

The Anesthetic Record

This is part of the permanent patient record and should include notation of patient status; the anesthetic drugs used, including time of administration; dose and effect; duration of the surgery; and notation of significant perioperative events. Ideally, heart rate, respiratory rate, blood pressure, and any other variables monitored should be recorded at regular intervals (5 to 10 min). Recording these data at regular intervals creates a visual aid that assists in determining the change in patient status during the anesthetic period. For example, a steadily increasing heart rate accompanied by a steadily decreasing blood pressure during a 15-min interval could signal hypotension caused by fluid loss or excessive anesthetic depth. This is easily observed on the anesthetic record but may not be noticed without the visual prompt of the data recorded over time.

Perioperative Analgesia

Concurrent administration of various analgesic drugs during inhalation anesthesia is useful to enhance intraoperative and postoperative analgesia. These drugs can be continued into the post-anesthetic period to maintain analgesia. Infusions of low doses of ketamine, lidocaine, opioids, and their combinations have been described as adjuncts to inhalation anesthesia (Table 26.13).^{24–26} When using these drugs, the concentration of inhalant anesthetic can often be significantly reduced. Increased respiratory depression is a concern, and the adequacy of ventilation should be closely monitored.

Recovery

Recovery begins when the procedure for which a patient has been anesthetized is finished, and the anesthetic drugs have been discontinued. Patient status should be monitored regularly during recovery until the patient is conscious, extubated, and heart rate, respiratory rate, and body temperature have returned to normal. Young healthy animals undergoing routine procedures usually do not need supplemental oxygen during recovery. However, contin-

Table 26.13. Drugs and drug combinations administered by constant-rate infusion to enhance intraoperative analgesia

Drug(s)	Infusion Rate	Comments
Ketamine	2–10 $\mu\text{g}/\text{kg}/\text{h}$	Useful as an adjunct to other perioperative analgesics
Fentanyl	1–5 $\mu\text{g}/\text{kg}/\text{h}$	Useful alone or with other perioperative analgesics; first administer loading dose of 2 $\mu\text{g}/\text{kg}$
Lidocaine	40 $\mu\text{g}/\text{kg}/\text{min}$	Useful as an adjunct to other perioperative analgesics; loading dose of 2 mg/kg
Morphine-lidocaine-ketamine	0.24/0.3/0.06 mg/kg/h ^a	Useful alone or with other perioperative analgesics

^aTo 1 L of crystalloid, add 24 mg morphine, 300 mg lidocaine, and 60 mg ketamine. Administer at 10 mL/kg/h intraoperatively. Concentration can be adjusted (increased) to fit postoperative maintenance fluid rates.

uous use of pulse oximetry is helpful to identify unexpected postanesthetic hypoxemia. Hypoxemia caused by respiratory depression, atelectasis-related ventilation/perfusion mismatch, and/or rapidly decreased fraction of inspired oxygen (e.g., near 100% oxygen to 21% room air) is easily addressed if detected early. If nitrous oxide was used during anesthetic maintenance, the breathing circuit should be repeatedly flushed with oxygen and the patient allowed to breathe an oxygen-enriched gas mixture for 5 to 10 min after discontinuation of nitrous oxide. This helps prevent the diffusion hypoxia that can develop if the inspired oxygen concentration suddenly decreases while nitrous oxide is rapidly moving from the blood into the alveolar gas. Sick or debilitated dogs and cats benefit from supplemental oxygen during recovery, particularly if hypothermic, because shivering can significantly increase oxygen consumption. The tracheal tube cuff should be deflated and untied when a patient is disconnected from the anesthetic machine. This permits extubation in the event that the patient rapidly awakens and begins chewing, but care should be exercised when moving the animal to the recovery area so premature accidental extubation does not occur. If an esophageal stethoscope or temperature probe was used, it should be removed at this time. Dogs and cats should be extubated as soon as the swallowing reflex occurs, unless there is a specific contraindication to removing the tracheal tube at this time (e.g., brachycephalic airway syndrome). Dogs and cats should never be left to recover unobserved. Recover patients in a well-ventilated area to minimize exhaled anesthetic gas pollution of the workspace.

Occasionally, a dog or cat will awaken suddenly from anesthesia, become disoriented, and will vocalize, paddle, and appear incoherent. This sudden arousal can be caused by emergence delirium or pain, and it is important to distinguish between them. Emergence delirium occurs most frequently in non-premedicated animals and in particular those awakening rapidly from anesthesia. With emergence delirium, the dog or cat will typically soon become quiet and more comfortable, usually within 10 min. A quiet, reassuring voice and restraint are all that are usually necessary to guide the animal through this period of excitement. If pain is believed to be the cause of the rough recovery, rapid-acting opioid analgesics (e.g., fentanyl) should be administered intravenously. Postoperative pain control is managed best with preanesthetic analgesic administration of relatively long-lasting analgesics, local anesthetics, and attention to signs of pain.

Dogs or cats receiving perioperative fluids can develop a fully distended or overdistended urinary bladder that can cause signs of discomfort. If a full bladder is palpated, it can be gently expressed before recovery. Occasionally, a low dose of acepromazine (0.03 to 0.05 mg/kg intravenously) is necessary to quiet an excited animal.

Perioperative Hypothermia

Because of the loss of normal thermoregulatory core-to-periphery temperature gradients and impaired central thermoregulatory responses, some decrease in core body temperature is unavoidable during anesthesia and surgery. The patient's tempera-

ture should be monitored, especially if supplemental heat sources are used (e.g., forced warm-air systems), because accidental hyperthermia is possible. It is more effective to prevent hypothermia rather than trying to warm a hypothermic patient during recovery, because skin vasoconstriction in response to hypothermia inhibits warming of blood near the body surface. Anesthetic-induced vasodilation facilitates warming and heat gain. Insulating and warming devices should be used during anesthesia and recovery.²⁷ Devices that are available for warming patients include circulating warm-water heating blankets, infrared heat lamps, incubators, and circulating warm-air blankets. Electric heating pads should never be used, because they have been associated with severe burns.²⁸ These burns usually are manifest from several days to 1 week after contact with the heating pad. The burn pattern often traces the pattern of the heating wire within the blanket. Care must be used with heat lamps or surgical gloves filled with warm water, because they also have produced thermal burns by being placed too close to unprotected skin. An advantage of using warm water and forced-air heating blankets is that temperature is uniform over their entire surface, and their maximum temperature is well below 105°F, the maximum safe patient heating-source interface.²⁹ Warming will be hastened if the patient's limbs are cocooned within the warming device. Incubators are convenient for warming small dogs and cats, and, if needed, supplemental oxygen can also be introduced through the incubator during the warming period. A circulating warm-air blanket that cocoons the patient is the most effective device for maintaining body temperature and perioperative warming.^{29,30}

Delayed Anesthetic Recovery

Occasionally, a dog or cat that received several drugs during the anesthetic episode will remain mildly hypothermic and unresponsive. In these instances, consideration should be given to antagonism of reversible drugs (α_2 -adrenergic agonists or opioids) that were given as part of the anesthetic regimen. Relatively small intravenous boluses of naloxone (2 to 3 μ g/kg) can be used to reverse the central nervous system and thermoregulatory depression associated with the opioids while leaving opioid analgesia mostly intact.

Severe hypoglycemia is an easily corrected problem that can result in delayed anesthetic recovery. Blood glucose concentration should be measured if hypoglycemia is suspected, and intravenous dextrose-containing fluids given until blood glucose concentrations normalize. Arterial hypotension associated with blood loss or poor cardiac function cause altered mentation and slow recovery. Periodic measurement of arterial blood pressure during recovery, especially in debilitated patients, is warranted. Hypercarbia (PaCO₂ approaching 100 mm Hg) associated with respiratory-depressant anesthetic and adjunctive drugs may cause severe mental impairment and possibly respiratory arrest. Use of capnometry or arterial blood-gas analysis during the anesthetic and recovery period helps facilitate early detection and correction of respiratory depression. Occasionally, animals with undiagnosed, compensated central nervous system disease (e.g., hy-

drocephalus) may decompensate under anesthesia, resulting in impaired brain function. Prevention of hypercarbia, hypoxemia, and hypotension and rapid implementation of resuscitative measures (e.g., mannitol and controlled ventilation) may limit brain injury and speed recovery. Many problems that lead to delayed recovery from anesthesia can be prevented or otherwise managed with appropriate patient monitoring during and after anesthetic drug delivery.

Recovery

Introduction

Anesthesia in adult horses is complicated by a relatively unique set of problems associated with their temperament, large body mass, and thoracoabdominal anatomy. Thus, although an understanding of the pharmacology of the drugs used is essential for safe anesthetic practice, the knowledge base must not stop there. Prolonged recumbency is an unnatural position for horses. This, coupled with horses' seeming desire to escape unfamiliar situations by running, makes induction and recovery from anesthesia difficult. Particularly challenging are those situations when an injured or painful horse must be anesthetized.^{1,2} In addition, the potential for inadequate muscle blood flow and deleterious changes in cardiopulmonary function associated with lateral and dorsal recumbency must be understood. A number of studies have been published examining perioperative morbidity and mortality in horses.³⁻⁶ The reported mortality rates associated with elective equine anesthesia range from 0.1% to 1.0%, with higher incidences reported for emergency and out-of-hours procedures.³ The largest study performed to date indicates that there are statistically significant differences in the incidence of mortality dependent on the person performing the anesthesia and the person performing the surgery.³ Other factors cited include age (high risk in the very young and low risk for young adults, with increasing risk with age), duration of surgery (higher risk for longer surgery), type of surgery (fractures at higher risk), timing of surgery (outside of "normal hours" at greater risk), the drugs used for sedation prior to anesthesia (greatest risk when no drugs are used; reduced risk for acepromazine and greater risk for

romifidine administration), and the use of inhalant anesthetics (increased risk with inhalant anesthetic induction, and increased risk of inhalant anesthesia when compared with total intravenous anesthesia).³ The studies reported to date have not examined the effect of monitoring techniques (arterial blood pressure and arterial blood gases) or the other anesthetic adjuncts that could be used (e.g., controlled ventilation or use of vasopressors). These techniques and adjuncts may play a major role in the safety of any anesthetic; thus, any discussion that does not take them into account is incomplete. This chapter focuses on practical aspects of handling horses and the use of specific drugs, alone and in combination.

Physical Restraint

Prior to the development of appropriate sedatives, tranquilizers, and other anesthetics, physical restraint was a primary method by which practitioners accomplished the treatment and the completion of some surgical and diagnostic techniques. With the advent of useful anesthetics, the reliance on physical restraint has diminished, but the techniques remain an integral part of safe equine practice. Physical restraint may be as innocuous as taking hold of a horse's halter or picking up a patient's leg to limit movement. In most situations, some level of physical restraint is combined with appropriate drugs to induce a tractable patient. The method of physical restraint should be based on (a) the age, size, and temperament of the horse; (b) its physical status; (c) the number and training of available personnel; and (d) the duration and nature of the procedure.

Methods of Drug Delivery

Anesthetics are administered to horses by topical, oral, subcutaneous, intramuscular, epidural, intravenous, and inhalant routes. The effective application of anesthetics topically is probably limited to the eye and mucous membranes. Oral formulations for tranquilization can be drenched or mixed with feed but are somewhat unpredictable because the potential for limited consumption and absorption makes it difficult to predict the timing and magnitude of the effects produced. Intramuscular injection is more effective than subcutaneous injection. Sedatives and tranquilizers are often administered intramuscularly because of ease of administration, longer action, and a decrease in the intensity of deleterious side effects when compared with intravenous administration. Disadvantages of intramuscular administration of drugs

include delayed onset of action, decreased intensity of effect, and (because a larger quantity of drug is required) increased cost. Epidural or spinal injection of drugs can be used for analgesia. Drugs used by the epidural route include the local anesthetics, α_2 -adrenergic agonists, and opioid receptor agonists. The intravenous route is preferred by most veterinary practitioners. Sedatives, tranquilizers, and injectable anesthetics (barbiturates and ketamine) can be administered intravenously. Intravenous injection induces rapid onset of action, higher peak intensity of effect, briefer action, and a greater ability to titrate the desired effect by repeated administration. Inhalation anesthesia (e.g., halothane, isoflurane, or sevoflurane) requires the constant administration of drug that is delivered in oxygen.

Equipment

The equipment required for the delivery of anesthetic to equine patients varies from a syringe and needle to expensive inhalation anesthetic systems equipped with ventilators. Most equine anesthesia is performed as short-term anesthesia in the field. In this setting, the ability to supplement the inspired oxygen concentration of patients is usually limited. In the absence of the ability to supplement inspired oxygen, time of recumbency should be limited to 1 h. Oxygen supplementation benefits all anesthetized patients. Methods of supplementing oxygen in the field include the use of insufflation and the use of a demand valve. Insufflation is performed by inserting a tube into the horse's nose. Oxygen can be supplied in a small tank equipped with a pressure-reducing valve and flowmeter. Flow should be set at a minimum of 15 L/min in order to be effective.⁷ A size-E oxygen cylinder contains approximately 650 L of oxygen when full, so it can supply 40 to 45 min of oxygen at 15 L/min flow. If apnea occurs, the flow rate can be increased and a breath can be delivered by occluding the nostrils until the thoracic wall rises appropriately, and then releasing the nostrils to allow exhalation. Alternatively, a demand valve (Fig. 27.1) can be used. A demand valve delivers oxygen by one of two mechanisms. When the horse inhales, the demand valve is triggered and delivers oxygen at high flow rates. The increased airway pressure generated by exhalation shuts the demand valve off. In the absence of ventilation, the demand valve can be triggered by the operator by pushing a button. The button is released upon appropriate chest expansion, the flow stops, and the patient exhales. A demand valve can be used with a tube that is inserted in the nostril and advanced in the airway (if the nostrils are occluded) but is best used in combination with an appropriately placed endotracheal tube.

Oxygenation should be maximized if extended anesthesia is contemplated. The best way to provide optimal oxygenation is to use an anesthetic machine in combination with an endotracheal tube that allows the airway to be sealed. Anesthetic machines for adult horses provide for the delivery of high oxygen concentrations (greater than 95%) whether or not inhalation anesthetics are being used. Oxygen flow rates to maintain high inspired-oxygen concentrations depend on a horse's metabolic rate but are in the range of 2 to 5 L/min in adult horses.

Endotracheal tubes are helpful both in the field and in more so-

Fig. 27.1. A demand valve coupled with an oxygen source such as a size-E tank can be used for resuscitation in case of respiratory or cardiovascular collapse. The demand valve is connected to a 12- to 14-mm (internal diameter) endotracheal tube placed via the nostril into the pharynx. One hand is used to activate the demand valve while the other is used to occlude the airway by squeezing the area just caudal to the nostrils. End inflation by releasing the trigger mechanism at the point when a normal thoracic excursion has been completed. Repeat this maneuver four to six times a minute until spontaneous respiration resumes.

phisticated settings where inhalation anesthetics are employed. To be effective, endotracheal tubes should seal the airway. This is usually done by inflating a cuff. Endotracheal tubes are usually placed orally. The use of a bite block, easily made with 2-inch polyvinyl chloride pipe, will extend the life of the tube. Endotracheal tubes can also be placed via the ventral meatus of the nasal cavity. This route is particularly useful for intraoral surgery. Smaller endotracheal tubes should be used. Prior to anesthesia, the halter should be checked to ensure that it is appropriately applied and sufficiently strong to withstand the forces generated during induction and recovery.

Safe anesthesia in horses depends on maintaining relatively light levels of anesthesia, which is sometimes difficult to assess. Should the horse move, maintaining control is important until additional anesthetic can be administered. The use of a chest rope (Fig. 27.2) and casting harness or hobble system enables control of movement. A hobble system is easily devised by using a 35- to 40-foot length of 1-inch cotton rope. Soft, larger-diameter rope is preferred because the chance of a rope burn is minimized.

Some anesthetic techniques require only drugs, needles, syringes, and the ability to make a venipuncture. The placement of an intravenous catheter increases the safety of anesthesia by assuring venous access, ensuring (with proper placement) that medications are given intravenously, and reducing the number of venipunctures to one. Anesthetic agents, particularly the thiobarbiturates and to a lesser extent guaifenesin, are irritating and can cause tissue destruction when administered extravascularly. The relative guarantee of venous access is important when administering anesthetic agents, because of the dilemmas faced when an

Fig. 27.2. A horse placed in right lateral recumbency for surgery. All ventral surfaces are padded with foam rubber. The front and rear legs are separated with pads in an attempt to reduce venous compression. A chest rope is used to position the front legs. The position reduces the “lever arm” effect of the front legs and reduces pressure on the weight supporting the shoulder. The chest rope should not be overtightened because respiration could be impeded.

anesthetic agent is administered to no apparent effect. The lack of effect could be caused by perivascular injection of the drug, administration of an inadequate dose, or an idiosyncratic reaction of the patient. The presence of a properly placed catheter ensures that the drug was administered intravascularly and enables administration of additional drug if required. Useful catheter sizes for horses are 10 to 14 gauge for adult horses and 14 to 20 gauge for foals. The jugular vein is the usual site for catheterization. In the absence of patent jugular veins, the median, cephalic, lateral thoracic, or saphenous veins can be used. In those settings where inhalation anesthesia of horses for longer than 1 h is routine and frequent, additional equipment is required. The maintenance of adequate arterial blood pressure in horses has been shown to correlate with a reduced number of postanesthetic complications.⁸ Arterial blood pressure can be measured inexpensively using an aneroid manometer following aseptic placement of a catheter (18 to 22 gauge) in a peripheral artery. Aneroid manometers enable the estimation of mean arterial blood pressure.⁹ At more expense, some monitors with blood pressure transducers enable measurement of systolic, mean, and diastolic blood pressures and may automatically display these values digitally. The maintenance of a mean arterial blood pressure greater than 60 to 70 mm Hg is associated with a reduction in postoperative complications, so the use of such devices and the correction of hypotension when it occurs are necessary, particularly in horses anesthetized for 45 min or longer.^{6,10} Appropriate padding helps to prevent pressure injury to muscle tissues. Commercially available foam-rubber pads, air mattresses, and water mattresses can be used for this purpose.

Preparation of Patients

A physical examination should be performed prior to the administration of any anesthetic drug. If a horse is only to be tranquil-

ized, a brief physical examination should emphasize the cardiovascular and respiratory systems. If recumbency is to be induced, a more complete physical examination should be performed. A thorough evaluation of the respiratory system is warranted. Physical signs of respiratory disease include cough, discharge at the nostrils or eyes, submandibular lymph node enlargement, fever, and increases in respiratory rate. Auscultation should be performed over both sides of the thorax. Occlusion of the nostrils or the use of a plastic rebreathing bag to stimulate deep breathing enables a better evaluation of breath sounds. Palpation of the trachea and larynx may elicit a cough. Incipient respiratory disease can be further evaluated by performing a white blood cell count, and counts in excess of 12,000 to 14,000 cells/mL are cause for further evaluation. Serum fibrinogen levels can also be used as an index of systemic inflammation. Horses with respiratory infections should be allowed 3 weeks to recover prior to elective procedures. Many horses present with subclinical respiratory disease. General anesthesia has been associated with depression of immune function. A horse with subclinical respiratory disease could develop overt disease following anesthesia.

Respiratory stridor is another cause for concern. Most anesthetics cause relaxation of the muscles of the upper airway, particularly the nostrils.¹¹ Relaxation of these muscles may allow the nostrils to sag inward on inhalation, partially occluding the airway. A tracheostomy should be performed prior to the induction of anesthesia if there is severe upper-airway obstruction or if the nasal cavity will be occluded as part of the surgery. For example, surgical techniques for removal of the nasal septum and ethmoid hematomas require the placement of an absorbent pack in the nasal cavity in order to effect hemostasis. A tracheostomy is required because horses are obligate nasal breathers.

The cardiovascular system is evaluated clinically by auscultating for heart sounds, palpating peripheral pulses, evaluating the color of mucous membranes, and assessing capillary refill time and skin turgor. Physical signs of cardiovascular abnormalities may include exercise intolerance, distension of the jugular veins with and without jugular pulses, and pallor. Cardiac auscultation must be performed in a quiet environment. Heart rate should be determined, and the presence or absence of pauses noted. Pauses should disappear if the horse is exercised briefly. Occasional pauses can be evaluated further with an electrocardiogram. Common physiological rhythm variations in horses include first-degree heart block, second-degree heart block, sinus arrest or sinoatrial block, and variably configured P waves. The most common arrhythmia of clinical significance in horses is atrial flutter or fibrillation. A presumptive diagnosis of atrial flutter can be made by auscultating heart sounds of various intensities that occur at irregular rates. The palpation of pulses of varying strengths occurring at irregular intervals provides more evidence. A diagnosis of atrial fibrillation can be confirmed with an electrocardiogram. Atrial and ventricular premature contractions are occasionally observed in horses prior to surgery. Atrial premature contractions seem to have little significance. Premature ventricular contractions, particularly if they occur at a rate faster than three per minute, should be evaluated further. Cardiac murmurs can be ausculted in a relatively high percentage of adult horses.¹²

Most soft systolic murmurs (grade III out of VI or less) are interpreted as innocent flow murmurs in the absence of other signs of cardiac disease. Potential sources of significant murmurs in horses include ventricular septal defects, mitral valve insufficiency, and aortic insufficiency.

Neuromuscular function, in particular the presence or absence of ataxia, should be evaluated to anticipate possible problems with recovery from anesthesia. Other pertinent factors would include a history of “tying up” (rhabdomyolysis) or hyperkalemic periodic paralysis.

Following a complete physical examination of the animal and documentation of its medical history, ancillary tests and procedures should be performed as indicated by the physical status and history. The determination of packed cell volume and plasma total protein is easy and inexpensive, and it provides baseline information about the oxygen-carrying capacity and hydration status of the patient.

Some surgical procedures, such as ovariectomy, are facilitated if food is withheld for 24 to 48 h prior to anesthesia. A prolonged fast does not seem to be necessary for other procedures. Gastric emptying occurs rapidly in horses; thus, a 4- to 6-h period of withholding food should be adequate. Access to water should be maintained. It has been suggested that horses anesthetized at higher altitudes benefit from a longer period without food because of their propensity for gas distension. The shoes should be removed or at least covered to decrease the chance that the horse will lacerate itself on recovery. Before induction, the horse’s mouth should be rinsed to remove foreign material.

Standing Chemical Restraint

A wide variety of agents have been used to produce chemical restraint in standing horses (Table 27.1). Current practice has evolved to the point where three groups of agents are commonly used: phenothiazines, α_2 -adrenergic agonists, and opioid receptor agonists. Butyrophenone tranquilizers were reported to be effective in horses, but more recent reports suggest significant undesirable adverse effects that prevent their recommendation.^{13,14} Diazepam is used as a muscle relaxant in horses, but the level of

sedation produced is not profound enough to be useful for restraint.¹⁵ Chloral hydrate is a sedative-hypnotic that was widely used for sedation and anesthesia prior to the availability of inhalation anesthetics. The best use of chloral hydrate was for augmentation of the effects of other sedatives and tranquilizers in particularly obstreperous horses. Chloral hydrate is given intravenously and produces severe tissue necrosis if given perivascularly. Chloral hydrate is not currently available in pharmaceutical preparations suitable for horses.

Phenothiazine Tranquilizers

These produce calming and a relaxed state from which horses can be aroused. Phenothiazine tranquilizers can be administered orally, intramuscularly, and intravenously to horses. The two drugs that are in common use are promazine and acepromazine. Phenothiazines produce tranquilization by blocking the action of neurotransmitters both centrally and peripherally. As in other species, hypotension caused by α_1 -adrenergic blockade can be produced. Hypotension is of particular concern in nervous or excitable horses or in horses that have sustained blood loss or are dehydrated. The respiratory effects of phenothiazines are minimal and are generally limited to decreases in respiratory rate. Persistent penile paralysis can occur after phenothiazine administration to horses. The mechanism of the effect is unknown. Penile paralysis is uncommon but remains a consideration. Treatment should include support of the penis to prevent or reduce swelling. Benztrapine mesylate may be effective in resolving penile paralysis:¹⁶ 8 mg of benztrapine was administered to two adult horses, and paralysis resolved within 10 min.¹⁶ Benztrapine is used in the treatment of Parkinson’s disease and is believed to have central anticholinergic effects.

Acepromazine is available as a 1% solution (10 mg/mL) for parenteral injection. The onset of effect of acepromazine occurs within 15 to 30 min of administration. The duration of tranquilization following administration depends on the dose but may persist for 6 to 10 h. Acepromazine produces calming, with minimal muscle relaxation or ataxia. Acepromazine does not produce analgesia but may potentiate other drugs such as the opioids that are analgesics. Acepromazine will not transform an aggressive

Table 27.1. Drugs used for standing chemical restraint, for analgesia, and as preanesthetics

Drug	Dose and Route	Onset of Effect	Comments
Acepromazine	0.02–0.05 mg/kg IM, IV	30–40 min IV, IM	Use cautiously in stressed or hypotensive horses
Xylazine	0.5–1.0 mg/kg IV	3–5 min IV	Ataxia produced, head-down posture
	1.0–2.2 mg/kg IM	10–20 min IM	Start with a low dose and repeat as needed
Detomidine	0.01–0.02 mg/kg IV	3–5 min IV	Ataxia produced, head-down posture
	0.02–0.04 mg/kg IM	10–20 min IM	Start with a low dose and repeat as needed
			Can be given orally
Butorphanol	0.01–0.03 mg/kg IV	3–5 min	Usually used in combination with a sedative or tranquilizer
Morphine	0.3–0.5 mg/kg IV	3–5 min	Sedate with xylazine or detomidine prior to administering morphine
			Potential for excitement.
			Reversible with naloxone

IM, intramuscularly; IV, intravenously; and PO, per os (orally).

horse into a docile one but will reduce the animal's awareness and response to external stimuli. Increasing the dose does not ensure a more pronounced effect, because approximately 30% to 40% of horses administered acepromazine do not attain the desired effect. Acepromazine is used as an aid to training, to produce standing restraint, and prior to transportation because it is long acting, inexpensive, and does not produce severe ataxia. The most reliable indication that a horse has been sedated with acepromazine is extrusion of the penis from the sheath.¹⁷ Other signs include some drooping of the eyelids and slight protrusion of the third eyelid. Contraindications to the use of acepromazine would include the previously mentioned blood-loss or shocklike state, because of the α_1 -adrenergic antagonist effects of acepromazine. The resulting hypotension is particularly prone to occur after intravenous administration of acepromazine and can cause syncope and recumbency. Treatment includes the intravenous administration of large volumes of polyionic fluids. Known bleeding disorders are another contraindication to acepromazine, because phenothiazines can inhibit platelet function.

α_2 -Adrenoceptor Agonists

These drugs produce sedation, analgesia, and muscle relaxation when administered intravenously or intramuscularly to horses. The three α_2 -adrenoceptor agonists currently available for equine use in the United States are xylazine, detomidine, and romifidine, with medetomidine used in other countries.¹⁸ The effects of the drugs are similar, but detomidine is approximately 80 to 100 times more potent than xylazine and its action lasts twice as long. Romifidine has a duration of action similar to detomidine, and its sedative effects are less profound than those of either xylazine or detomidine. α_2 -Adrenergic agonists are used for the temporary relief of colic pain, as adjuncts to general anesthesia, and alone and in combination with other drugs for standing chemical restraint. Xylazine and detomidine have also been administered epidurally to produce regional analgesia.^{19,20} α_2 -Adrenergic agonists reach peak effect in 3 to 5 min after intravenous administration and within 10 to 15 min of intramuscular administration. Oral administration is usually saved for occasions when a horse is not amenable to injections because of inconsistent effects. Oral (sublingual) administration of detomidine has been shown to produce profound sedation 45 min after administration.²¹

Sedation with α_2 -adrenergic agonists is characterized by profound depression, with the horse assuming a head-down posture. The horse may attempt to head press. The eyelids and lips droop, and the horse may sway because of the muscle relaxation and ataxia produced. The muscles of the nostrils relax, which may lead to snoring or potentially obstruction in predisposed horses. Normal horses rarely become recumbent following α_2 -adrenergic agonist administration, but they may be difficult to move because of ataxia and muscle relaxation. α_2 -Adrenergic agonists may have more pronounced effects in foals, so the dose should be reduced. As in other species, the administration of α_2 -adrenergic agonists is characterized by decreases in cardiac output, primarily caused by increases in vascular resistance and decreases in heart rate. α_2 -Adrenergic agonists may induce or exacerbate first-degree and second-degree atrioventricular blockade.

Respiration is depressed, but the effect is usually not apparent unless other drugs are coadministered or anesthesia is induced. The frequency and volume of urination are increased after administration of α_2 -adrenergic agonists. In adult horses, serum glucose levels increase and serum insulin levels decrease.²² The effects of α_2 -adrenergic agonists can be antagonized by the administration of yohimbine, atipamezole, or tolazoline.²³

α_2 -Adrenergic agonists are frequently used in horses with abdominal pain to facilitate evaluation and for pain relief. By repeated evaluation and general consensus, α_2 -adrenergic agonists are the most effective available drugs for the treatment of colic pain.^{24,25} The use of α_2 -adrenergic agonists is controversial, however, because in addition to relieving colic pain, they cause decreases in intestinal propulsive activity. Thus, although the pain is controlled, the resolution of the cause of the abdominal pain may be slowed. The duration of the reduction in propulsive activity approximates the duration of sedation. A rational approach is to administer small doses of α_2 -adrenergic agonists intravenously and frequently reevaluate the patient, and then readminister the drug as necessary. Xylazine may be more useful in this setting than detomidine because xylazine has a briefer action, prompting more frequent reevaluation.

Opioid Receptor Agonists

Opioids have been used to produce analgesia and augment chemical restraint in horses. Because of their ability to cause nervousness and excitability, opioids are most frequently used in combination with sedatives or tranquilizers to produce standing chemical restraint. Butorphanol, a synthetic opioid agonist-antagonist, is approved for treatment of abdominal pain in horses. Butorphanol is less apt to cause excitement than are opioid agonists but can cause nervousness and ataxia at higher doses. Both the analgesia and nervousness produced by opioid agonists and agonists-antagonists can be reversed by naloxone, an opioid antagonist. Caution should be used, however, because the duration of effect of some opioid agonists, such as morphine, may be longer than that of the antagonist. This could lead to renarcotization (resumed excitement) 4 to 6 h after narcotic administration. Such excitement responds to the administration of additional antagonist or a tranquilizer. The clinical use of opioids is discussed in the Standing Chemical Restraint section. A myriad of potential combinations can be used to produce standing chemical restraint, but most combine a sedative-tranquilizer with an opioid.

Acepromazine and Xylazine Combination

This combination has been used to improve tranquilization with some reduction in deleterious side effects.²⁶ Reduced doses of both drugs are used, typically 0.02 to 0.03 mg/kg of acepromazine and 0.2 to 0.5 mg/kg of xylazine. The drugs can be combined in the same syringe and are usually given intravenously. The reduced dose of xylazine produces less ataxia and less of a head-down posture than would be seen with xylazine alone (given in a higher dose). Thus, the horse stands more squarely on all four feet. The combination produces faster onset and longer action than either agent given alone. The suppliers of xylazine caution against its coadministration with tranquilizers.

Sedative/Tranquilizer-Opioid Combinations

The combination of xylazine and butorphanol has been investigated.²⁷ When combined, the dose of xylazine is usually reduced because butorphanol provides some analgesia with few deleterious cardiovascular side effects. Because of the reduced dose of xylazine, the horse is usually less ataxic. Occasionally, horses twitch and jerk their heads after being given this combination. Head pressing may occur. The drugs can be given in combination in the same syringe. The analgesia produced is not sufficient to perform a skin incision, so local anesthetic blockade may be needed. Butorphanol has also been used in combination with detomidine.²⁸

The combination of α_2 -adrenergic agonists and morphine has been used to produce standing chemical restraint for surgery.^{29,30} Morphine should not be given until a horse is fully sedate, because of the potential for excitement. Within 5 min of morphine administration, the horse assumes a head-down, sawhorse position. The placement of a nose twitch and elevation of the head may be helpful in stabilizing patients on all four feet. Although analgesia is produced, horses remain sensitive to touch, so the technique is usually combined with local blockade. Both drugs are potentially reversible using an α_2 -adrenergic antagonist (e.g., yohimbine or tolazoline) and an opioid receptor antagonist (e.g., naloxone). As mentioned, occasionally, renarcotization (excitement or nervousness) occurs following administration of the combination, owing to the long half-life of morphine in horses. The excitement can be abated by administration of a narcotic antagonist or simply by tranquilizing the patient.

Analgesia

The recognition and management of pain has long been a part of equine practice. The goals of pain management cover a wide range from simply reducing the inflammation and discomfort of mild arthritis to the ordeal of exerting control over a violent, thrashing mare with a distended abdomen. Traditional approaches to providing analgesia include the administration of nonsteroidal anti-inflammatory drugs (NSAIDs), local anesthetics, and many of the drugs used for standing chemical restraint (α_2 -adrenergic agonists and opioids). Other drugs, not classically considered analgesics, such as steroids, orgotein, methocarbamol, and polysulfated glycosaminoglycans, are used because they are anti-inflammatory and, as such, may increase the comfort of individuals. In addition, acupuncture has been reported to relieve back pain in exercising horses and to reduce the anesthetic requirement for other drugs.^{31,32}

Pain is infrequently mentioned as a presenting complaint by horse owners. Most gait abnormalities occur when an animal alters its locomotion in order to reduce pain. The pain is localized by progressively and selectively desensitizing regions and structures until the gait abnormality is altered or resolved. Once localized, the source of the pain is investigated with imaging modalities and is modified or, if possible, removed. Alternatives to removal include the administration of systemic analgesics or sensory denervation. Colic represents another presenting pain sign. Frequently, the response to analgesic administration aids in the

determination of the severity of the disease. Mild episodes of colic are initially treated with NSAIDs. If the analgesia produced by NSAIDs is insufficient, short-acting α_2 -adrenergic agonists are used to provide analgesia and facilitate further diagnostic procedures. The response to α_2 -adrenergic agonist administration and the information gleaned from diagnostic procedures are used to determine the severity of the disease and whether an abdominal exploratory surgery is required. The use of α_2 -adrenergic agonists and opioids in colic treatment is limited by their effects on gastrointestinal motility. The reductions in motility and increases in sphincter tone may slow the resolution of hypomotile states and contribute to postoperative ileus. Other drugs (lidocaine and ketamine) and therapeutic modalities (acupuncture) are being investigated to determine their utility in producing analgesia for colic pain with fewer overall side effects.

A number of NSAIDs have been approved for use in horses (Table 27.2).³³ Phenylbutazone administered orally and intravenously is widely used for the treatment of inflammation and pain associated with acute and chronic musculoskeletal injuries and conditions. Phenylbutazone administration enables some unsound horses to live apparently comfortable lives and may permit performance in horses that cannot otherwise compete. For this reason, phenylbutazone administration in many racing jurisdictions is limited to a maximum allowable plasma concentration. Phenylbutazone and other NSAIDs are also used to provide perioperative analgesia for orthopedic and other surgery. Ketoprofen, flunixin meglumine, naproxen, meclofenamic acid, and diclofenac are additional NSAIDs approved for use in horses in the United States. These other drugs are primarily used as alternatives to phenylbutazone for selected indications. Flunixin meglumine is also used for relief of the pain associated with colic. Diclofenac is approved for topical administration as a liposome-based topical cream. It is approved for control of pain and inflammation associated with osteoarthritis of the tarsal, carpal, and distal joints. Renal failure, gastrointestinal ulceration, diarrhea, hypoproteinemia, and anemia are reported side effects of NSAID administration.^{34,35} The incidence of side effects is dose dependent and is greatest in foals, in hypovolemic animals, and when the drugs are administered for extended periods. Anecdotal evidence suggests that some NSAIDs are more effective when given in combination, but the relevant scientific literature is limited.³⁶ A number of NSAIDs with increased selectivity for the inhibition of inducible prostaglandin synthesis have been developed for other species. The development and use of similar compounds for horses is minimal and will probably be limited by cost.

The use of local and regional analgesic techniques in horses is increasing. Local anesthetic agents are frequently used in equine dentistry, in the diagnosis of lameness, and to desensitize areas for standing surgery. Local anesthetics are also increasingly being used in combination with general anesthesia to reduce central sensitization, reducing the requirements for postoperative analgesia. The epidural or spinal administration of local anesthetics desensitizes the perineum for surgery or obstetric manipulations. The epidural administration of α_2 -adrenergic agonists and opioids, alone and in combination with local anesthetics, pro-

Table 27.2. Nonsteroidal anti-inflammatory drugs used for analgesia

Drug	Dose and Route	Dosing Interval	Comments
Phenylbutazone	2.2–4.4 mg/kg IV, PO	8–12 h	Very irritating given perivascularly
Flunixin meglumine	1.1 mg/kg IV, PO, IM	12–24 h	Infrequently used IM because of local reactions
Ketoprofen	2.2 mg/kg IV	12–24 h	Once daily for 5 days
Meclofenamic acid	2.20 mg/kg PO	24 h	Approved but not marketed for horses
Naproxen	10 mg/kg PO	24 h	Approved but not marketed for horses
Carprofen	0.7 mg/kg IM	24 h	Less than 25% of the dog dose

IM, intramuscularly; IV, intravenously; and PO, per os (orally).

vides analgesia for the perineum and hindquarters of increased duration with less muscle relaxation and ataxia.³⁷ Detomidine has been used to produce analgesia as far rostral as the 14th thoracic dermatome without producing recumbency, indicating selectivity for inhibiting pain over motor fibers.²⁰ The placement of a catheter in the epidural space allows for repeat administration, extending repeated administration for as long as 14 days.³⁸

Intravenous Anesthesia

A number of injectable drug combinations have been used to produce anesthesia in horses (Table 27.3).³⁹ The most commonly used agents include the thiobarbiturates, ketamine, and guaifenesin or diazepam in combination. It is paramount that horses be calmed prior to the induction of anesthesia. The administration of appropriate doses of preanesthetic agents, primarily phenothiazines and α_2 -adrenergic agonists, not only produces calm, sedate patients, but allows for a reduced dose of anesthetic. The maxim to “never anesthetize an excited horse” should serve as a warning. Intravenous anesthesia is commonly used because of the ambulatory nature of equine practice.

Although all anesthetized horses benefit from oxygen supplementation, intravenous anesthesia can usually be safely produced in healthy horses for periods up to 1 h without oxygen supplementation.

Cyclohexamine anesthetics (ketamine and tiletamine) produce a state that has been called *dissociative anesthesia* and is characterized by comparatively good cardiopulmonary support and short duration. Heart rate, arterial blood pressure, and cardiac output are well maintained. Although respiration is depressed, with a characteristic apneustic breathing pattern, apnea is infrequent. The main complication of cyclohexamine anesthesia is poor to inadequate skeletal muscle relaxation. Cyclohexamine anesthetics should *not* be given to horses unless a profound degree of skeletal muscle relaxation is present. Skeletal muscle is usually relaxed by the administration of an α_2 -agonist and diazepam or guaifenesin. A commonly used technique for the production of intravenous anesthesia is the combination of xylazine (1.0 mg/kg intravenously [IV]) with ketamine (2.2 mg/kg IV).⁴⁰ Xylazine should be given 3 to 5 min prior to ketamine to ensure the horse is sedate and muscle relaxation is evident. Horses become recumbent within 90 to 120 s of ketamine administration,

Table 27.3. Drugs used for induction and maintenance of anesthesia in sedate horses

Drug	Dose	Comments
Ketamine	1.5–2.0 mg/kg IV	Horses must be maximally relaxed prior to administration Relaxation can be produced with xylazine, diazepam, or guaifenesin
Thiopental	4–6 mg/kg IV with guaifenesin 7–12 mg/kg without guaifenesin	Potential for apnea with administration of large boluses Use with guaifenesin to allow a reduction in dose
Guaifenesin	50 mg/kg IV, to effect	Primarily a muscle relaxant Do not use alone
Diazepam	0.06–0.1 mg/kg IV	Use in sedate horses in combination with ketamine or thiopental Primarily a muscle relaxant
Tiletamine-zolazepam	0.7–1.0 mg/kg IV	Used primarily with ketamine Horse should be fully sedate before administration Produces 30 min of anesthesia with good muscle relaxation Hypoventilation may occur
“Triple-drip” (mixture of guaifenesin 5%, ketamine 0.1%, and xylazine 0.05%)	2 mL/kg/h	Not used for induction in adult horses Used to extend xylazine-ketamine or xylazine-diazepam-ketamine anesthesia Monitor ventilation and the degree of muscle relaxation

IM, intramuscularly; IV, intravenously; and PO, per os (orally).

are anesthetized for approximately 15 to 20 min, and stand within 30 to 45 min after induction. Horses that are not completely sedated prior to ketamine administration may not lie down or may stay recumbent only briefly.⁴¹ Recoveries from xylazine-ketamine anesthesia are generally smooth, with horses requiring a single attempt to stand. The addition of diazepam (0.05 to 0.1 mg/kg IV) to xylazine-ketamine anesthesia shortens the time to induction and makes it more predictable, improves muscle relaxation, and extends anesthesia time approximately 5 min.^{42,43} Guaifenesin can also be used to augment muscle relaxation. Xylazine-ketamine anesthesia can be extended by readministering half of the original dose of each agent, by administering boluses of thiobarbiturates (thiopental, 1.0 mg/kg IV), or by the administration of guaifenesin.⁴⁴ The combination of xylazine (1.0 mg/kg IV) with a commercially available cyclohexamine combination of tiletamine and zolazepam (Telazol, 1.0 to 1.5 mg/kg IV) produces somewhat longer-term anesthesia (25 to 35 min) with improved muscle relaxation and greater respiratory depression.⁴⁵ Zolazepam is a benzodiazepine tranquilizer (similar to diazepam) that relaxes skeletal muscle. The recoveries from xylazine-tiletamine-zolazepam anesthesia are not as smooth as those following xylazine-ketamine anesthesia. The use of a combination of detomidine, ketamine, and tiletamine-zolazepam in xylazine-sedated horses has been described.⁴⁶ Tiletamine-zolazepam powder (500 mg) is reconstituted with 4 mL of 100 mg/mL of ketamine and 1 mL of 10 mg/mL of detomidine. This combination is administered at a dose of 1 mL/150 kg body weight and produces a smooth induction and approximately 40 min of recumbency with minimal analgesic effect. These combinations can be used for induction of anesthesia prior to the administration of inhalant anesthetic agents. Neither ketamine, diazepam, nor tiletamine-zolazepam are approved for use in horses.

Thiobarbiturates can be used to produce short-term or long-term intravenous anesthesia in horses. Horses should be sedated prior to thiobarbiturate administration because this allows for a reduction of dose. The dose can be further reduced if guaifenesin is administered prior to or in combination with a barbiturate. Induction of anesthesia with thiobarbiturates in non-premedicated horses is often stormy. Induction and recovery can be smoothed by prior administration of a sedative or tranquilizer. The larger the dose of thiobarbiturate, the more likely that apnea will occur. Anesthesia from a single barbiturate bolus lasts approximately 15 to 20 min, with recovery occurring within 45 to 60 min. More than one attempt to stand may be required, and there may be a period of ataxia. Recovery is usually acceptable if the total intravenous dose of thiobarbiturate is less than 7 mg/kg. The use of thiobarbiturates as the *sole* anesthetic agent has been largely supplanted by other techniques, although thiopental is still frequently used in combination with other agents (guaifenesin) or to induce anesthesia that is maintained with inhalant agents.

Guaifenesin is a centrally acting skeletal muscle relaxant that produces mild sedation and variable analgesia. Guaifenesin is intravenously administered in 5%, 10%, and 15% concentrations given to effect (50 to 100 mg/kg). Frequently, a pressurized de-

Fig. 27.3. Guaifenesin is administered in large volumes. The use of a pressure bag shortens the time of delivery, facilitating induction of anesthesia.

livery system is used because large volumes must be administered rapidly (Fig. 27.3). Higher concentrations of guaifenesin are difficult to store and may be associated with hemolysis.⁴⁷ Guaifenesin should *not* be given alone, because it does not provide sufficient analgesia for surgery. Guaifenesin is usually administered in combination with agents that produce analgesia (xylazine and ketamine) or a hypnotic state (thiobarbiturates). Guaifenesin is incorporated in many anesthetic techniques because it allows a dose reduction in sedatives and anesthetics that produce greater cardiopulmonary depression. Guaifenesin produces profound skeletal muscle relaxation with comparatively minimal depression of arterial blood pressure and cardiac output. Diaphragmatic function is minimally depressed, but arterial pH and blood gases are affected when recumbency is produced. Horses should be sedated prior to the start of guaifenesin infusion. Guaifenesin can be mixed with thiobarbiturates (0.2% to 0.3% thiopental, 2 to 3 g, in 1 L of guaifenesin), enabling a reduction in the dose of thiobarbiturate required. The combination is administered rapidly, to effect. Once recumbency has been produced, the rate of administration is slowed or stopped, de-

pending on the depth of anesthesia required. The induction dose produces anesthesia that lasts 15 to 25 min. If longer periods are required, additional guaifenesin-thiopental can be administered. Alternatively, guaifenesin can be administered to effect (buckling of the knees and lowering of the head), followed by a bolus of thiobarbiturate (thiopental, 3 to 4 mg/kg) or ketamine (1.5 to 2.2 mg/kg). This latter technique enables a more accurate prediction of when recumbency will occur.

The combination of an α_2 -adrenergic agonist, guaifenesin, and ketamine has been used to produce anesthesia in horses or as a method of extending the anesthesia produced by other techniques (Table 27.3).⁴⁸ One combination is formulated by combining 500 mg of xylazine, 2000 mg of ketamine, and 50 g of guaifenesin in 1 L of sterile water. Anesthesia is usually induced by administering xylazine and then ketamine, as previously described, but may be induced by rapidly administering the combination to effect (approximately 1 to 2 mL/kg) followed by an infusion of 2.2 mL/kg/h for maintenance. This combination provides useful anesthesia with good muscle relaxation. Respiratory depression and bradycardia are primary concerns and should be monitored carefully. Additionally, the appearance of the eyeball helps in determining whether a horse is appropriately anesthetized. Patients should have a brisk palpebral reflex, occasional nystagmus should be present, and the eye should appear wet, which is evidence of tear production. Recovery from anesthesia is generally good.

Inhalation Anesthesia

Inhalation anesthetics, which are frequently used for maintenance of general anesthesia in horses, are occasionally used for induction of anesthesia in foals following nasotracheal intubation, while adult horses are more safely induced with an intravenous technique. Halothane, isoflurane, and sevoflurane are commonly used clinically. Nitrous oxide is not recommended because of the difficulties in maintaining adequate oxygenation in recumbent horses. Nitrous oxide diffuses into closed gas spaces (intestinal gas) and enlarges them, predisposing horses to bloat and ileus. Inhalation anesthetics are usually delivered in oxygen via a sealed airway, thus optimizing the inspired concentration of oxygen. The administration of inhalation anesthetic agents to horses requires specifically designed large animal anesthetic machines and precision, out-of-the-circle vaporizers. Inhalation anesthesia is usually used for horses that are anesthetized for longer than 45 min and for those that have cardiovascular or respiratory compromise. Inhalant administration requires vigilant monitoring of anesthetic depth and cardiopulmonary function. The anesthetic effects produced by various inhalant anesthetics are very similar.⁴⁹ Inhalant anesthetics are cardiopulmonary depressants.⁵⁰ Cardiac output may be somewhat better maintained with isoflurane and sevoflurane, but arterial blood pressure may be lowered. Respiratory depression is comparable, but horses breathing isoflurane or sevoflurane may breathe more slowly. Horses awaken most rapidly after sevoflurane administration followed by isoflurane and then halothane, relative to the solubility coefficients of the drugs.^{51,52} This may alter the management of

the latter part of the anesthetic period in that the administration of sevoflurane or isoflurane may have to be continued longer than for halothane in order to assure that a horse does not attempt to rise too quickly following the termination of the procedure.

Monitoring and Perianesthetic Supportive Care

Monitoring is the key to safe anesthetic practice. The American College of Veterinary Anesthesiologists has developed a set of guidelines for anesthetic monitoring that call for routine assessment and recording of indices of circulation, oxygenation, and ventilation at regular intervals (assessment every 5 min and recording at least every 10 min).⁵³ Horses are specifically mentioned, with the suggestions that a continuous electrocardiogram and a noninvasive blood flow or blood pressure monitor and/or direct monitor of arterial blood pressure be employed in horses anesthetized for longer than 45 min and/or horses anesthetized with inhalant anesthetics. Documentation of all drugs administered and the dose, time, and route of their administration along with a regular recording of the monitored variables complete the anesthetic record. In addition to these indices, anesthetic depth should be regularly assessed, and appropriate adjustments made as necessary. Documentation, through the development of an anesthetic record, of the physical status of the patient and the drugs administered, and periodic evaluations of the drug's cardiopulmonary effects, are necessary, not only for safe anesthesia but also to help minimize the veterinarian's liability should complications arise that result in examination of the methods used. Horses that have lost blood or are in shock should be aggressively treated with intravenous fluids prior to induction of anesthesia.

Physical methods of monitoring (no equipment required) usually suffice for short-term anesthesia. The skills required for physical monitoring of anesthesia parallel those skills required to perform a physical exam. The eye is of particular interest. During surgical levels of anesthesia with inhalants, horses have a dull palpebral reflex (the eyes close slowly when the eyelashes are stimulated) and a strong corneal reflex (the eyes close rapidly when pressure is applied to the cornea). Nystagmus can be present, but it is usually slow and the eye should be moist. Spontaneous blinking or rapid nystagmus are signs of light planes of anesthesia. Eye signs are not helpful during anesthesia with the cyclohexamine anesthetics (ketamine and tiletamine), because these agents cause rapid nystagmus, blinking, and tearing, irrespective of the anesthetic plane. For longer anesthetic periods, particularly those where hypotension or respiratory depression is expected, arterial blood pressure should be measured. The maintenance of mean arterial blood pressure higher than 60 mm of Hg has been identified as a critical factor in preventing postanesthetic myopathies in horses.^{6,54} The preferred method of measurement of arterial blood pressure is the use of an indwelling arterial catheter and a measuring device that indicates pressure in millimeters of mercury (mm Hg). Blood pressure alterations are a reasonably good index of anesthetic depth in addition to their use in the assessment of cardiovascular status. Blood pressure

falls as anesthesia deepens and increases as anesthesia lightens. Mean arterial blood pressure should range between 60 and 90 mm Hg during anesthesia. A mean arterial blood pressure lower than 60 mm Hg is associated with the loss of autoregulation of blood flow to some vascular beds and should be avoided.⁶ Hypotension is treated by decreasing the delivery of anesthetics (if possible), administering intravenous fluids (crystalloids and colloids), and administering vasoactive drugs. If the anesthetic plane is appropriate, the rate of fluid administration should be increased. The maintenance rate of fluid administration during anesthesia ranges from 5 to 10 mL/kg/h. Fluids can be rapidly administered with a pump if hypotension occurs. Fluid rates should be decreased if the packed cell volume falls below 20% or the total protein concentration falls below 3.5 g/dL. Hypovolemia in the presence of low packed cell volume and total protein must be corrected by using blood or blood products.

Hypotension that does not respond to fluid therapy is treated with inotropic or vasoactive agents such as dobutamine or ephedrine. Dobutamine is a synthetic catecholamine that increases cardiac output and arterial blood pressure by increasing the strength of myocardial contractions.⁵⁵ Dobutamine is administered slowly (infused) to effect and then titrated to maintain a desired arterial blood pressure. Signs of overdose include tachycardia, hypertension, and supraventricular and ventricular premature arrhythmias. The infusion should be reduced or discontinued if signs of toxicity occur. Dobutamine has a brief effect, so its effects decrease rapidly when it is discontinued. Ephedrine produces similar effects increasing arterial blood pressure and cardiac output.⁵⁶ Ephedrine is given as an intravenous bolus and produces effects that persist for 20 to 30 min or longer. The administration of calcium solutions may produce increases in arterial blood pressure particularly if ionized calcium levels are marginal or decreased.⁵⁷

Anesthetized horses hypoventilate to varying degrees. The compromises produced by hypoventilation are generally well tolerated during briefer anesthetic periods (less than 45 min) in healthy horses. The compromises become more critical as anesthesia lengthens or if disease is present. Horses anesthetized for longer than 45 to 60 min benefit from oxygen supplementation and may benefit from assisted ventilation. Other maneuvers, including the application of positive end-expiratory pressure, the use of bronchodilators, and selective ventilation, have been investigated but have not been widely adopted.⁵⁸⁻⁶⁰ In the absence of arterial blood-gas analysis, oxygen should be supplemented during prolonged anesthesia. Arterial blood-gas analysis can help identify horses that are hypoventilating or shunting pulmonary blood flow and thus direct therapeutic interventions.

Acute bouts of hyperkalemic periodic paralysis have been reported during anesthesia.^{61,62} In addition, laryngeal and pharyngeal dysfunction has been reported that could compromise airway function.⁶³ Chronic treatment of hyperkalemic periodic paralysis with acetazolamide seems to be effective in reducing the incidence of hyperkalemia, but patients predisposed to the disease are at increased risk. Signs of hyperkalemia in anesthetized horses include protrusion of the third eyelid, muscle fasciculations, bradycardia, and electrocardiographic changes, in-

cluding flattening of P waves, tenting of T waves, and widening of the QRS complex. Hypotension may be present. Anticholinergics are frequently ineffective in the treatment of bradycardia. Initial treatment should include the administration of calcium-containing solutions such as calcium gluconate to counteract the cellular effects of hyperkalemia. Large quantities of potassium-deficient fluids should be administered intravenously to reduce potassium levels by dilution. Two other methods of reducing serum potassium levels include the administration of sodium bicarbonate and the use of glucose-containing solutions with dextrose.

Recovery

This is a critical phase of equine anesthesia but in many ways the least controllable.⁶⁴ As a horse awakens from anesthesia, it may try to rise prematurely and subsequently fall, creating excitement. This excitement may lead to further attempts to stand with poor results. Ideally, horses regain consciousness within 10 to 20 min of anesthetic discontinuation, roll to sternal recumbency for a brief period, and then rise. Most horses return to standing within 1 h of anesthetic drug discontinuation. Attempts to speed the recovery process usually cause horses to have a prolonged period of unsteadiness once they stand. Recovery should only be prompted if a horse had cardiopulmonary embarrassment while anesthetized. In this instance, rolling the horse into sternal recumbency during recovery improves oxygenation. Insufflation or the use of a demand valve can also support oxygenation.⁷ Horses that try to rise too quickly can be sedated with small doses of intravenous xylazine (0.2 mg/kg). Laryngospasm is infrequent in horses. Some anesthetists prefer to leave the endotracheal tube in place until a horse is standing. Others remove the endotracheal tube when a horse begins to swallow (in lateral recumbency). It is important that horses swallow when the endotracheal tube is removed so that the soft palate is replaced in its normal position under the epiglottis. Occasionally, particularly after dorsal recumbency, congestion of the nasal passage causes snoring. Congestion can be alleviated by the intranasal administration of phenylephrine prior to recovery or the passage of a 30- to 40-cm-long, 10- to 14-mm (internal diameter) endotracheal tube (Fig. 27.4) into the nasopharynx via the ventral meatus.⁶⁵ The tube is tied to the halter to prevent aspiration and is removed after the horse stands.

Presumably, smoother recoveries are facilitated by placing horses in a quiet, darkened environment. Good footing is important. As a horse tries to stand, it needs to be able to plant its feet and not have them slip. The horse can be aided to its feet by attaching head and tail ropes. In stalls specifically designed for recovery, strong metal rings can be attached to opposite walls. The head and tail ropes can be passed through the rings (Fig. 27.5), removing the supporting personnel from the immediate area of the horse.

Horses that fail to rise within 90 min of the end of anesthesia should be evaluated further. Potential causes include weakness, rhabdomyolysis, or neurogenic paralysis. Weakness may be the result of residual tranquilization or electrolyte abnormalities

Fig. 27.4. A 12- to 14-mm (internal diameter) endotracheal tube can be inserted into the pharynx via the ventral meatus to reduce respiratory stridor during recovery. The tube can be placed at any point during anesthesia, tied to the halter during recovery, and then removed when the horse is standing. A piece of polyvinylchloride pipe used as an aide for orotracheal intubation is shown.

Fig. 27.5. Head and tail ropes are used to assist the recovery from anesthesia. The ropes are run through strong rings that are attached to opposite walls of the recovery stall. This allows some support and control of the horse's movements once it stands without placing assisting personnel in a position where they might be injured. The horse needs to move its head to balance itself as it stands, so the head rope should not be pulled until the animal is standing.

(hypocalcemia or hyperkalemia). Rhabdomyolysis and neurogenic paralysis are difficult to differentiate. Horses often attempt to stand but cannot or stand on three legs if a single limb is affected. Orthopedic injury should be ruled out. The treatment of rhabdomyolysis and neurogenic paralysis is similar and essentially supportive. Intravenous fluids are indicated to promote perfusion and assure urine formation to minimize the chances for myoglobinuric renal failure. Acepromazine in small doses can be administered to calm horses and to promote peripheral perfusion.

Small doses of diazepam (0.02 to 0.04 mg/kg IV) can reduce muscle cramping. The muscle relaxant dantrolene and nonsteroidal anti-inflammatory agents have also been advocated. Unaffected weight-bearing limbs should be wrapped with support bandages. Horses that have a single limb affected usually can stand and have a good prognosis for recovery. Prolonged recumbency worsens the prognosis. Early aggressive treatment is required for a successful outcome.

- Analgesia

Introduction

As in other species, sedation and anesthesia are often required for surgical or diagnostic procedures in ruminants. The decision to induce general anesthesia may be influenced by a ruminant's temperament and its specific anatomical and physiological characteristics. Ruminants usually accept physical restraint well and that, in conjunction with local or regional anesthesia, is often sufficient to enable completion of many procedures. Other diagnostic and surgical procedures that are more complex require general anesthesia.

In addition to discussing techniques for cattle, goats, and sheep, anesthetic techniques for South American camelids, primarily llamas and alpacas, are discussed. South American camelids do not accept restraint as well as domestic ruminants and often require sedation before local or regional anesthesia. Although they have some unique species characteristics regarding anesthesia, many of the principles and techniques used in food-animal and equine anesthesia also apply to South American camelids. Except for differences in size, anesthetic management of alpacas and llamas is similar.

Preanesthetic Preparation

Considerations for preanesthetic preparation include fasting, assessment of hematologic and blood chemistry values, venous

catheterization, and estimation of body weight. Domestic ruminants have a multicompartmental stomach with a large rumen that does not empty completely. South American camelids have a stomach divided into three compartments.¹ Each species, therefore, is susceptible to complications associated with recumbency and anesthesia: tympany, regurgitation, and aspiration pneumonia. To reduce the risk associated with these potential complications, calves, sheep, goats, and camelids should be fasted 12 to 18 h and deprived of water for 8 to 12 h prior to anesthesia. Adult cattle should be fasted 18 to 24 h and deprived of water for 12 to 18 h. In nonelective cases, this is often not possible, and precautions should be taken to avoid aspiration of gastric fluid and ingesta. Fasting neonates is not advisable because hypoglycemia may result. Fasting and water deprivation will decrease the likelihood of tympany and regurgitation by decreasing the volume of fermentable ingesta. Fasting can also cause bradycardia in cattle.² Additionally, pulmonary functional residual capacity may be better preserved in fasted anesthetized ruminants.³ Although gas does not appear to accumulate in the first compartment of anesthetized camelids, these precautions are recommended to decrease the incidence of regurgitation. Even with these precautions, some ruminants will become tympanitic, whereas others will regurgitate.

Hematologic and blood chemistry values may be determined before anesthesia. Results should be compared with reference values.⁴⁻⁷ Venipuncture and catheterization of the jugular vein are often performed prior to anesthesia. Adult cattle require 12- to 14-gauge catheters, whereas 16-gauge catheters are appropriate for adult camelids, calves, and large goats and sheep, and 18-gauge catheters are appropriate for juvenile camelids, sheep, and goats. Physical restraint during venipuncture or catheterization varies and can consist of a handler holding the animal's halter or use of head gates and chutes for adult cattle and llamas. If a camelid is fractious, grasping its ear may be helpful. Turning the animal's head to either side may hinder venipuncture and catheter placement in goats and camelids. Infiltration of local anesthetic to desensitize skin structures at the site of catheterization is recommended.

Camelids do not have a jugular groove. The jugular vein lies deep to the sternomandibularis and brachiocephalicus muscles, ventral to cervical vertebral transverse processes, and superficial to the carotid artery and vagosympathetic trunk within the carotid sheath for most of its length.⁸⁻¹⁰ Beginning at a point about 15 cm caudal to the ramus of the mandible, the rostral course of the jugular vein is separated from the carotid artery by the omohy-

oideus muscle. The bifurcation of the jugular vein is located at the intersection of a line drawn caudally along the ventral aspect of the body of the mandible and another line connecting the base of the ear and the lateral aspect of the cervical transverse processes. Venipuncture or catheterization can be performed at the bifurcation or at any point caudal to it. Because of the close proximity of the carotid artery to the jugular vein, one must confirm that the vein has been catheterized and not the artery. After occlusion of the vessel, one will be unable to see the jugular vein distend; however, the vein can be palpated particularly rostrally and more easily in females and altered males because their skin is thinner. On occasion, one will be able to see the jugular vein distend on crias and juvenile camelids. Camelids can have four to five jugular venous valves that prevent flow of venous blood into the head when the head is lowered during grazing.⁸ Contact with jugular venous valves may prevent catheterization; a site caudal to the point where the valve was contacted should be used.

For accurate drug administration, the animal must be weighed. It is easy to overestimate the body weight of camelids because they are fairly tall, and their long hair coat obscures their body condition. Adult male llamas usually weigh 140 to 175 kg, occasionally reaching or exceeding 200 kg. Adult female llamas usually weigh 100 to 150 kg but may occasionally exceed 200 kg. Adult male alpacas usually weigh 60 to 100 kg, and adult female alpacas usually weigh 50 to 80 kg. The body weight of crias and small juveniles may be determined on a bathroom scale.

Anticholinergics are usually not administered to domestic ruminants prior to induction of anesthesia. They do not consistently decrease salivary secretions unless used in higher doses given frequently. Anticholinergics, while decreasing the volume of secretions, make them more viscous and difficult to clear from the trachea. The usual doses of atropine used to prevent bradycardia in domestic ruminants (0.06 to 0.1 mg/kg intravenously [IV]) do not prevent salivation during anesthesia. Camelids are prone to increased vagal discharge during intubation or painful stimuli during surgery. Atropine administration (0.02 mg/kg IV or 0.04 mg/kg intramuscularly [IM]) is recommended to prevent bradyarrhythmia and will also decrease salivary secretions.¹¹ Glycopyrrolate (0.005 to 0.01 mg/kg IM or 0.002 to 0.005 mg/kg IV) may be substituted for atropine.^{12,13}

Sedation/Restraint

Drugs traditionally used to tranquilize and/or sedate ruminants include acepromazine, the α_2 -agonists such as xylazine, detomidine, medetomidine, and romifidine; pentobarbital, chloral hydrate, diazepam, and midazolam.

Acepromazine is the most commonly used phenothiazine derivative tranquilizer in veterinary anesthesia. It is not commonly used in ruminants but can be used in a manner similar to its use in horses. In general, though, lower doses of acepromazine are required for cattle than for horses. The usual doses of acepromazine used in sheep and goats are 0.03 to 0.05 mg/kg IV and 0.05 to 0.1 mg/kg IV,¹⁴ which may increase the risk of regurgitation during anesthesia.¹⁴ Acepromazine should not be injected into the coccygeal vein. The close proximity of the coccygeal ar-

tery makes the risk of inadvertent intra-arterial injection possible, with subsequent loss of the tail. Acepromazine can also cause prolapse of the penis and is contraindicated in debilitated and hypovolemic patients.

Xylazine, detomidine, romifidine, and medetomidine induce sedation by stimulating the central α_2 -adrenoceptors. Xylazine is often used to sedate or, in higher doses, restrain (recumbency and heavy sedation) ruminants. There appears to be some variation in response between species and within a species. Xylazine is a more potent sedative in ruminants than in horses.¹⁵ Goats appear to be more sensitive to xylazine than are sheep,^{13,14,16} with cattle appearing to be of intermediate sensitivity when compared with sheep and goats. South American camelids appear to be intermediate between cattle and horses in sensitivity to xylazine, and alpacas appear to be less sensitive to xylazine than are llamas. Hereford cattle are more sensitive to xylazine than are Holstein cattle,¹⁷ and anecdotal evidence indicates that Brahmans are perhaps the most sensitive of cattle breeds.¹⁸ Extreme environmental conditions can cause cattle to have a pronounced and prolonged response to xylazine.¹⁹ Variation in response to the analgesic effects of xylazine between breeds of sheep has been reported.^{20,21} Detomidine has been used to a lesser extent in ruminants but provides sedation and/or analgesia in domestic ruminants not unlike that obtained in horses. Medetomidine and romifidine have been used to a lesser extent in ruminants.

Although complete data are not available on the cardiovascular and respiratory effects of xylazine in camelids, bradycardia²² typically occurs as it does in other species.^{17,23–25} Poorly trained or berserk male camelids tend to be less responsive, and debilitated individuals are more depressed by sedative doses of xylazine. Xylazine causes hyperglycemia and hypoinsulinemia in cattle and sheep.^{26–31} Hypoxemia and hypercarbia are common side effects in domestic ruminants,^{14,17,22,32} and sheep are at risk of developing pulmonary edema.³³ Xylazine has an oxytocin-like effect on the uterus of pregnant cattle³⁴ and sheep.³⁵ Detomidine may not have this same effect on the gravid uterus³⁶ and would appear to be the α_2 -agonist of choice for sedating pregnant cattle or sheep.

The degree of sedation or restraint produced by α_2 agents depends on the dose and overall animal temperament. Low doses of xylazine (0.015 to 0.025 mg/kg IV or IM) typically provide sedation without recumbency in domestic ruminants.^{12,13} Higher doses (0.1 to 0.2 mg/kg IV) provide sedation without recumbency in camelids.³⁷ Detomidine can be given at 2.5 to 10.0 μ g/kg IV in cattle^{13,36,38,39} and at 10 to 20 μ g/kg in sheep¹⁴ to provide standing sedation for approximately 30 to 60 min. Medetomidine has been given at a dose of 5 μ g/kg IV to cattle³⁹ or at 10 μ g/kg IM to llamas⁴⁰ for brief periods of standing sedation with minimal analgesia.

Higher doses of xylazine will induce recumbency, heavy sedation, or possibly light planes of general anesthesia in domestic ruminants and camelids. Xylazine (goats, 0.05 mg/kg IV or 0.1 mg/kg IM;^{13,14,41} sheep, 0.1 to 0.2 mg/kg IV or 0.2 to 0.3 mg/kg IM;^{13,14,41} and cattle, 0.1 mg/kg IV or 0.2 mg/kg IM¹⁸) will induce recumbency for approximately 1 h. Xylazine (0.3 to 0.4 mg/kg IV) usually induces 20 to 30 min of recumbency in lla-

mas.^{8–11,37} Alpacas may require an increased dose, approximately 10% to 20%, to achieve the same result.⁴² A high dose of detomidine, 30 µg/kg IV, will produce recumbency in sheep. This dose is equivalent to xylazine at 0.15 mg/kg IV, medetomidine at 10 µg/kg IV, or romifidine at 50 µg/kg IV.⁴³ In llamas, detomidine in doses as high as 40 µg/kg IV provides mild sedation but not restraint.³⁷ Medetomidine given at 10 µg/kg IV induces recumbency in cattle.³⁹ When given at 20 to 30 µg/kg IM to llamas, medetomidine provides profound sedation and recumbency lasting up to 120 min.⁴⁰ Higher doses of all α_2 agents can be expected to induce longer periods of recumbency in all species.

Sedation following administration of α_2 -adrenoceptor agonists can be reversed by α_2 -adrenoceptor antagonists. When yohimbine is given at 0.12 mg/kg IV, its efficacy varies in cattle^{44,45} whereas it is somewhat ineffective in sheep.⁴⁶ Higher doses of yohimbine (1.0 mg/kg IV) will generally reverse xylazine sedation in sheep.⁴⁷ Tolazoline is usually given at 0.5 to 2.0 mg/kg IV,⁴⁵ but at 2.0 mg/kg IV it can cause hyperesthesia in cattle^{48,49} and at doses of 4 mg/kg can cause seizurelike activity in llamas.⁵⁰ Tolazoline can induce unwanted cardiovascular effects such as transient bradycardia, sinus arrest, and hypotension.⁵¹ Idazoxan can be given at doses of 0.05 mg/kg IV to sheep⁴⁶ and calves to reverse xylazine sedation.⁵¹ Atipamezole at doses varying from 20 to 60 µg/kg IV has been used to reverse medetomidine sedation in calves.^{13,52,53}

Yohimbine (0.12 mg/kg IV) has been used in llamas in combination with 4-aminopyridine (0.3 mg/kg IV) to produce complete recovery from xylazine sedation.²² Its use singly in camelids is also effective, and it can be administered at 0.12 mg/kg IV.³⁷ If sufficient arousal does not occur, additional yohimbine can be given. Tolazoline is also effective for reversing xylazine sedation in camelids. When given at the recommended equine dose to camelids, tolazoline causes severe complications: transitory apnea, cardiac arrest, seizurelike activity, depression, and vague signs of abdominal pain, followed by death within 24 h. One method of administering tolazoline to healthy camelids is to give 50% of the calculated dose (1.0 to 2.0 mg/kg IV) initially and the remainder if reversal is inadequate.³⁷ In most instances, the initial dose (1.0 mg/kg IV) of tolazoline is adequate for sufficient arousal. Following tolazoline administration at the full calculated dose of 2.0 mg/kg IV, opisthotonus can occur in some animals. After excitement subsides, recovery is usually uneventful.

Doxapram, an analeptic, has also been used to enhance the arousal response from yohimbine or tolazoline: 1.0 mg/kg IV has been somewhat effective in cattle⁵⁴ but ineffective in llamas at 2.0 mg/kg IV.²²

Pentobarbital (2 mg/kg IV) has been used in cattle for standing sedation and tranquilization.⁵⁵ Caution must be exercised to avoid inducing excitement. Pentobarbital provides moderate sedation for 30 min and mild sedation for an additional 60 min. Chloral hydrate or chloral hydrate–magnesium sulfate solutions can be used to sedate ruminants.¹⁸ These drugs must be injected slowly IV to avoid tissue necrosis. Diazepam (0.25 to 0.5 mg/kg IV) injected slowly will provide 30 min of sedation without analgesia in sheep and goats.^{14,41} Midazolam (0.4 to 0.6 mg IM^{56,57} or 0.3 mg/kg IV⁵⁸) will provide sedation and recumbency in

sheep and goats for 10 to 20 min. Midazolam given at 1.0 mg/kg IM⁵⁶ or 0.6 mg/kg IV⁵⁸ can induce recumbency and heavy sedation in goats. Increasing the midazolam dose to 1.2 mg/kg IV lengthens recumbency for up to 30 min.⁵⁷

Butorphanol is an opioid agonist-antagonist that provides sedation and analgesia in camelids and domestic ruminants. It is often given at 0.1 to 0.2 mg/kg IM in camelids⁵⁹ and at 0.05 to 0.5 mg/kg IM in sheep and goats.^{14,60,61} Ataxia and dysphoria have been reported following butorphanol administration (0.1 to 0.2 mg/kg IV) in sheep.⁶¹

Combinations of xylazine and butorphanol have been used in camelids and domestic ruminants to provide neuroleptanalgesia. Doses are 0.01 to 0.02 mg/kg IV of each drug administered separately to domestic ruminants and 0.2 mg/kg IV of each drug for camelids (M. J. Huber, personal communication, 1993). Action lasts approximately 1 h. Combinations of butorphanol, xylazine, and ketamine have also been used together in restraining camelids.⁶² This combination is prepared by adding 100 mg (1 mL) of xylazine and 10 mg (1 mL) of butorphanol to 10 mL of ketamine. It is administered at 1 mL/40 pounds IM to alpacas and at 1 mL/50 pounds IM to llamas.⁶² At this dose, recumbency occurs within 5 min and lasts approximately 25 min. Other combinations of butorphanol, xylazine, and ketamine have also been reported.⁶³ Given IV at 0.22 to 0.33 mg/kg xylazine, 0.22 to 0.33 mg/kg ketamine, and 0.077 to 0.11 mg/kg butorphanol, this combination is more predictable.⁶³ Animals will become recumbent, and analgesia lasts for 15 to 20 min. Administering a partial dose of ketamine will lengthen the analgesia. When this combination is given IM, the dose range is increased to 0.22 to 0.55 mg/kg for xylazine, 0.22 to 0.55 mg/kg for ketamine, and 0.055 to 0.11 mg/kg for butorphanol.⁶³ Onset occurs within 10 min, and the recumbency is extended to approximately 45 min.

Induction

Ruminants are not always sedated prior to induction of anesthesia. Atraumatic physical restraint can be used in lieu of sedatives in some circumstances. Because ruminants seldom experience emergence delirium, sedation during the recovery period is not required. In some instances, though, sedation is required to make handling of these animals, primarily adult bulls, safer during the induction period. Sedation will tend to lengthen the recovery period from general anesthesia³⁸ and increase the likelihood of regurgitation.¹⁴

General anesthesia can be induced by either injectable or inhalation techniques. Available drugs include thiobarbiturates, ketamine, guaifenesin, tiletamine-zolazepam, propofol, pentobarbital, halothane, isoflurane, and sevoflurane. Anesthesia can be induced in small ruminants, weighing less than 50 to 100 kg, either by mask with halothane, isoflurane, or sevoflurane or with injectable techniques. Anesthesia can be induced in larger animals with either intravenous or intramuscular techniques. Anesthesia can also be induced with halothane, isoflurane, or sevoflurane by mask in small or debilitated camelids or in camelids restrained with xylazine-ketamine, tiletamine-zolazepam, etc. Mask induction in healthy untranquilized adult camelids is usually not at-

tempted because application of the mask may provoke spitting. Addition of nitrous oxide (50% of total flow) to the inspired inhalant-gas mixture will speed induction. During induction, lower concentrations of halothane (3%), isoflurane (3%), or sevoflurane (4%) are administered when patients weigh less than 25 kg. Higher concentrations are used with larger patients.

Barbiturates

The thiobarbiturates thiopental and thiamylal have been used extensively in veterinary anesthesia, alone and in combination with guaifenesin. Used separately, they quickly induce anesthesia. Muscle relaxation is relatively poor but still sufficient to accomplish intubation. The acid-base status and physical status of patients affect the actions of these drugs. Acidemia increases the nonionized fraction (the active portion) of the drug, increasing its activity and thus decreasing the dose required.⁶⁴ In addition, the heart, brain, and other vital organs receive a larger portion of cardiac output when patients are in shock.⁶⁵ Because patients in shock are often acidemic, altered kinetics and hemodynamics can cause a relative overdose.

Recovery from induction doses of thiobarbiturates is based on redistribution of the drug from the brain to other tissues in the body. Metabolism of the agent continues for some time following recovery until final elimination occurs. Maintenance of anesthesia with thiobarbiturates is not recommended because saturation of tissues causes recovery to be dependent on metabolism and recovery will be prolonged. Concurrent use of large doses of nonsteroidal anti-inflammatory drugs (NSAIDs) may be contraindicated because recovery can be delayed as thiobarbiturate is displaced from protein.⁶⁶

Thiopental can be given at a dose of 6 to 10 mg/kg IV and will provide approximately 10 to 15 min of anesthesia. Camelids often require additional thiopental for tracheal intubation. Thiamylal is administered in similar fashion although in slightly lower doses, usually 25% to 30% less.

Pentobarbital has been used to anesthetize domestic ruminants but is no longer commonly used. If the situation arises in which it is used, the dose is 20 to 25 mg/kg IV, half given rapidly and the remainder to effect. When given at an anesthetic dose, pentobarbital causes profound respiratory depression and is not an effective analgesic. Sheep appear to metabolize pentobarbital more quickly than other species.¹⁴ Recovery in domestic ruminants is usually prolonged, and other anesthetic techniques are more appropriate.

Ketamine

This agent stimulates the limbic system, causing dysphoria, hallucinations, and excitement, in addition to tonic-clonic muscle activity when used alone in horses. Those same traits characterize its use in ruminants, although perhaps not to the same extent as in horses. It also provides mild cardiovascular stimulation. Although ketamine does not eliminate the swallowing reflex, tracheal intubation can be accomplished in most ruminants.

Ketamine will induce immobilization and incomplete analgesia when given alone, but it is usually combined with a sedative or tranquilizer. Most commonly, xylazine or diazepam is recom-

mended, although the availability of detomidine offers another alternative. Xylazine (0.1 to 0.2 mg/kg IM) can be given, followed by ketamine (10 to 15 mg/kg IM), to smaller domestic ruminants.^{14,41,67} In goats, it is preferable to use the lower dose of xylazine followed by ketamine.^{14,41} Anesthesia usually lasts about 45 min and can be prolonged by injection of 3 to 5 mg/kg IM of ketamine. The longer duration of action of xylazine obviates the need for its readministration in most cases. Alternatively, intravenous xylazine (0.03 to 0.05 mg/kg) followed by ketamine (3 to 5 mg/kg), or intramuscular xylazine (goats, 0.1 mg/kg; and sheep, 0.2 mg/kg) followed by intravenous ketamine (3 to 5 mg/kg), can provide anesthesia lasting up to 15 to 20 min.¹⁴ Adult cattle can be anesthetized for short periods with xylazine (0.1 to 0.2 mg/kg IV) followed by ketamine (2.0 mg/kg IV).⁶⁸ The lower dose of xylazine is used when cattle weigh more than 600 kg.⁶⁸ Anesthesia lasts approximately 30 min but can be prolonged for 15 min with additional ketamine (0.75 to 1.25 mg/kg IV).⁶⁸ When evaluated in sheep, xylazine (0.1 mg/kg IV) and ketamine (7.5 mg/kg IV) provided anesthesia lasting 25 min while decreasing cardiac output, mean arterial pressure, and peripheral vascular resistance.⁶⁹ Medetomidine has been combined with ketamine to induce anesthesia in calves. Because medetomidine (20 µg/kg IV) is much more potent than xylazine, lower doses of ketamine (0.5 mg/kg IV) can be used.⁵³ However, a local anesthetic block at the surgical site may be required when ketamine is used at this dose.⁵³ When using α_2 -agonist-ketamine combinations, anesthesia can be reversed with α_2 -adrenoceptor antagonists without much excitement during recovery.

Diazepam (0.1 mg/kg IV) followed immediately by ketamine (4.5 mg/kg IV) can be used in most domestic ruminants. Muscle relaxation is usually adequate for tracheal intubation, although the swallowing reflex may not be completely obtunded. Anesthesia usually lasts 10 to 15 min following diazepam-ketamine administration, with recumbency of up to 30 min. Higher doses of diazepam (0.25 to 0.5 mg/kg IV) with ketamine (4.0 to 7.5 mg/kg IV) have also been used in sheep and provide the same duration of anesthesia.^{14,41,69} Investigations into the cardiopulmonary effects of diazepam (0.375 mg/kg IV) and ketamine (7.5 mg/kg IV) in sheep have shown a decrease in cardiac output and an increase in peripheral vascular resistance without arterial pressure being affected.⁶⁹ Midazolam has been substituted for diazepam in goats and is given at 0.4 mg/kg IM followed by ketamine at 4.0 mg/kg IV after recumbency occurs (approximately 15 min). Anesthesia lasts approximately 15 min.⁵⁶

Xylazine (0.25 to 0.35 mg/kg IM) and ketamine (6.0 to 10.0 mg/kg IM, 15 min later) usually provide 30 to 60 min of recumbency in camelids.^{8,11} The simultaneous administration of xylazine (0.44 mg/kg IM) and ketamine (4.0 mg/kg IM) usually provides restraint for 15 to 20 min.^{10,70} Higher doses of xylazine (0.8 mg/kg IM) and ketamine (8.0 mg/kg IM) given simultaneously usually induce anesthesia within 5 min, and the duration of anesthesia provided is approximately 30 min.⁷⁰ Anesthesia depth varies with the amount given and the camelid's temperament but is usually sufficient for minor procedures such as suturing lacerations, draining abscesses, or applying casts. When any of these combinations provides insufficient anesthetic depth, supplement-

tal local anesthesia may be required in order to complete the surgery. Tracheal intubation may not be possible. However, these combinations heavily sedate (if not anesthetize) and immobilize the patient, facilitating venipuncture and administration of additional anesthetic agent or application of a face mask to increase the anesthesia depth when necessary. Xylazine (0.25 mg/kg IV) and ketamine (3.0 to 5.0 mg/kg IV) may be administered 5 min apart to obtain a more uniform response and sufficient anesthesia depth for tracheal intubation.⁸ Diazepam (0.1 mg/kg IV) and ketamine (4.5 mg/kg IV) as used for domestic ruminants produces recumbency that lasts approximately 20 min but does not reliably provide enough muscle relaxation for tracheal intubation in camelids.

Guaifenesin

This agent is a centrally acting skeletal muscle relaxant that exerts its effect at the internuncial neurons in the spinal cord and at polysynaptic nerve endings.⁷¹ It can be used alone to induce recumbency in domestic ruminants and camelids, but this usage is not recommended because it imparts little, if any, analgesia.⁷² Addition of ketamine or thiobarbiturate to guaifenesin solution improves induction quality and decreases the volume required for anesthetic induction. Muscle relaxation is improved when compared with induction with ketamine alone or the thiobarbiturates given alone. Typically, 5% guaifenesin solutions are used. Hemolysis can occur with 10% guaifenesin solutions.⁷³ Commonly, these solutions are given rapidly to effect, either by gravity and large-gauge catheter or by pressurizing the bottle. The calculated volume dose when using 5% guaifenesin solution is 2.0 mL/kg. The amount of ketamine added to guaifenesin varies but is commonly 1.0 g/50 g of guaifenesin. The amount of thiobarbiturate added to guaifenesin varies but is commonly 2.0 g/50 g of guaifenesin. For convenience, guaifenesin-based mixtures may be injected with large syringes rather than administered by infusion to camelids and small ruminants.

Following induction, guaifenesin-based solutions (with thiopental or ketamine) can be infused to effect to maintain anesthesia. If desired, xylazine can also be added to ketamine-guaifenesin solutions for induction and maintenance of anesthesia in cattle^{68,74} and sheep.⁷⁵ Final concentrations are guaifenesin, 50 mg/mL; ketamine, 1 to 2 mg/mL; and xylazine, 0.1 mg/mL. This solution is infused at 0.5 to 1.0 mL/kg IV for induction. Anesthesia is maintained by infusion of the mixture at 1.5 mL/kg/h for calves,⁷⁴ 2 mL/kg/h for adult cattle,⁶⁸ and 2 mL/kg/h for sheep,⁷⁵ although the final administration rate will vary with case requirements. If the procedure requires more than 2 mL/kg of the guaifenesin-ketamine-xylazine mixture in order to complete the surgery, the amount of xylazine added should be decreased by at least 50% because its action may last longer than that of the other two agents in the mixture. Alternatively, a solution with a final concentration of guaifenesin (50 mg/mL), ketamine (1 mg/mL), and xylazine (0.05 mg/mL) can be formulated and infused at 2.0 mL/kg/h IV for maintenance to avoid the potential cumulative effects of xylazine overdose. Because ruminants may regurgitate during xylazine-ketamine-guaifenesin anesthesia, intubation is highly recommended.

Tiletamine-Zolazepam

A proprietary combination of equal parts of tiletamine (a dissociative anesthetic agent similar to, but more potent than, ketamine) and zolazepam (a potent benzodiazepine sedative similar to diazepam) is available for use as an anesthetic agent in cats and dogs. When used alone, tiletamine induces poor muscle relaxation and causes excitement during recovery. The addition of zolazepam to tiletamine modifies these effects. As with ketamine, the swallowing reflex remains but is obtunded. Like ketamine-benzodiazepine combinations, this combination provides slight cardiovascular stimulation, causing the heart rate to increase.⁷⁶ Elimination of tiletamine and zolazepam is not uniform, with variation occurring for each drug's clearance among species. Differential clearance of the two drugs can affect recovery quality.⁷⁶

In many respects, tiletamine-zolazepam can be considered to be similar to ketamine premixed with diazepam. When used alone in horses, it provides unsatisfactory anesthesia.⁷⁷ Muscle relaxation is poor, and recovery is characterized by excitement. However, when combined with a sedative such as xylazine, it can be used successfully in horses. Because of differences in temperament between horses and domestic ruminants and camelids, tiletamine-zolazepam can be used successfully in most ruminants with or without xylazine. However, addition of xylazine to tiletamine-zolazepam will lengthen and enhance the overall anesthetic effect.

Tiletamine-zolazepam given at 4.0 mg/kg IV causes minimal cardiovascular alteration in calves and provides anesthesia of 45- to 60-min duration.⁷⁸ Xylazine (0.1 mg/kg IM) followed immediately by tiletamine-zolazepam (4.0 mg/kg IM) produces onset of anesthesia within 3 min, and anesthesia duration of approximately 1 h.⁷⁹ Calves are fully recovered approximately 130 min after injection. Increasing xylazine to 0.2 mg/kg IM increases duration of anesthesia and recumbency and the incidence of apnea.⁷⁹ Xylazine can also be administered at a lower dose of 0.05 mg/kg IV followed by tiletamine-zolazepam at 1.0 mg/kg IV to induce anesthesia of shorter duration.⁶⁸

Tiletamine-zolazepam given at 12.0 mg/kg IV in sheep has provided approximately 2.5 h of surgical anesthesia, with a total recumbency time of 3.2 h.⁸⁰ More recent investigations in sheep have shown that tiletamine-zolazepam, dosed at 12 to 24 mg/kg IV, causes cardiopulmonary depression, with anesthesia of approximately 40 min.⁸¹ Rather than using these relatively large doses, it is more appropriate to decrease the initial dose of tiletamine-zolazepam to 2.0 to 4.0 mg/kg IV and administer additional tiletamine-zolazepam as required to prolong anesthesia. Butorphanol (0.5 mg/kg IV) combined with tiletamine-zolazepam (12 mg/kg IV) given either simultaneously or 10 min apart induces 25 to 50 min of anesthesia in sheep, with mild cardiopulmonary depression.⁸² Tiletamine-zolazepam (4.0 mg/kg IM) can immobilize llamas for up to 2 h.⁸³ The length of recumbency is unaffected by administration of flumazenil, indicating that the duration of action is more likely influenced by tiletamine than by zolazepam.⁸³ Cardiovascular function is preserved although hypercarbia and hypoxemia can occur in some animals. Airway reflexes are maintained. Local anesthesia may still be re-

quired for some surgical procedures.⁸³ In camelids, tiletamine-zolazepam (2.0 mg/kg IV) alone provides 15 to 20 min of anesthesia and 25 to 35 min of recumbency.³⁷ Anesthesia depth is adequate to intubate nasally, but muscle relaxation is poor and oral intubation is difficult.

Propofol

This nonbarbiturate, nonsteroidal hypnotic agent can be used to provide brief periods of anesthesia (5 to 10 min). The recommended dose is 4.0 to 6.0 mg/kg IV for the induction of domestic ruminants.^{14,84–86} Induction is smooth, as is recovery. If injected too rapidly, apnea may occur. Slow administration will prevent this complication. A 2-mg/kg IV dose has been used to induce anesthesia in camelids.⁸⁷ However, tracheal intubation is often difficult at this dose, and additional propofol is usually needed. A light plane of anesthesia can be maintained with a constant infusion of propofol at 0.4 mg/kg/min IV.⁸⁷ The approximate time from discontinuation of propofol infusion to sternal recumbency is 10 to 15 min.⁸⁷ The use of infusion pumps enables a more precise propofol administration.

Maintenance

Tracheal intubation is recommended in all ruminants and camelids because it provides a secure airway and prevents aspiration of salivary and ruminal contents if active or passive regurgitation occurs. In lightly anesthetized ruminants, active regurgitation can occur during intubation^{11,68} whereas passive regurgitation can occur at any time during anesthesia due to relaxation of the cardia. Because rumen contents contain more solid material than do the gastric contents of monogastric animals, there is greater potential for ingesta to obstruct the larynx while the more fluid portion drains from the mouth. Consequently, patients that are not intubated are at higher risk of aspiration of rumen contents. Intubated animals that have regurgitated during anesthesia are also at risk following extubation. Treatment involves removal of ingesta from the buccal cavity or buccal lavage prior to extubation. If active regurgitation has occurred, anesthesia depth should be rapidly increased and the airway quickly protected to prevent aspiration.

Several techniques can be used for intubation. Adult cattle can be intubated blindly or with digital palpation. Following insertion of a mouth speculum or the use of gauze loops, the animal's head and neck are hyperextended to make the orotracheal axis approach 180°. An endotracheal tube of appropriate size is inserted and manipulated into the larynx (Table 28.1). If that technique is unsuccessful, the anesthetist's hand should be inserted into the mouth with the tube. After the epiglottis is located and depressed, a finger can be placed between the arytenoid cartilages and the tube inserted into the trachea. If desired, an equine nasogastric tube can be inserted into the larynx and serve as a guide for the endotracheal tube. Depending on the size of the animal and the individual's arm, the airway might be obstructed when this technique is performed, so it is important that intubation is prompt. If the technique requires more than 1 min, the hand and arm should be withdrawn from

Table 28.1. Sizes of endotracheal tubes needed for ruminants and camelids of various body weights

Body Weight (kg)	Endotracheal Tube Size (mm i.d.)	
	Oral	Nasal
<30	4–7	4–6
30–60	8–10	6–8
60–100	10–12	8–10
100–200	12	10–12
200–300	14–16	
300–400	16–22	
400–600	22–26	
>600	26	

i.d., internal diameter.

the oral cavity to allow the animal to ventilate before the attempt at intubation is continued.

When blind orotracheal intubation is unsuccessful in calves or other small ruminants, a laryngoscope with a 250- to 350-mm blade is required. Visibility of the larynx is improved by hyperextending the animal's head and neck to make the orotracheal axis approach 180°. Using suction or gauze on a sponge forceps to swab the pharynx will improve visibility if secretions are an impediment. Attempting intubation when the anesthetic plane is insufficient may provoke active regurgitation. With adequate depth of anesthesia, this reflex is eliminated. The epiglottis is depressed so that the larynx is visible. The endotracheal tube should be placed in the oral pharynx and inserted into the larynx during inspiration. If desired, a stylet (e.g., a 1-m 0.5-cm stylet⁸⁸ or a large male dog urinary catheter) can be inserted through the endotracheal tube. The stylet should be about 1.5 times the length of the endotracheal tube. The stylet is placed through the larynx, and the endotracheal tube is then passed beyond the end of the stylet into the trachea.

Blind oral intubation is more difficult in sheep and goats, and intubation is best performed with laryngoscopy. To perform blind oral intubation, the animal's head and neck are extended after placement of the endotracheal tube in the oral pharynx. The larynx can be palpated and the tube directed into the larynx.⁴¹ Members of both of these species have active laryngeal reflexes that may be obtunded by topical application of 2% lidocaine. This can be performed with an adjustable pattern plant sprayer⁸⁹ or with a syringe. The use of cetacaine[®] is not recommended because overdosage can easily occur and because benzocaine-based local anesthetics can cause methemoglobinemia.⁹⁰ After desensitization of the larynx, intubation can be performed with the same technique used in calves. Oral intubation performed in camelids is similar to that used in domestic ruminants. Blind oral intubation is usually unsuccessful, and laryngoscopy with a 250- to 350-mm laryngoscope is recommended. Desensitization of the larynx is usually not required.

Blind nasotracheal intubation has been described in awake or mildly sedated calves, although it requires an endotracheal tube one size smaller than that used orally.⁹¹ The technique in calves is very similar to that described for foals and is useful for induction of inhalation anesthesia or to facilitate oral surgery. Particular attention is needed to ensure that the tube is directed into the ventral meatus. Following placement of the tube in the nasopharynx, the calf's head and neck are extended to facilitate passage into the larynx. The tube is secured in place and connected to the anesthetic-delivery system connected to the anesthetic machine.

Nasotracheal intubation is also possible in sheep³⁸ and camelids,⁹² although it requires an endotracheal tube one size smaller than that used orally. Camelids are prone to epistaxis, so the use of a lubricant that contains phenylephrine is recommended. Blind nasal intubation is technically easier than blind oral intubation, but nasal intubation under laryngoscopic control is technically more difficult than orotracheal intubation. Even though nasotracheal intubation can be more difficult, it offers the option of the animal recovering with the endotracheal tube in place as a method of preventing airway obstruction during recovery. The endotracheal tube is advanced with slow gentle pressure through the external nares into the ventral meatus. An obstruction encountered at approximately 10 cm in adults is usually the middle meatus. An obstruction encountered more caudally, approximately 25 cm in adults, is likely the nasopharyngeal diverticulum.⁹² In either case, the tube should be withdrawn and redirected. If the endotracheal tube cannot be redirected past the nasopharyngeal diverticulum, placement of a prebent stylet into the tube to direct its tip ventrally is usually effective.

After the endotracheal tube has been advanced into the nasopharynx, the camelid's head and neck should be extended and the tube manipulated into the larynx. If the tube will not enter the larynx, placing the prebent stylet in the endotracheal tube to direct the tube tip ventrally into the larynx instead of the esophagus is helpful. Although visibility of the larynx is somewhat limited, oral laryngoscopy will aid intubation and confirm correct placement of the tube.

Endotracheal intubation can be confirmed with several techniques. Initially, they include visualization of the endotracheal tube passing into the larynx. When transparent endotracheal tubes are used, water-vapor condensation will appear and then disappear during each breath. One can feel gas being expelled from the tube during exhalation, and, when the endotracheal tube is connected to the anesthesia machine, synchrony between movement of the rebreathing bag and the thorax will be noted. Finally, if a capnograph is available, carbon dioxide will be detected in exhaled gas.

Anesthesia in ruminants can be maintained with halothane, isoflurane, or sevoflurane. Although methoxyflurane can be used in small domestic ruminants and camelids, induction and recovery are prolonged. Liver failure has been reported in hyperimmunized goats subjected to halothane anesthesia,⁹³ but a study performed in young healthy goats showed that halothane or isoflurane is unlikely to cause hepatic injury.⁹⁴ The NSAID flunixin meglumine should not be used immediately before or after

methoxyflurane anesthesia because renal failure may result.⁹⁵ It would appear that the use of this combination of drugs should be avoided in all species, including ruminants.

Conventional small animal anesthesia machines can be used to anesthetize ruminants weighing less than 60 kg. Conventional human anesthesia machines or small animal machines with expanded soda lime canisters are adequate for animals weighing up to 200 kg. Conventional large animal anesthesia machines can be used to anesthetize cattle weighing over 200 kg. Anesthesia is usually induced with 3% to 5% halothane, 3% to 5% isoflurane, or 4% to 6% sevoflurane and with oxygen flow rates of 20 mL/kg/min. Anesthesia is induced in animals of lesser body weight by using agent concentrations at the lower end of the range. Anesthesia is usually maintained with 1.5% to 2.0% halothane, 1.5% to 2.5% isoflurane, or 2.5% to 3.5% sevoflurane with oxygen flow rates reduced to 12 mL/kg/min. These vaporizer settings correspond to end-expired anesthetic concentrations of 1.25 to 1.5 minimum alveolar concentration (MAC) and should be adequate for ruminants that were not sedated prior to induction. Ruminants that have been sedated prior to induction can usually be maintained on end-expired anesthetic concentrations of 1.0 to 1.25 MAC, although final concentrations may vary depending on the sedative used. Because domestic ruminants have a respiratory pattern characterized by rapid respiratory rate and small tidal volume (with more dead-space ventilation), higher vaporizer settings (e.g., 2% to 3% halothane) may be required to better maintain anesthesia in spontaneously breathing patients.

Supportive Therapy

This is an important part of anesthetic practice. As veterinarians become more familiar with use of the anesthetic drugs, longer and more involved surgical procedures are attempted. As duration and difficulty increase, the likelihood of complications can also increase. Attention to supportive therapy in anesthetized ruminants and camelids can decrease the incidence of complications and improve outcome. Supportive therapy includes patient positioning, fluid administration, mechanical ventilation, cardiovascular support, and good monitoring techniques.

Patient Positioning

Improper positioning and padding of anesthetized horses have been implicated as causes of postanesthetic myopathy and/or neuropathy.⁹⁶ A similar situation may occur in adult cattle. Postanesthetic myopathy does not appear to readily occur in calves, goats, sheep, and South American camelids. Anesthetized ruminants should be positioned on a smooth, flat, padded surface. Larger adult cattle require either water beds, dunnage bags, or 10-cm high-density foam pads, whereas 5-cm-thick pads are sufficient for sheep, goats, and South American camelids. Patients positioned in dorsal recumbency should be balanced squarely on their back with both gluteal areas bearing equal weight. The forelegs and hind legs should be flexed and relaxed. External support should be placed under the maxilla to prevent hyperextension of the neck.

Fig. 28.1. Cattle positioned in lateral recumbency should be placed on padding with an inner tube placed over the dependent foreleg and that leg drawn cranially. Support should be placed under the nondependent foreleg and hind leg so they are parallel to the table.

Adult cattle in lateral recumbency should have an automobile inner tube (valve stem pointed down) placed under the shoulder of the dependent foreleg to help minimize pressure on the radial nerve as it traverses the musculospiral groove of the humerus. The point of the elbow should be positioned at 5 o'clock in the inner tube for cattle in right lateral recumbency or at 7 o'clock for cattle in left lateral recumbency. In addition, the dependent foreleg is drawn anteriorly so that the weight of the thorax rests on the triceps rather than on the humerus. Nonelastic tape covering the portion of the inner tube not under the shoulder will prevent overexpansion of that section of inner tube and will help to ensure shoulder support (Fig. 28.1). The other three legs are positioned perpendicular to the body, with the uppermost legs elevated and parallel to the table surface. Support of these legs will improve venous drainage and prevent injury to the brachial plexus. The head and neck are maintained in a slightly extended position, with the head resting on a pad or Turkish towel (Fig. 28.2). If possible, the patient's head should be positioned so that salivary secretions and gastric contents, if regurgitation occurs, will drain from the mouth and not wick between the animal's head and the pad and contact the eye. The dependent eye should be closed prior to placing the head on the padding, and bland ocular ointment should be instilled in the other eye. Camelids have prominent eyes, so special attention should be given to the dependent eye to avoid injury. Use of circulating warm-water heating blankets or convective warm-air blowers should be considered to prevent hypothermia in juvenile cattle, sheep, camelids, and goats. Adults are not as likely to become hypothermic, so the use of warm-water heating blankets is not required.

Fluid Administration

Fluid administration during anesthesia is important to correct preexisting dehydration, if present, provide volume to offset anesthesia-related vasodilatation, and provide maintenance needs. A balanced electrolyte solution is preferred. Lactated Ringer's solution, Normosol-R,[®] or the equivalent are most commonly used and are administered rapidly (10 to 25 mL/kg/h) in

Fig. 28.2. Position of the head and neck to enable fluid to drain from the oral cavity.

hypotensive patients. After hypotension is corrected, fluid administration may be slowed to 4 to 6 mL/kg/h. Although ruminants salivate copiously while anesthetized, replacement of bicarbonate is usually not required. Other fluids (e.g., saline) may be given when indicated. To increase fluid delivery rate when needed, two administration sets can be connected to one catheter with a Y connector, multiple catheters can be placed, a peristaltic pump can be used, or the fluid source may be pressurized. For convenience, fluids packaged in 3-L or 5-L bags can be used for large-volume administration. When administering large volumes of fluid, serial determinations of hematocrit and plasma total solids should be performed to prevent hemodilution and pulmonary edema. Hematocrit should remain above 25% and plasma total solids above 4 g/dL. Plasma or whole blood transfusion should be considered for hypoproteinemic or anemic individuals. Administration of sodium bicarbonate is indicated for correction of severe metabolic acidemia as determined by analysis of blood gas or total carbon dioxide.

Respiratory Supportive Therapy

Although anesthetized South American camelids ventilate well, domestic ruminants tend to hypoventilate while anesthetized. Mechanical ventilation should be considered when the procedure will exceed 1.5 h and is indicated to prevent hypoventilation in individuals that will not maintain sufficient alveolar ventilation. To minimize the effects of mechanical ventilation on the cardiovascular system, inspiratory time should be no more than 2 to 3 s, inspiratory pressure should be 20 to 30 cm of water, tidal volume should be 13 to 22 mL/kg, and respiratory rate should be 6 to 10 breaths/min. Hypocarbemia alone can cause bradycardia in ruminants. In the absence of blood-gas analysis, overall minute volume should be decreased if unexplained bradycardia occurs.

During intravenous anesthesia, ruminants also benefit from supplemental oxygen. If the animal is intubated, the endotracheal tube can be connected to a demand valve. This piece of equipment is connected to an oxygen source that enables the patient to breathe spontaneously.⁹⁷ Compression of a button on the demand

valve enables the anesthetist to “sigh” the patient. Because demand valves are designed for humans, there is an increase in the work of breathing associated with their use in large animals.⁹⁸ Intubated ruminants can also be insufflated with oxygen (5 L/min for small ruminants and 15 L/min for adult cattle). A flowmeter is connected to an oxygen source, and the tubing from the flowmeter is then inserted into the endotracheal tube.⁹⁹

Cardiovascular Supportive Therapy

Hypotension has been implicated as a cause of either postanesthetic myopathy or neuropathy.^{96,100,101} To help avoid these postanesthetic complications in ruminants, normotension should be maintained during anesthesia. Hypotension may be corrected simply by adjusting anesthetic depth. Although vasopressors can be used to correct hypotension, expansion of vascular volume either with rapid fluid administration or with the use of inotropes is a better alternative. Inotropes are preferred because they can increase stroke volume and cardiac output. Calcium borogluconate (23% solution) may also increase myocardial contractility and can be given as a slow infusion (0.5 to 1.0 mL/kg/h IV) to effect. Calcium administration may cause bradycardia, however, necessitating the use of a chronotrope if hypotension persists. Ephedrine, a mixed α and β sympathomimetic drug, can be used at 0.02 to 0.06 mg/kg IV to increase blood pressure simply by increasing cardiac contractility.¹⁰² Lack of response at low doses can indicate excessive depth of anesthesia. Dobutamine, a synthetic β -agonist, can also be used to improve cardiac output. At low doses, it increases myocardial contractility and, at higher doses, heart rate as well.¹⁰³ Dobutamine is preferred over dopamine because hemodynamics improve, with smaller increases in heart rate.¹⁰⁴ It is infused at 1.0 to 2.0 μ g/kg/min IV to effect.¹⁰³ Use of an infusion pump is recommended for convenience and consistency. After correction of hypotension, infusion rate can often be decreased for maintenance.

Monitoring

As with any species, good anesthetic techniques require monitoring to ensure that drug administration meets the animal's requirements and to prevent excessive insult to the cardiovascular, respiratory, nervous, and musculoskeletal systems, thereby decreasing the risk of complications. Monitoring includes techniques that require the tactile, visual, and hearing skills of the anesthetist, as well as the more sophisticated techniques that require instrumentation. Attention is directed to three systems: the cardiovascular, respiratory, and central nervous systems. Ideally, one monitors variables that respond rapidly to changes in anesthetic depth, which gives the anesthetist time to alter anesthetic administration before the anesthetic plane becomes either excessive or insufficient. While monitoring is done constantly, most variables are recorded at 5-min intervals. In many instances, monitoring equipment is used to aid evaluation of physiological responses to anesthesia and, therefore, anesthetic depth. Use of these instruments can make evaluation more precise and the selection of ancillary drugs more rational.

Variables that can be used to monitor the cardiovascular system are heart rate, pulse pressure (pulse strength), color of mu-

cous membranes, and capillary refill time. In healthy anesthetized adult cattle, the heart rate is usually 60 to 90 beats/min. Animals that have received an anticholinergic will have an increased heart rate. The normal heart rate for calves, sheep, and goats varies with age. Juveniles will have a heart rate of 90 to 130 beats/min, which decreases as they mature. The normal heart rate for adult anesthetized camelids after the administration of an anticholinergic is 80 to 100 beats/min. For anesthetized juvenile camelids after the administration of an anticholinergic, it is 100 to 125 beats/min. The heart rate may exceed the normal range at the beginning of anesthesia, because of excitement associated with induction or hypotension, but, most often, it returns to the normal range within 10 to 20 min. In compromised patients, the heart rate begins to approach the normal range during anesthesia as oxygen, fluid, and analgesic support begin to stabilize the patient. The heart rate usually decreases as anesthesia depth increases, although that response can be masked by prior administration of anticholinergics.

Pulse pressure can be ascertained at several locations and should be full and bounding. The common digital, caudal auricular, radial, and saphenous arteries are commonly palpated. The facial artery can be palpated in young calves, but it becomes more difficult to do so as an animal ages. Because most anesthetic agents depress the cardiovascular system and overdosage causes the heart to function less effectively as a pump, diminished pulse pressure is indicative of increased anesthetic depth. Pulse pressure should be strong and palpated at different locations for comparison. Noting the amount of turgor present in the vessel during diastole can give an indication of diastolic pressure. If the vessel is easily collapsed by digital pressure during diastole, then diastolic pressure and, therefore, systolic and mean pressure can be assumed to be low even though pulse pressure may feel adequate.

Mucous membranes should be pink, although the mucous membranes of some ruminants and camelids are pigmented, making assessment difficult. Cyanosis must also be noted, although animals breathing oxygen and an inhalation agent may be apneic for several minutes before cyanosis occurs. Because at least 5 g/dL of reduced hemoglobin is required before cyanosis can be detected, severely anemic animals may not show this sign. Flushed mucous membranes are associated with vasodilatation, which can be caused by hypercarbia, halothane, α -adrenergic antagonists, or histamine release, or may be associated with postural hypostatic congestion.¹⁰⁵ Brick-red mucous membranes are associated with endotoxic shock. Following digital compression to blanch an area of the gum, capillary refill should occur in 1 to 2 s. Both of these variables give an indication of tissue perfusion. Excessive depth of anesthesia will cause the mucous membranes to become pale and capillary refill time to increase. By combining data from these variables, one can qualitatively assess adequacy of blood pressure. For example, if an animal has a normal heart rate, strong pulse pressure, pink mucous membranes, and short capillary refill time, and its peripheral arteries are not easily collapsed by digital pressure during diastole, then one can assume that blood pressure is in the normal range. Conversely, if pulse pressure is weak, mucous membranes are pale, capillary re-

fill time is prolonged, and the peripheral arteries are easily occluded by digital pressure, then the animal's blood pressure is below normal and either anesthesia depth is excessive and/or cardiovascular support is needed.

The respiratory system is evaluated by monitoring respiratory rate and tidal volume. Spontaneous breathing rates are usually 20 to 30 breaths/min or higher in adult cattle; calves, sheep, and goats usually have respiratory rates of 20 to 40 breaths/min. Awake cattle have a decreased tidal volume when compared with horses.¹⁰⁶ That relationship persists in anesthetized cattle and other domestic ruminants in that they have a decreased tidal volume when compared with other species. Tidal volume is estimated by observing the amount the rebreathing bag empties during inspiration. Increasing the anesthetic depth can usually be expected to cause tidal volume and eventually respiratory rate to decrease. Normal values for respiratory rate in anesthetized camelids are 15 to 30 breaths/min for adults and 20 to 35 breaths/min for juveniles. Camelids tend to ventilate reasonably well when breathing spontaneously as judged by analysis of blood gas and respiratory gas during sevoflurane, isoflurane, or halothane anesthesia.

The central nervous system can be monitored by observation of ocular reflexes. The palpebral reflex disappears with minimal anesthesia depth in cattle, sheep, and goats and is usually of no value during anesthesia. The globe will rotate as anesthetic depth changes in cattle^{3,39,107} (Fig. 28.3). The eyeball is normally centered between the palpebrae in awake cattle in lateral recumbency. As anesthesia is induced, the eyeball rotates ventrally, with the cornea being partially obscured by the lower eyelid. As anesthesia deepens, the pupil becomes completely hidden by the lower eyelid; this sign indicates stage III, plane 2 to 3 anesthesia. A further increase in anesthetic depth is accompanied by dorsal rotation of the eyeball. Dorsal movement is complete when the cornea is centered between the palpebrae; this sign indicates deep surgical anesthesia with profound muscle relaxation. During recovery, the eyeball rotates in reverse order to that during induction.^{3,39,107} The globe does not rotate in response to changes in anesthesia depth in goats, sheep, or South American camelids. Usually, the palpebral reflex of the dorsal eyelid of camelids remains during surgical anesthesia. However, if the camelid can move its ventral eyelid without tactile stimulation, anesthetic depth is decreasing and eventually limb movement will occur.³⁷ Nystagmus usually does not occur during anesthesia of domestic ruminants or camelids. When it does occur, it cannot be correlated with changes in anesthesia depth. The corneal reflex should always be present.

Some ruminants will display involuntary swallowing motions under anesthesia without exhibiting other signs of insufficient anesthesia depth. This reflex may indicate that anesthesia depth is somewhat light but still appropriate. Response to pain from the surgical procedure can also be used to estimate anesthesia depth. In some instances, camelids may respond by showing a more active palpebral reflex. Purposeful movement in all species indicates insufficient depth of anesthesia. An increase in arterial pressure associated with the surgical manipulation does not necessarily indicate inadequate anesthesia if purposeful movement does not occur.

Fig. 28.3. Ocular rotation in a downward direction is indicative of surgical anesthesia.

Electrocardiography (ECG) is used with either standard limb leads (I, II, and III) or a dipole lead for detection of cardiac rate and rhythm disturbances. The lead that has the largest amplitude should be selected. A recorder is optional and useful because it enables one to record an ECG at the beginning of the case for future reference. Most ECG units emit an audible tone whenever a QRS complex is detected. Anesthetists should learn to always listen to the audible rhythm in the background during the case, especially during distractions. Because an ECG gives no information regarding blood pressure or pulse strength, emphasis should be placed on monitoring pulse and arterial pressure instead of relying solely on the ECG.

Mean arterial pressure provides an accurate variable for assessing anesthesia depth. In most instances, changes in anesthesia depth become evident quickly through increases or decreases in blood pressure. Additionally, it is a more definitive variable than monitoring pulse pressure alone. Monitoring pulse pressure determines the difference between systolic and diastolic pressure. An animal with systolic and diastolic pressures of 120/90 mm Hg will have pulse pressure similar to that of another animal with pressures of 90/60 mm Hg. However, a large difference exists in mean pressure or perfusion pressure. The former animal will have a mean pressure of about 100 mm Hg, whereas the latter will have a mean pressure of about 70 mm Hg. Since animals with low mean pressure during anesthesia are more at risk of developing complications, identification of this situation is important.^{100,101} Normal arterial pressure values in anesthetized cattle are systolic pressure, 120 to 150 mm Hg; diastolic pressure, 80 to 110 mm Hg; and mean pressure 90 to 120 mm Hg; and are typically greater than in standing cattle.¹⁰⁸ Normal values for systolic and diastolic pressure in sheep, goats, and camelids are 90–120/60–80 mm Hg. Normal values for mean pressure in sheep, goats, and camelids are 75 to 100 mm Hg. However, if camelids are aroused by painful stimuli, mean arterial pressure may approach 150 mm Hg. Arterial pressure can be monitored either indirectly or directly. Indirect methods of determining arterial pressure require the use of various infrasonic and ultrasonic devices to detect blood flow in peripheral arteries. Doppler and

Dinamap[®] devices can be used with cuffs wrapped around the tail of cattle and the limbs of sheep and goats,¹⁸ or around the tail or the limbs of South American camelids.¹⁰ The cuff diameter should be 40% of limb or tail circumference.¹⁰⁹ Direct methods require catheterization of an artery and use of a pressure transducer and amplifier or an aneroid manometer to determine pressure values. A transducer system determines systolic, diastolic, and mean arterial pressures. An aneroid manometer can be substituted for the pressure transducer and amplifier, but only the mean pressure can be obtained.¹¹⁰ Mean pressure changes rapidly in response to changes in anesthetic depth, and even the use of this rather simple system enables anesthetists to make appropriate responses.

Percutaneous arterial catheterization is easily performed in most ruminants and is relatively free of complications.^{110,111} The caudal auricular, saphenous, and common digital arteries are most commonly catheterized vessels when over-the-needle Teflon (polytetrafluoroethylene) catheters are used. Passage of this type of catheter through the unbroken skin will often damage the catheter, making arterial placement difficult. Thus, incising the skin or piercing it with a slightly larger needle at the catheterization site is recommended.¹¹¹ A skin incision is usually unnecessary when the caudal auricular artery is catheterized, because the skin is relatively thin in that location and the artery is often inadvertently pierced because the skin is relatively immobile in that area. For adults, 3- to 5-cm 18- to 20-gauge catheters are used, with 2.5- to 3-cm 20- to 22-gauge catheters used in juveniles. An extension set with stopcock is used to connect the arterial catheter to a syringe containing heparinized (2.0 units/mL) saline and a piece of noncompliant tubing attached to the pressure transducer or aneroid manometer. After the arterial catheter is removed, digital pressure is maintained at the site to prevent hematoma formation. If desired, a pressure bandage can be used.

Central venous pressure can be determined to assess venous return, myocardial function, and the need for fluid replacement. This is a good variable to use—along with serial determinations of hematocrit, plasma total solids, and urine production—in evaluating fluid replacement but often provides little information regarding changes in anesthesia depth. Normal values are 5 to 10 cm of water pressure.

Normal values for arterial blood-gas analysis are similar to those for other species.^{5,6} Respiratory gas can be analyzed to determine end-tidal carbon dioxide and inhalant anesthetic concentration. Because domestic ruminants have a respiratory pattern characterized by small tidal volume, end-expired gas might not be sufficiently representative of alveolar gas and accurate results might not be obtained. End-tidal gas analysis is more accurate when assessing carbon dioxide during controlled ventilation. Anesthetic analyzers that use optical low-spectrum infrared measurement cannot distinguish between methane and halothane in expired gas of herbivores and will report falsely increased concentrations of halothane, and to a lesser degree isoflurane, in the anesthetic circuit.¹¹² The presence of methane does not affect analyzers that use high-spectrum infrared measurement or piezoelectric measurement.¹¹² Analyzers that use low-spectrum infrared measurement can be used in herbivores by intermittently

(every 15 to 30 min) placing a small container of activated charcoal in the sample path to adsorb halothane.¹¹³ Methane will pass through the charcoal without adsorption and be measured. After removing the charcoal container from the sample path, one can subtract the concentration of background methane from the displayed value to determine halothane or isoflurane concentration.

Recovery

Ruminants and South American camelids recover well from general anesthesia and seldom experience emergence delirium, make premature attempts to stand, or sustain injuries. When an α_2 -agonist is used as part of the anesthetic regimen, an α_2 -antagonist can be used to hasten recovery.^{13,22,39,44,45,49,53,89,114}

Domestic ruminants should not be extubated until the laryngeal reflex has returned. Orally intubated camelids should not be extubated until the animal is swallowing, coughing, and actively trying to expel the endotracheal tube. Precautions should be taken to prevent camelids from damaging or aspirating the endotracheal tube. If a patient has regurgitated, the buccal cavity and pharynx should be lavaged to prevent aspiration of the material. In these instances, the endotracheal tube should be withdrawn with the cuff inflated in an attempt to remove any material that may have located to the trachea. Since camelids are obligate nasal breathers,⁹² gas exchange must be confirmed after extubation; the airway commonly becomes obstructed during the transition from oral endotracheal intubation to nasal breathing and, in severe cases, can necessitate tracheotomy. The endotracheal tube of nasally intubated camelids can be removed after they stand. Although ruminants recover well from general anesthesia with minimal assistance, an attendant should be available.

Intraoperative Complications

Fortunately, major complications do not occur often during or following well-planned anesthesia in ruminants. However, one must be vigilant so that the unexpected occurrence of a complication can be recognized and effectively treated. As is the case in anesthesia of all species, potential complications are better prevented, and therefore emphasis should be placed on formation and implementation of a rational anesthetic regimen. Airway obstruction, apnea, and hypothermia are diagnosed and treated in a manner similar to the ways in which other domestic species are diagnosed and treated.

Although anesthetized camelids do not appear to become tympanic, fermentation of ingesta and the animal's inability to eructate ruminal content often cause tympany during anesthesia. As tympany develops, more pressure is placed on the diaphragm, decreasing functional residual capacity and impeding ventilation.¹¹⁵ In addition, tympany increases the risk of regurgitation. Therapy involves passage of a stomach tube to decompress the rumen. On occasion, one will be unable to pass the stomach tube into the rumen. In these difficult cases, placing the animal in sternal recumbency will aid the procedure. When that is not possible, the rumen can be decompressed with a 12-gauge needle inserted through the abdominal wall. Fortunately, ruminal tympany is

usually of the nonfrothy type, and decompression is easily accomplished. External pressure placed on the rumen will help expel gas from the orogastric tube. Ruminal tympany can also occur during the use of nitrous oxide, which tends to accumulate in gas-filled viscus.¹¹⁶ Discontinuation of nitrous oxide administration along with decompression of the rumen is recommended.

Connective tissue is not as fibrous in ruminants' lungs, and therefore excessive airway pressure can cause pneumothorax and emphysema more easily than in horses.¹¹⁷ Signs include dyspnea and increased resistance to inspiration because of tension pneumothorax. It is treated by placement of a chest tube and aspiration of the gas. It is much easier to prevent than treat. Do not use excessive airway pressure (>30 cm of water) when "sighing" animals or when using controlled ventilation.

Cardiac arrhythmias usually do not occur in anesthetized ruminants. Atrial fibrillation can occur in cattle as a sequela to metabolic derangement secondary to gastrointestinal obstruction. Atrial fibrillation usually resolves when the primary problem is corrected. Because cattle are amenable to physical restraint and local anesthesia, corrective surgery is often performed without general anesthesia. Diagnosis can be confirmed with ECG. The oculocardiac reflex is a well-recognized reflex in most animals and can be treated similarly in ruminants.^{116,118} Cardiac arrest is treated with similar techniques commonly used in horses.^{119–121}

Postoperative Complications

Because ruminants and camelids tend to recover well from general anesthesia, long-bone fractures, cervical fractures, or other catastrophic injuries seldom occur. Should they occur, therapy is based on severity of the fracture and the economic value of the animal. Postoperative myopathy-neuropathy can occur in larger cattle but is not a problem in calves, sheep, goats, or camelids. The problem is recognized when muscle weakness or motor nerve dysfunction are observed, with some animals being unable to stand. Therapy is symptomatic, with intravenous fluids administered to maintain hydration, acid-base status, and electrolytes; along with analgesics, NSAIDs, and vitamin E–selenium compounds as indicated. Slings the animal may be helpful but can increase muscle damage. Myopathy may take several days to resolve and can be life-threatening. Again, it is better to prevent muscle or nerve damage by positioning anesthetized animals properly and avoiding excessive depth of anesthesia.

A less common cause of delayed recovery is muscle weakness caused by neuromuscular blockade. Because ruminants have very low levels of pseudocholinesterase, metabolism of succinylcholine is slow, causing prolonged effects of this drug.¹²² Neuromuscular blockade may also be caused by interaction of anesthetics and aminoglycoside antibiotics¹²³ or by incomplete reversal of nondepolarizing muscle relaxants.¹²⁴ Muscle relaxants are rarely administered to ruminants.

Thrombophlebitis can occur after perivascular injection of irritating compounds, although usually not with the frequency or severity that occurs in horses, and is treated similarly.¹²⁵ Corneal ulcers can also occur following anesthesia.¹²⁶

Aspiration pneumonia occurs after regurgitation of rumen or

gastric contents and subsequent inhalation of the material. Active regurgitation might cause the material to be inhaled deeply into the pulmonary tree, initiating bronchospasm and physical obstruction of the airways. Signs include dyspnea and, depending on severity, cyanosis. If the patient survives the initial insult, pneumonia is certain. Broad-spectrum antibiotics, anti-inflammatory therapy, etc., are indicated.¹²⁷ Silent or passive regurgitation can occur with the same results, except that there usually is not as much particulate material in the regurgitant. Similar treatment is instituted. Because of the potential severity of this complication, prevention must be emphasized. Tracheal intubation is recommended, and, if not possible, the occiput should be elevated to encourage fluids to drain from the mouth rather than into the trachea³⁸ (Fig. 28.2).

Analgesia

Providing postoperative analgesia is an important component of veterinary anesthesia. There are very few approved drugs for provision of analgesia in domestic ruminants and none approved for use in South American camelids. Drugs that have been used in other species include the NSAIDs, carprofen, flunixin, phenylbutazone, and ketoprofen; the opioids and opiates, butorphanol, buprenorphine, fentanyl, and morphine; and lidocaine and ketamine. Although α_2 -agonists can provide analgesia, their behavioral effects usually limit their use in ruminants. When applicable, local anesthetic agents can be used to desensitize structures and tissue.¹²⁸ Epidural administration of local anesthetic agents and opioids and opiates may be appropriate for some procedures.

Flunixin, which is approved for use in cattle, is dosed at 1.1 to 2.2 mg/kg IV per day. Carprofen can be given at 0.7 mg/kg IV daily.¹²⁹ When given at 4.0 mg/kg, therapeutic levels are maintained for at least 72 h.¹²⁹ Ketoprofen can be dosed at 3.3 mg/kg IV daily.¹²⁹ Phenylbutazone is recommended at a dose of 2.2 mg/kg orally every 48 h.¹²⁹ Withdrawal times following the use of NSAIDs in ruminants are not well defined either for meat or for milk, and caution must be exercised to prevent residues from entering the food supply.¹²⁹ More latitude is available when administering NSAIDs to ruminants used in biomedical research.

Use of all the NSAIDs carries the risk of ulcer formation in the third gastric compartment of South American camelids. When extended use of these agents is anticipated, it is recommended—in an effort to determine the minimal dose needed to provide analgesic effect—that dosage amount and frequency be decreased after the desired effect is obtained. Flunixin is commonly used for analgesia in South American camelids. The dose range is 0.5 to 1.1 mg/kg IV given once daily.¹³⁰ Flunixin has been given at 1.1 mg/kg twice daily. Phenylbutazone is less commonly used in camelids. When used, it is administered in a manner similar to that in domestic ruminants (i.e., 2.2 mg/kg orally every 48 h).¹³¹ Ketoprofen has also been used in llamas at a dose of 1 to 2 mg/kg IV once daily.¹³²

Opioids have been used to provide analgesia to domestic ruminants and South American camelids. Most commonly, either butorphanol (0.05 to 0.2 mg/kg IM four times a day) or morphine (0.5 to 0.1 mg/kg IM four times a day) has been recom-

mended.¹³ The effect for both drugs lasts 3 to 6 h. The use of other opioids, such as buprenorphine, fentanyl (both injectable and transdermal), hydromorphone, and oxymorphone, may be considered in dosages similar to those used in canine or equine patients.^{133–136} The dose may be adjusted if the behavioral effects become problematic (i.e., too much sedation, dysphoria, or locomotor activity).

Epidural opioids have been used extensively to provide analgesia in companion animals^{133,134,137,138} and in horses.¹³⁹ Morphine, which is the most commonly used agent, is typically administered at a dose of 0.1 mg/kg to ease postoperative abdominal and orthopedic pain and to prevent tenesmus in horses¹³⁹ and camelids.³⁷ Analgesia begins in 30 to 60 min, with the action lasting 12 to 24 h. Injection is typically through the sacrocaudal space but can also be made at the lumbosacral space. A ruminant or camelid that becomes recumbent should be placed in sternal recumbency. As in other species, the lumbosacral space is caudal to a line connecting the anterior border of the wings of the ileum. In camelids, one can usually easily palpate the spinous process of the last lumbar vertebra and direct the needle caudal to it to enter the space. The spinous process of the first sacral vertebra is much smaller than that of the last lumbar vertebra and is difficult to palpate. Usually, an 18-gauge 7-cm spinal needle is adequate. If the injection is made at the lumbosacral space, one must aspirate prior to injection to ensure that the intrathecal space has not been entered. Dose requirements are 50% to 70% less when an agent is given intrathecally compared with epidural injection. If cerebrospinal fluid is obtained, the analgesic dose must be decreased or the needle must be withdrawn for epidural placement of the drug.

Infusions of ketamine and lidocaine have been used to provide analgesia in large and small animal patients. Ketamine is effective in small animal patients when administered at a loading dose of 0.5 mg/kg IV followed by an infusion at 10 µg/kg/min.¹⁴⁰ Ketamine has also been given alone at 6.6 to 13.3 µg/kg/min IV in horses¹⁴¹ and at 40 µg/kg/min in camelids without untoward behavioral effects.¹⁴² If desired, a loading dose of 0.5 mg/kg can also be used in ruminants. Systemic lidocaine administration has been effective in reducing overall anesthetic requirements in animals under inhalation anesthesia.^{143–145} The reported lidocaine loading dose ranges from 2.5 to 5.0 mg/kg IV to be followed by an infusion of 50 to 100 µg/kg/min.^{143,145}

Provision of general anesthesia and analgesia to domestic ruminants and South American camelids for complex diagnostic and surgical procedures can be very rewarding. Although each species may exhibit unique characteristics, meeting the challenges of anesthetizing a wide variety of ruminants and camelids contributes greatly to the overall veterinary care of these species.

Prevention and Treatment

Introduction

Swine (*Sus scrofa domestica*) present a special challenge to immobilization and anesthesia. A thorough understanding of their physiological response to mechanical restraint, anesthesia, and surgery is essential for their safe handling.

Pigs come in all sizes. They range from piglets (0.5 to 3 kg) and miniatures (10 to 30 kg) to individuals that can weigh in excess of 400 kg. Most research is conducted in pigs weighing less than 50 kg, as is most field and hospital surgery. Exceptions include cesarean sections in mature sows and surgery in large boars.

The pig's anatomical structure is not conducive to manual restraint, especially when it has grown large. The pig's body is shaped such that, in the wild, it can scurry through underbrush and escape through small openings in an effort to elude its enemies. No part of its body is easily grasped for restraint.

Pigs have only a few superficial veins (primarily on the dorso-lateral surface of their ears) into which an injection can be made. As a result, drugs injected by the intramuscular route have become popular for immobilization and for induction of anesthesia. Intramuscular injections must be made with needles in excess of 3 cm in length. Shorter needles may result in injection into fatty tissue, delaying drug absorption into the bloodstream and delivery to the central nervous system (CNS). Injection into fatty tissue is one of the most common reasons for alteration of the expected response to an intended intramuscular injection of an anesthetic.

Most discussions are directly related to the importance of swine as an agricultural entity because individual market pigs have limited economic value. Valuable breeding stock is an exception. The overall value of individuals and the species as a whole increases when we consider their selective breeding potential and contribution to medical research. Pigs are physiologically more closely related to humans than are most other species. Because of this similarity, swine play an important role in human medical research. The cardiopulmonary system and other organ systems, including the skin and gastrointestinal tract, are similar to those in humans. Thus, pigs have become widely used as laboratory research animals. This has increased in recent years with the advent of genetic research directed toward various human diseases.

Several publications have reviewed anesthetic and analgesic techniques in swine for research purposes.¹⁻⁴ Domestic or commercial species (i.e., food-producing swine) have undergone genetic alterations that impact their reaction to stress and other responses to surgery and anesthesia. Veterinarians should be familiar with these variations so as to minimize the occurrence of preventable emergencies (e.g., malignant hyperthermia).

Sexual maturity occurs at approximately 6 months of age. Body weight among breeds is highly variable. Studies comparing three miniature breeds of pigs at 4 months of age clearly revealed a significant difference in heart weight to body weight ratio. When measured under the same conditions, cardiovascular parameters were significantly different among these pigs.⁵ This suggests that biological measurements should not be extrapolated among breeds or from one age to another. This variability implies the need for more information regarding the norm for various ages, sizes, breeds, and genders.

Preparation for Anesthesia

Elective surgery involving the abdominal organs is made easier when mature pigs are starved for 12 to 24 h. It is less stressful for

an isolated pig that can see and have nose contact with its fellow penmates while food is being withheld. Gastrointestinal gas will rapidly accumulate in improperly starved pigs. A full abdomen can produce enormous pressure on the diaphragm, decreasing pulmonary functional residual capacity and decreasing alveolar ventilation, as well as complicating intra-abdominal organ manipulation. This is particularly true when surgery is 2 to 3 h long. Bloat will often develop in nonfasted pigs receiving an anticholinergic. The consequences of these alterations are complicated by deep general anesthesia and any position associated with a head-down tilt. Pigs are often restrained by hoisting them by their rear legs. The head-down position can interfere with breathing already depressed by the anesthetic. When surgery is completed, the pig should be placed in an independent stall until it has completely recovered from anesthesia. Otherwise, penmates may cannibalize the recovering pig.

Sows presented for cesarean surgery are often hypotensive. If labor has been prolonged, it is not uncommon for them to be suffering from shock. It is wise to administer large amounts of balanced electrolyte fluids and antibiotics prior to surgery. Sows under these circumstances are not good candidates for extradural or subarachnoid analgesia. Either may lead to hypotension, and heavy fluid loading combined with ephedrine or phenylephrine is recommended. Fluid loading is often a difficult chore, because large peripheral veins are scarce in most breeds. An exception is mature Landrace sows (Fig. 29.1).

Restraint

Baby pigs and small potbellied pigs are easily restrained by placing one hand over their back and the other under their sternum. Rough handling, particularly during hot weather, should be avoided because it can easily cause overheating and acute death. Mature swine may be restrained with a soft cotton rope looped around the maxilla just behind the upper canine teeth. A steel-cable hog snare is also used for this purpose but is painful, and pigs soon learn to avoid its placement. Head catches similar to those designed for cattle and small ruminants can be used, but because of the shape of the pig's head and neck, a considerable amount of pressure must be exerted on the squeeze to secure the head. This excessive pressure can result in airway occlusion. A pig in the head squeeze must be observed closely to ensure that its airway remains functional.

A mobile device commonly used for restraint is a webbed-top stanchion. This apparatus is preferred over most commercial devices because it can be used to restrain pigs of all sizes. If the device is of sufficient size, several pigs can be placed on it at one time for anesthetic induction or other minor procedures. Extradural injection is easily performed when a pig is restrained in the webbing. Furthermore, the stanchion can serve as an operating table for minor elective procedures. Nylon webbing is easily sterilized by using a cold antiseptic solution or by steaming. The cart is mobile and can be used to weigh the patient and transport it into the surgery room for induction of anesthesia. Other devices are available but are expensive and designed to accommodate only one pig at a time. The size of the pig that can be restrained is also limited.

Fig. 29.1. Cannulation of the central ear vein of a Landrace sow with a 16-gauge catheter. A rubber band has been placed tightly around the base of the ear to engorge the veins so they are more easily identified.

Injection Sites

Pigs have a proclivity to store body fat. Thus, any injection intended for intramuscular deposition must be made with a needle that will reach muscular tissue. It is not desirable to inject into the ham muscles of pigs destined for human food. Although subcutaneous injections can be made, the pig's tight skin prevents injection of large volumes other than in the flank region and lateral side of the neck immediately posterior to the ear. The blood supply to fatty tissue is poor, and drug uptake and distribution from this tissue are very slow. Clinically, this often conveys a misconception about drug efficacy. The convenience of intramuscular injection is attractive, but if the drug is injected into fat, drug onset will be delayed and recovery will be prolonged. The possibility of injection into fatty tissue detracts from intramuscular injection technique in swine. This problem is frequently encountered in potbellied pigs when injections are made either in the neck or rump areas (Figs. 29.2 and 29.3).

For induction of anesthesia, intravenous injection is preferred, but the accessibility of veins is sparse in some breeds. In Landrace swine, the auricular veins are usually large and easily cannulated. Most injections are made in the central or ventrolateral auricular veins. The major artery is located on the dorsolateral aspect of the ear. Injection of an anesthetic (e.g., barbiturates) into the artery can cause tissue slough of the distal end of the ear. Using a tourniquet, it is possible to raise the cephalic vein located on the dorsomedial aspect of the forelimb between the elbow and carpus. However, this is often difficult in a struggling pig. A single needle puncture is almost essential; otherwise, a hematoma will often form, resulting in venous constriction.

In the rear limb, the femoral vein is prominent. Patient restraint for injection is a problem that often cannot be overcome unless a sedative is given. The medial and lateral saphenous veins are seldom used because of their small size and the difficulty of patient restraint when attempting vena puncture. The jugular vein can be entered if appropriate restraint is applied, but only if the vein is well cannulated should an anesthetic be injected. Of con-

Fig. 29.2. Injection into neck region of an adult potbellied pig requires at least a 1.5-inch needle to reach muscle tissue.

cern is the close proximity of the carotid artery. An alternative to the jugular vein is the anterior vena cava. Entrance is made in the jugular furrow just lateral to the manubrium sterni, with the needle directed at the opposing shoulder. The right side is usually selected for vena cava puncture, even though the left side can be used. Injections should be given slowly. The anterior vena cava puncture is primarily used for blood-sample collection and is not recommended for anesthetic drug administration.

Tracheal Intubation

The technique of inserting a tube into each individual nostril, connected by a Y piece (Carlen's adaptor) and attached to the anesthetic rebreathing system, should be discouraged. This method does nothing to protect the airway from aspiration of vomitus. Further, any attempt to ventilate an apneic pig with nasal intubation can result in gastric distension (meteorism) and displacement of the diaphragm anteriorly. Functional lung capacity is decreased, increasing the likelihood of hypoxemia. The importance of tracheal intubation cannot be overemphasized. It provides a means of alveolar ventilation and protects the airway and lungs from aspiration of foreign material.⁶

Two primary body positions, dorsal or sternal recumbency, are used for tracheal intubation. The technique that best serves the anesthetist should be chosen. Once proficiency has been gained, body position is of little or no importance. Placing pigs in sternal recumbency appears to be best for those anesthetists that have had little or no experience. Gauze strips or small cotton ropes are placed behind the upper and lower canine teeth to open the pig's mouth. A mouth wedge designed specifically for swine may be

Fig. 29.3. Injection into the rump of an adult potbellied pig requires at least a 1.5-inch needle for intramuscular drug deposition.

used with or without gauze strips. The pig's head should be extended, but excessive extension will make the arytenoid cartilages (i.e., laryngeal opening) more difficult to identify and in some cases can actually occlude the airway. For pigs weighing more than 50 kg, a laryngoscope with a 205-mm blade with an extension (4 to 8 cm long) is desirable. Although some anesthetists use the blade tip to depress the epiglottis, it is more desirable to set the blade so that when the handle is raised the tip of the blade displaces the base of the epiglottis ventrally, providing maximal exposure of the laryngeal opening. A local anesthetic (e.g., 1 to 3 mL of a 2% to 4% solution of lidocaine sprayed directly into the laryngeal opening) will relieve laryngeal spasms and coughing when intubating a lightly anesthetized pig. Succinylcholine (1 to 2 mg/kg intravenously [IV]) may be given, but this drug may trigger malignant hyperthermia in susceptible swine. Furthermore, because the rimpharynx is so small and because the mouth cannot be opened widely, a plastic guide stylet (three times the length of the endotracheal tube) placed a short distance into the trachea can be safely used to guide the endotracheal tube through the larynx. Only cuffed tubes should be used in mature swine. When using a guide tube, it must be held stationary as the endotracheal tube is being inserted over it. A stiff stylet that is advanced deeply into the respiratory passages can injure the bronchial and peribronchial tissues. Tension pneumothorax could be a sequela.

A quick review of the anatomy of the pig's larynx (Fig. 29.4A and B) illustrates the tortuous course a tube must take to pass through the larynx and reach the trachea. When passing the tube without the aid of a stylet in a pig placed in a sternal position, the natural tube curvature is placed so that the tip is ventral. As the tube is advanced, it will meet resistance when the tip contacts the posterior floor of the larynx. At this point, rotate the tube 180° and apply minimal pressure. A correctly sized tube will be felt to start its descent into the trachea, at which time it should again be rotated back to its original position (i.e., with the curvature dorsal and the tip ventral). Some individuals with extremely fat jowls (e.g., large potbellied pigs) can often best be intubated while in lateral or dorsal recumbency (Fig. 29.4C). These posi-

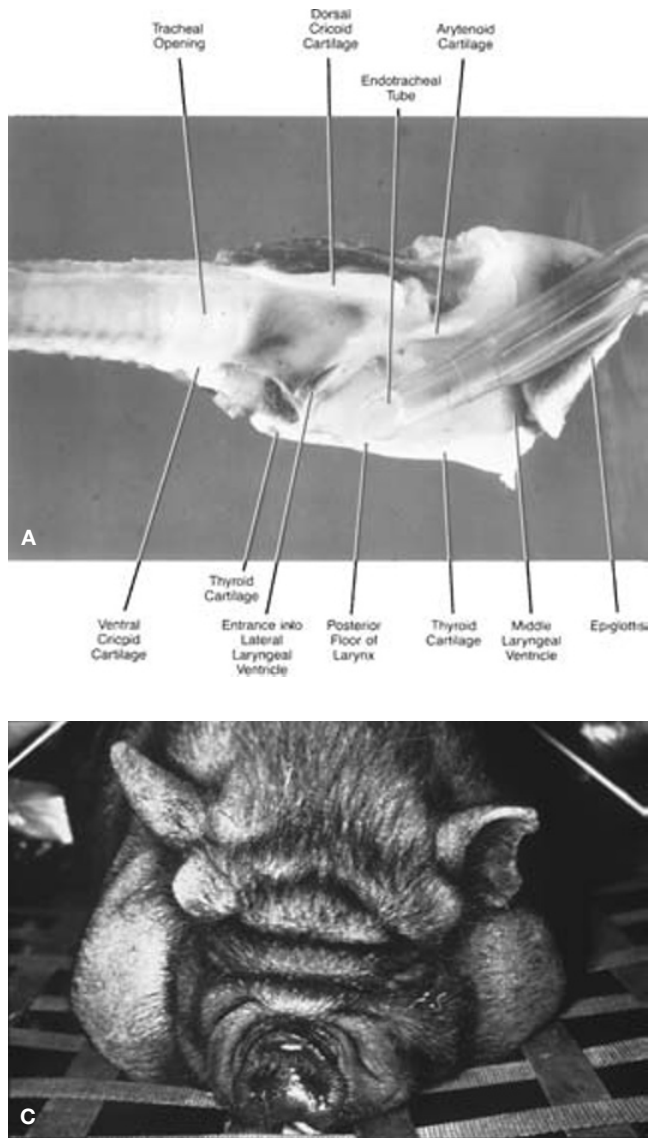

Fig. 29.4. **A:** A sagittal view of a pig's larynx and trachea. Note the acute angle between posterior portion of the larynx and the tracheal opening. Passage of the endotracheal tube is often difficult because of the entrapment of its tip in the floor of the larynx. Prior placement of a guide stylet through the tracheal opening will prevent entrapment of the endotracheal tube in the middle laryngeal ventricle just anterior to the thyroid cartilage and the posterior floor of the larynx anterior to the cricoid cartilage when the tube is passed into the trachea. **B:** A sagittal view of a potbellied pig's head with the endotracheal tube being positioned with the aid of a guide stylet. Note the small oral passageway and the tortuous route the tube must take through the larynx to finally enter the trachea. **C:** Potbellied pigs are often difficult to intubate, especially when extremely brachycephalic.

tions allow for a more direct route through the larynx and into the trachea. The size of the endotracheal tube is important. Practically, one should have three sizes at hand: the one thought to be correct, one size larger, and one size smaller. Tube sizes will range from 3 to 4 mm for piglets up to 16 to 18 mm in large boars or sows (Table 29.1).

Traumatic intubation that injures the delicate laryngeal mucosa can have a serious consequence. Formation of a hematoma or generalized laryngeal edema may go unnoticed, only to become evident when the tube is removed during recovery. Under all circumstances, the tube should not be removed until the pig is indicating laryngotracheal tube awareness as it awakens (e.g., coughing) or otherwise rejects the tube. A light spray of 2% to 4% lidocaine into the laryngeal opening just prior to or at the time of tube removal will often prevent laryngospasm after tube withdrawal.

The use of a laryngeal mask airway for induction of anesthesia with inhalation anesthetics eliminates the requirement for IV

Table 29.1. Endotracheal tube sizes for swine.

Swine size	Tube size (mm)
Piglets	3–5
10–15 kg	5–7
20–50 kg	8–10
100–200 kg	10–14
Larger pigs	16–18

injected drugs for induction, thus eliminating a major step in the anesthetic process of swine.⁷ This technique was initially designed for people and has not been evaluated for use with artificial ventilation, which requires sealing of the upper airway. Endotracheal intubation is not technically difficult for experienced individuals.

Anesthetic Induction, Monitoring, and Recovery

Induction and Monitoring

The thiobarbiturates are the standard to which other injectable anesthetics are compared. Two other major classes of anesthetics that are commonly used in swine are the dissociatives (e.g., ketamine) and the inhalants. Induction drug popularity ebbs and flows but in large part is governed by proper preanesthetic medication. As in other species, so long as pigs are not overdosed, the chosen induction drug or drugs are of minimal importance.

The thiobarbiturates are considered monoanesthetics but are poor analgesics. The anesthetic dose is very close to the apneic dose. Repeated injection will saturate tissues and prolong recovery. There is no specific antagonist for barbiturates. Some drug combinations will provide better laryngeal relaxation than do barbiturates. A combination that provides good laryngeal relaxation consists of guaifenesin, ketamine, and xylazine (triple drip).

When anesthesia is being induced with an inhalant (e.g., halothane or isoflurane) in oxygen, there is a minimal amount of time to complete the intubation procedure once the nose cone is removed. Until regular breathing and signs of surgical anesthesia occur, the nose cone should be kept in place. Thus, the general procedure is to remove the nose cone, open the pig's mouth and quickly spray the laryngeal opening with lidocaine, replace the nose cone, and continue with inhalant administration. For intubation, the laryngeal opening is exposed and identified with a laryngoscope, and the tube put in place by one of two methods described earlier. After proper positioning of the tube, the cuff is inflated so that when a pressure of 18 to 20 cm H₂O is applied to the rebreathing circuit, a slight escapement of air can be heard from the pig's mouth.

Apnea is simply dealt with by rhythmically squeezing the rebreathing bag four to eight times per minute or by the use of an Ambu resuscitator bag when the patient is not connected to an anesthetic-rebreathing system. With the latter, either oxygen or ambient air can be used. Excessive ventilation will decrease blood carbon dioxide (CO₂) concentration and may prolong apnea. Experience gained in intubating pigs will increase an anesthetist's confidence and proficiency. Furthermore, an assistant who understands the anatomy of the pig's airway and appreciates the importance of keeping the pig's head and neck properly positioned is essential for a clean, safe, tracheal intubation.

The bispectral index (BIS) is a variable derived from an electroencephalogram that has been reported to be a measure of the hypnotic component of the anesthetic state. It has been used in people and animals to provide a measure of anesthetic depth. In swine, BIS values have a poor correlation with anesthetic depth and do not predict changes in arterial blood pressure or heart rate.^{8,9} Nor have bispectral index values been useful for predicting recovery from either sevoflurane or propofol anesthesia.⁹ It appears that BIS values should not be solely relied on to monitor anesthesia depth in swine.

Care During Recovery

Apnea resulting from laryngeal hematoma, edema, and/or spasms can occur and quickly cause death once the endotracheal

tube is removed. Spraying the larynx with a modest amount of phenylephrine (Neosynephrine) prior to tube removal may be helpful in decreasing vascular congestion and edema formation in some cases. Thus, monitoring respiration and other signs during recovery is of the utmost importance. Less vigilant monitoring is required once a pig has gained its righting reflex and can maintain sternal position. Difficulty in breathing and restlessness accompanied by hypoxemia are usually the first signs of a traumatic recovery that must be dealt with at once, because time is crucial. Laryngeal edema can be treated by reintubation, but attempting to intubate a struggling pig is usually futile. If the intravenous catheter is still in place, the pig can be reanesthetized and an endotracheal tube quickly positioned to support ventilation. In extreme emergencies, it may be more efficient and less time consuming to quickly perform a tracheostomy after local anesthetic infiltration of tissues around the trachea.

It is important to keep piglets warm during recovery. If the chest or abdomen has been opened for any length of time in small pigs, it is essential to prevent further loss of body temperature and provide a source of external heat by covering the pig with a blanket or by using a warm-air-circulating device. Wrapping the extremities in bubble sheeting, the type used to pack fragile items for shipment, is helpful. Also, a sheet of this material between the patient and a cold surgical tabletop will help maintain body temperature. Warm fluids should be administered whenever possible.

Postoperative pain should be treated with appropriate analgesics. α_2 -Adrenoceptor agonists, opioids, and local anesthetics can be administered alone or in combination to induce analgesia. These drugs have also been injected alone and in combination in the epidural space to provide postoperative analgesia. Opioid agonist-antagonists that can be injected parenterally in pigs to relieve postoperative pain include pentazocine (0.4 to 0.5 mg/kg intramuscularly [IM]), butorphanol (0.1 to 0.5 mg/kg IM or IV), nalbuphine (0.15 to 0.2 mg/kg IM), and buprenorphine (0.1 to 0.2 mg/kg IM or IV). Transdermal fentanyl patches that deliver 50 or 100 μ g/h can also be used to control postoperative pain for 3 to 4 days.

Injectable Drugs

Parasympatholytic Drugs

The anticholinergic drugs atropine sulfate and glycopyrrolate are commonly used in swine. Because bradycardia is seldom a problem in anesthetized swine, the main use of these drugs is to inhibit excessive salivation. Neither drug is routinely required. Generally, the pig has a heart rate faster than 80 beats/min. Under clinical situations, a heart rate faster than 120 beats/min is not uncommon. Anticholinergics increase heart rate and thus myocardial work and oxygen consumption. Tachycardia can lead to a variety of other arrhythmias and, if not properly dealt with, can end in cardiac arrest. Preexisting bradycardia (i.e., heart rates below 50 beats/min) should be treated with either atropine (0.02 to 0.04 mg/kg IM) or glycopyrrolate (0.005 to 0.01 mg/kg IM) prior to anesthesia induction. Unlike cats and cattle, swine will respond to anticholinergics with a drier mouth. The airway will be drier and intubation easier. The major contraindication to this

class of drugs is an existing tachycardia, as may be seen in patients with fever, extreme excitement, or hyperthyroidism.

Because swine occasionally vomit during the recovery period, glycopyrrolate would seem to be the anticholinergic of choice. This drug tends to decrease gastric fluid secretion and acid content and, unlike atropine, promotes gastric emptying. Further, glycopyrrolate is a large quaternary ammonia compound and does not readily cross the blood-brain barrier. In people, glycopyrrolate is considered to be about twice as potent an antisialagogue as atropine and has a longer action.¹⁰

Ataractics (Tranquilizers)

Phenothiazine derivatives are not as effective in swine as in many other species. Although tranquilized swine are easier to approach, they will still resist mechanical restraint vigorously. It seems that the most effective tranquilizer in swine is azaperone (a butyrophenone derivative). Most tranquilizers offer little or no analgesia. Thus, their use in anesthetizing swine is limited unless they are combined with other drugs that induce analgesia and depress CNS activity. For example, Innovar-Vet (droperidol and fentanyl) will provide reasonable calming if administered in pigs experiencing pain. However, if aroused, pigs often sneeze and appear to become more excited after drug injection. When Innovar-Vet is combined with xylazine, sedation is more pronounced, and pigs often lie quietly for some time. However, pigs will often respond vigorously to painful manipulation. Veterinary practitioners have reportedly given extremely large doses of phenothiazine tranquilizers along with local analgesics to induce intense quiescence in older sows undergoing cesarean section. The use of these high doses can induce intense vascular alpha-receptor blockade, resulting in hypotensive shock, and should be discouraged. Many of these sows fail to recover, even though their piglets reportedly recover satisfactorily. The use of high doses of a tranquilizer as a substitute for an anesthetic is improper in any species.

Butyrophenone tranquilizers include droperidol, fluanisone, and azaperone. Although azaperone is often used as a preanesthetic, its predominant use (2.5 mg/kg IM) is to prevent fighting and anxiety among newly mixed pigs. Large doses will induce deep tranquilization and hypotension. The recommended intramuscular dose of azaperone for preanesthetic tranquilization ranges from 2 mg/kg in older, large swine to 8 mg/kg in young swine for purposes of immobilization. The use of droperidol as a sedative in pigs has also been described. A dose of 0.3 mg/kg IM induced sedation within 5 min, with a duration of about 2 h.¹¹

The benzodiazepines (i.e., minor tranquilizers) are useful in swine but expensive. Although there are many benzodiazepine derivatives, diazepam and midazolam are most frequently used in North America. Reportedly, flurazepam (2 mg/kg IV),¹² lorazepam (0.1 mg/kg IV),¹³ brotizolam (1 to 10 mg/kg orally),¹⁴ and zolazepam (a component of Telazol) produce good effects in swine. Benzodiazepines induce hypnosis, sedation, and muscle relaxation, but little or no analgesia. Thus, they are generally combined with an anesthetic or strong analgesic to enhance anesthetic action. Diazepam (1 to 10 mg/kg IM or 0.5 to 2.0 mg/kg IV) is usually combined with ketamine and xylazine or with an

inhalant for its additive muscle-relaxing and sedative effects. Diazepam, as is true of most benzodiazepine derivatives, will decrease anesthetic requirement even though it is not a strong analgesic. When given in large doses, benzodiazepines prolong recovery. This is particularly true in older sows and boars given large intramuscular doses. Midazolam, unlike diazepam, is water soluble and may be given by either the intravenous route or intramuscular route without causing severe pain. The dose ranges from 0.1 to 0.5 mg/kg, with 0.5 mg/kg IM providing adequate sedation for conducting minor procedures in swine.¹¹ Midazolam is approximately twice as potent as diazepam.

Sedation can be achieved with intranasally injected midazolam (0.2 or 0.4 mg/kg).¹⁵ Midazolam induces significant calming and sedation within 3 to 4 min. The optimal intranasal dose of midazolam to induce rapid and reliable sedation in laboratory piglets is approximately 0.2 mg/kg.

Flumazenil is a specific benzodiazepine antagonist. The minimal effective dose for reversal of diazepam or midazolam has not been established in swine. Clinical experience suggests that a dose of 1 part flumazenil to 13 parts of a benzodiazepine agonist will adequately antagonize lingering sedation and muscle relaxation (e.g., if 1.3 mg/kg of diazepam is given, 0.1 mg/kg of flumazenil is required). When using this ratio, flumazenil demonstrates good efficacy in antagonizing the residual muscle-relaxing actions of zolazepam in mature swine.

α_2 -Adrenoceptor Agonists

The α_2 -adrenoceptor agonists available for veterinary use include xylazine, detomidine, romifidine, and medetomidine. However, only xylazine has been used to any great extent in swine. Although xylazine is an extremely potent sedative in other animal species, it is not in swine. After injection of xylazine or detomidine, some sedation is apparent. Pigs will usually lie down in 10 to 15 min but, when approached, will rapidly rise and flee. Thus, in swine, xylazine is usually combined with other drugs. For example, xylazine and ketamine have become a popular anesthetic drug combination for use in swine. The dose of xylazine ranges from 1 to 2 mg/kg administered either IM or IV. The intravenous dose of detomidine or medetomidine is 40 μ g/kg, whereas the intramuscular dose of either agent is reportedly 80 μ g/kg. Sedation from α_2 -adrenoceptor agonists can be effectively antagonized with either yohimbine (0.15 to 0.2 mg/kg IV) or tolazoline (2 to 4 mg/kg IV). Atipamezole, which is also a very effective α -adrenoceptor antagonist, has been used at doses ranging from 200 to 300 μ g/kg IM to reverse α_2 -agonist effects in pigs.¹⁶

In isoflurane (1.3% end-tidal sample)-anesthetized swine (15 to 35 kg), studies designed to test the analgesic effects of xylazine, medetomidine, and detomidine revealed that xylazine (2 mg/kg) and medetomidine (40 μ g/kg), but neither detomidine (40 μ g/kg) nor the α_2 -antagonist atipamezole (200 μ g/kg), provided short-term analgesia.¹⁷ All α_2 -agonists increased blood pressure. Of interest, atipamezole administration increased blood pressure, apparently as a result of an increase in heart rate, that persisted throughout the postanesthetic observation period. These results suggest that α_2 -agonists provide only short-term analgesia and

that their use as preemptive analgesics may not be an appropriate choice.

α_2 -Agonist Epidural Analgesia

Xylazine has both α_1 and α_2 activity, whereas detomidine acts predominately at α_2 -adrenoceptors. Both alpha-subtype receptors are located in the dorsal horn of the spinal cord.^{18,19} Also, analgesia can be induced by both α_1 - and α_2 -adrenergic agonists when injected intrathecally.²⁰ This finding supports the speculation that xylazine-induced analgesia is mediated in part by α -adrenoceptor stimulation. The ratio of α_1 - to α_2 -adrenoceptors in the spinal cord of domestic swine has not been determined. Xylazine induces more profound analgesia than does detomidine in this species.¹⁹ In pigs receiving either intrathecal xylazine or detomidine, the response is different after a pure α_2 -antagonist (e.g., atipamezole) is administered. In detomidine-treated pigs, sedation, analgesia, and immobilization are quickly abolished after intravenous injection of atipamezole. In xylazine-treated pigs, however, sedation is abolished, but loss of motor and sensory responses posterior to the site of xylazine injection remains.¹⁹ Seemingly, this indicates the presence of a xylazine-induced spinal local analgesic effect. This has also been reported in horses and cattle.²¹⁻²³ Although epidural injection of either xylazine or detomidine induces some sedation, analgesia, and immobilization, the intensity of analgesia appears to be greater with xylazine. Xylazine's superior analgesic action could be mediated by either its α_1 -adrenoceptor activity located in the dorsal horn of the spinal cord and/or a local analgesic effect independent of α -adrenoceptor stimulation.¹⁹

With this knowledge, sows weighing from 150 to 225 kg scheduled for a cesarean section can be given an epidural injection of 10 mL of 2% lidocaine containing xylazine at a dose of 0.5 to 1.0 mg/kg. The onset of sedation, analgesia, and rear-limb immobilization are rapid. Complete immobilization of the rear quarters lasts for approximately 3 to 4 h. Sows will lie quietly for over 1 h, at which time some front-limb movement may occur. Even though there is some xylazine-induced sedation, the forelimbs should be tethered. Piglets are lively when delivered and experience no difficulty in breathing. Lingering sedation can be effectively antagonized with either yohimbine (0.15 to 0.2 mg/kg IV), tolazoline (2 to 4 mg/kg IV), or atipamezole (200 to 300 μ g/kg IM). Veterinarians skilled in the technique of epidural injection will find this a useful anesthetic regimen for use in swine when analgesia posterior to the umbilicus and mild sedation are both required.

Barbiturates

Because barbiturates are given primarily by intravenous injection in the ear vein, dilute solutions are preferred (i.e., 5% concentration or less). Perivascular injection will often cause sloughing of the skin surrounding the vessel. The thiobarbiturates (i.e., thiopental and thiamylal) and oxybarbiturates can be used in swine either by a repeated bolus technique or by continuous infusion.^{24,25} If properly ventilated, pigs will survive extraordinarily large doses over time, but recovery may be extremely long. Because of their rapid onset and shorter duration of action in

swine, thiobarbiturates (e.g., thiopental) are preferred over oxybarbiturates (e.g., pentobarbital). The effect of a barbiturate may be enhanced with xylazine (1 to 2 mg/kg), ketamine (2 to 4 mg/kg), a benzodiazepine (e.g., diazepam, 2 to 4 mg/kg), or another tranquilizer (e.g., azaperone, 2 to 4 mg/kg). When a barbiturate is used alone for more than a brief period of surgical anesthesia, the patient's trachea should be intubated, and a means of instituting positive pressure ventilation must be at hand. An Ambu bag will serve this purpose well because it may be used to ventilate with ambient air or oxygen. Properly ventilated pigs can tolerate three times the surgical dose of a barbiturate. Death of swine from barbiturates is usually a direct result of respiratory arrest.

Pentobarbital is vaguely classed as a short-acting barbiturate, but when dosed repeatedly or administered as a constant infusion, recovery will be prolonged. The anesthetic dose of pentobarbital ranges from 20 to 40 mg/kg IV. When given as a continuous infusion, the recommended dose is 5 to 15 mg \cdot k⁻¹ \cdot h⁻¹.^{24,25} Xylazine will decrease the anesthetizing dose of pentobarbital measurably, as will diazepam or ketamine.²⁴

Pentobarbital is an extremely effective anticonvulsant. Diazepam can be given for this purpose but has a shorter period of action and is much more expensive. In addition, dysphoria, often seen in swine recovering from ketamine administration, can be controlled with pentobarbital (6 to 10 mg/kg IV or IM). When possible, the smaller dose is given slowly IV. When intravenous injection is not possible, the larger dose (10 mg/kg) diluted to 3% or less with saline or water may be given IM. When administered IM as a dilute solution, pentobarbital should be injected deeply into a large muscle mass. In commercial swine, the most appropriate site for intramuscular injection is the neck muscle just caudal to the ear.

Commercially available thiobarbiturates are sold as desiccated powders and solubilized with either distilled water or saline. Concentrations of 2.5% to 5% are preferred. Until the removal of thiamylal from the market, it was the most widely used barbiturate in veterinary patients, including swine. Thiobarbiturates are characterized as being ultra-short-acting. This is somewhat of a misnomer inasmuch as duration of action correlates directly with total dose. More correctly stated, these barbiturates have a more rapid onset of action than oxybarbiturates.

The thiobarbiturates are more soluble in blood and tissue than are the oxybarbiturates (e.g., pentobarbital). Thus, the induction dose is less and recovery time is shorter after a single bolus injection of thiobarbiturate. As with the oxybarbiturates, thiobarbiturates are sometimes used as monoanesthetics. Analgesia is minimal until deep planes of anesthesia occur. As previously stated, the dose for deep surgical anesthesia is very close to the apneic dose. The induction dose of either thiopental or thiamylal ranges from 10 to 20 mg/kg IV. The higher dose is given in unpremedicated young swine and the lower dose in sedate or tranquilized swine. To a large extent, the dose depends on the degree of analgesia and immobilization required. For example, procedures that are pain free, such as radiography, require a minimal dose. The dose also depends on the physical condition of the patient and availability of respiratory support equipment. When thiamylal or

thiopental is used as a continuous infusion to maintain anesthesia, the recommended dose is 3 to 6 mg · kg⁻¹ · h⁻¹ IV.^{24,25}

Because the swallowing reflex remains intact after induction with a dissociative (e.g., ketamine or tiletamine), a small dose of thiopental (4 to 6 mg/kg IV) can be used to abolish laryngeal reflexes that interfere with endotracheal intubation. Specific antagonists for barbiturates are unavailable at this time. However, after ensuring a patent airway, an analeptic such as doxapram (0.50 to 1.0 mg/kg IV) can be used to stimulate breathing. This effect can be short-lived in patients that have received large doses of a barbiturate. Under such circumstances, mechanical ventilation should be initiated and continued until the pig reinitiates spontaneous breathing.

Injectable anesthetic drug combinations, because of ease of administration and economic concerns, have become extremely important in swine destined for short-term anesthesia. An important study used 46 mature swine to compare the effects of several anesthetic combinations. One group was given azaperone (1.0 mg/kg IM) and ketamine (2.5 mg/kg IM), a second group received etomidate (200 µg/kg IV) followed by midazolam (100 µg/kg IM), and a third group was given ketamine (2 mg/kg IM) and midazolam (100 µg/kg IM). The remainder of the pigs ($n = 15$) were given pentobarbital (15 to 20 mg/kg IV). Clinical comparison of the foregoing drug combinations with pentobarbital alone clearly revealed that pentobarbital caused more respiratory depression and a higher complication rate than all the other drug combinations.²⁶ Pentobarbital caused severe respiratory depression. Apnea occurred in two pigs and was fatal in one. Positive-pressure ventilation with oxygen was required in three other pigs to sustain pulmonary function. It seems that, although pentobarbital is a useful injectable anesthetic, surgical anesthesia with this drug requires close patient observation and ventilatory support. As a matter of fact, when pentobarbital is used alone, veterinarians should be prepared to deal with apnea; otherwise, anesthetic catastrophes are inevitable. In summary, the thiobarbiturates are useful in swine, but they cannot be recommended as monoanesthetics for prolonged surgery without controlled ventilation and/or when rapid patient recovery is required.

Methohexital is an ultra-short-acting methylated oxybarbiturate that is approximately three times as potent as thiopental. It is usually prepared in a 2.5% solution. In veterinary practice, it has been used primarily in sight hounds because of its brief action. It has proven an effective induction anesthetic in many species when administered IV. It may also be given to maintain anesthesia by continuous infusion. However, it induces muscle fasciculations during induction, and recovery is often described as rough in swine not receiving preanesthetic medication (e.g., xylazine or azaperone). Methohexital is used most often to induce anesthesia, followed by maintenance with an inhalant. As with the thiobarbiturates, the dose varies considerably and depends on the type and amount of preanesthetic given. In healthy, unpremedicated, commercial swine, the dose ranges from 6 to 10 mg/kg IV. In potbellied pigs, one-half to two-thirds the dose recommended for commercial swine appears to be appropriate.

Recovery from a single anesthetizing dose of methohexital is usually complete in 20 to 30 min. As with all barbiturates, respi-

ratory depression and apnea are the most serious problems encountered when high doses are injected rapidly IV or when repeat doses are given. The necessity for repeat administration has been largely resolved under field conditions by providing complete analgesia with local infiltration of the surgical site or epidural injection of a local anesthetic. Lidocaine (2%) is a reasonable choice for local infiltration and often enables completion of minor surgery as the pig recovers from barbiturate-induced unconsciousness.

Dissociatives

Drugs disconnecting higher brain centers (thalamocortical) from lower centers (limbic systems) are referred to as *dissociative* anesthetics. The first dissociative used in veterinary anesthesia was phencyclidine hydrochloride. Although its use in swine and bears gained some popularity, illicit use as a street drug resulted in its removal from the medical market. Subsequently, tamer and perhaps less addictive derivatives were synthesized: ketamine and tiletamine. These drugs have become popular for anesthesia induction and brief surgical procedures when combined with α_2 -agonists, opioids, and/or benzodiazepines.

Ketamine, an extremely popular and widely used anesthetic in people and animals, and its predecessor, phencyclidine, are often referred to as “pig tranquilizers” by uneducated individuals. Attempts to use these agents as monoanesthetics in swine have not induced effective surgical anesthesia. On the other hand, when combined with opioids, benzodiazepines, and or α_2 -agonists, the level of anesthesia and analgesia increases. Such drug combinations can be used to provide both long-term and short-term anesthesia in swine. Typically, prolonged anesthesia and analgesia requires coadministration of sedative and analgesic drugs. Without added sedation and analgesia, recoveries can be extremely rough and prolonged.²⁷

Tiletamine is available only in a proprietary compound (Telazol). This drug combination consists of a 1:1 mixture of tiletamine and zolazepam. The latter is a benzodiazepine similar to diazepam but more potent. Anesthesia induced with dissociatives is characterized by incomplete muscle relaxation, often referred to as a *cataleptoid state*. Zolazepam tends to relieve this problem by providing muscle relaxation but does not seem to add measurably to analgesia.

Dissociative-induced analgesia appears to result in part from its action on *N*-methyl-D-aspartate (NMDA) and opioid receptors. However, attempts to antagonize ketamine's action with naloxone have not been effective.²⁸ During ketamine anesthesia, the patient's eyes remain open and the swallowing reflex usually remains intact. However, this does not prevent the patient from aspirating vomitus should vomiting occur during anesthesia. Vomition can be a real threat when pigs are not properly fasted. In people, ketamine-induced analgesia has been described as intense.²⁹ From clinical and laboratory observations, ketamine does not appear to induce analgesia in swine of the same magnitude as that described in people.³⁰

Because ketamine induces excessive salivation in swine, it seems logical to administer an anticholinergic (atropine, 0.04 mg/kg IM). However, the use of atropine should be avoided in

patients with tachycardia or fever. When given IM at a dose of 10 to 12 mg/kg, ketamine will immobilize swine in approximately 5 min. Although xylazine does not provide good muscle relaxation or sedation when given alone, it will greatly enhance the anesthetic effects of ketamine. The xylazine dose range is 2 to 3 mg/kg IM or 1 to 2 mg/kg IV. When combined with ketamine, xylazine improves analgesia and muscle relaxation.⁴ When necessary, anesthesia can be prolonged in healthy patients by using 2 to 4 mg/kg of ketamine and 0.5 to 1.0 mg/kg of xylazine mixed in the same syringe and injected slowly IV. When an auricular vein can be cannulated prior to induction, ketamine should be administered IV. A smaller dose is required (4 to 6 mg/kg). Recovery is quicker and excitement during recovery is less likely to occur with the lower intravenous dose. Excitement during recovery is most often seen in old, mature sows and boars but is less likely when xylazine is a part of the anesthetic regimen.

Because physical restraint is frequently difficult in mature swine, the intramuscular route is often used to immobilize large patients. A drug combination that reportedly works well when administered IM is ketamine (4 mg/kg), oxymorphone (0.15 mg/kg), and xylazine (4 mg/kg). If an intravenous injection can be made, the dose of each drug is decreased by one-half.^{4,31} This drug combination, although expensive, offers relatively good analgesia and muscle relaxation. Recovery is generally smooth and can be hastened with naloxone and yohimbine administration. It should be remembered that oxymorphone and xylazine reversal antagonizes postoperative analgesia and sedation. An excitatory response may ensue.

Ketamine (6 to 8 mg/kg) and xylazine (1 to 2 mg/kg) drawn into the same syringe may be safely used to anesthetize large boars for castration. One-half of the drug combination is injected deep into the center of each testicle. Rapid castration removes the remaining drug contained in the testicle, promoting a rapid recovery. Large doses of pentobarbital have also been administered intratesticularly for the same purpose, but recoveries are considerably longer.

The 5-mL vials of Telazol contain 250 mg of tiletamine and 250 mg of zolazepam. Zolazepam is similar to diazepam but is water soluble and more potent than diazepam. As previously mentioned, zolazepam has a central muscle-relaxant action that partially relieves the cataleptoid state induced by a dissociative. Excessive or repeat dosing of Telazol can cause prolonged recovery, particularly in older swine and other large species. Telazol is approved only for intramuscular use in dogs and cats but has been widely used in other species, including swine.

Telazol alone does not provide enough CNS depression and analgesia for most surgical procedures but can be an effective anesthetic in swine when combined with the proper adjunct. Presently, xylazine is the most popular drug for this purpose. α_2 -Agonists have been shown to decrease the requirement for inhalant anesthesia by as much as 90%. Telazol (6.6 mg/kg IM) combined with xylazine (2.2 mg/kg IM) immobilizes 20- to 30-kg pigs in 1 to 2 min, and the anesthetic time extends up to approximately 1 h. Tracheal intubation is easily performed.³² These drugs can be mixed in the same syringe for easier administration. Prolonged recoveries have been experienced in old sows and

boars when given the dose reported for 20- to 30-kg pigs. Extended recoveries are more likely when this drug regimen is administered IM or after redosing to extend anesthesia. Prolonged recovery appears to be due in large part to zolazepam's lingering effects. Consequently, smaller intravenous doses are recommended for older swine (Telazol, 2.2 to 4.4 mg/kg; and xylazine, 1.1 mg/kg). When using the intravenous route, anesthesia may be safely extended by giving one-half the original dose as required.

Telazol and xylazine have been used extensively to immobilize collared peccaries (*Tayassu tajacu*) and feral swine (*Sus scrofa*) for several years. This drug combination, when precisely combined, is one of most effective immobilizing compounds for swine when injected IM. Of interest is a study that shows that a 1:1 mixture of Telazol and xylazine (100 mg Telazol + 100 mg xylazine/mL) effectively and safely immobilizes wild collared peccaries as well as feral domestic swine (*Sus scrofa*). The mixture dose of 4 to 5 mg/kg IM was effective in both species. Immobilization time was rapid (4 to 5 min), and recovery times ranged from 54 to 78 min.³³

Another report has suggested that a combination of Telazol and xylazine effectively and safely immobilized the babirusa species (*Babirusa babirusa*).³⁴ Anesthesia in females required a higher induction dose than did that in males. Xylazine was administered first in females at a dose of 1.88 ± 0.37 mg/kg IM, whereas males received 1.22 ± 0.16 mg/kg IM. After xylazine premedication, anesthesia was induced with Telazol at a dose of 2.2 mg/kg in females and 1.7 mg/kg IM in males. This anesthetic combination is reported to have rapidly induced immobilization, analgesia, and good muscle relaxation. However, supplemental ketamine was given to prolong anesthesia, when required. The sedative and muscle-relaxing actions of xylazine and zolazepam were safely and rapidly antagonized by yohimbine (0.15 mg/kg IM) and flumazenil (1 mg/20 mg of zolazepam IM), respectively. Interestingly, atipamezole (200 to 300 μ g/kg IM) appears to be a more effective α_2 -antagonist in swine than does yohimbine.

Injectable Drug Combinations

Telazol-Ketamine-Xylazine (TKX)

Zolazepam appears to be responsible for the posterior weakness observed in recovering mature swine when Telazol is given IM in anesthetic doses. To minimize this problem, the dissociative content in the Telazol mixture can be increased by adding ketamine. Xylazine is also added to increase the sedative and analgesic effects of the mixture. In an unused vial of Telazol, 2.5 mL of ketamine (100 mg/mL) and 2.5 mL of xylazine (100 mg/mL) are added to dissolve the powder. This mixture provides 100 mg of dissociative/mL (tiletamine plus ketamine) and 50 mg/mL each of xylazine and zolazepam. In this mixture, zolazepam constitutes only 25% of the total drug dose rather than the 50% found in the proprietary mixture.

For commercial swine, the recommended dose of this drug combination is 1 mL/35 to 75 kg IM, depending on the anesthetic depth required. For sedation and light anesthesia, potbellied pigs appear to require a smaller dose, approximately one-half that

given to commercial swine. Anesthesia may be extended by injecting one-half the intramuscular dose slowly IV to avoid apnea or by administering either halothane or isoflurane in oxygen from a nose cone. The inhalation anesthetic requirement is greatly decreased with this drug mixture.

In growing swine weighing 20 to 45 kg under field conditions, three injectable general anesthetic drug combinations were compared, including azaperone (2 mg/kg IM) + metomidate (10 mg/kg intraperitoneally); tiletamine + zolazepam (6 mg/kg IM) + xylazine (2 mg/kg IM); and tiletamine + zolazepam + ketamine + xylazine (TKX, 1 mL/45 kg IM) (as described previously). Clinical observations, plus pinprick and ease of drug mixture, were used to evaluate anesthetic effectiveness.³⁵ Although this study did not find any significant differences between the three anesthetic protocols, past experience and reports have clearly shown that TKX is superior to all combinations evaluated. Preparation of drug mixtures should not be considered a major disadvantage when such mixtures better provide for smooth induction, good analgesia, muscle relaxation, and rapid recovery.

In another study, four anesthetic drug combinations were evaluated in swine. These combinations included TKX (Telazol, 4.4 mg/kg IM; ketamine, 2.2 mg/kg IM; and xylazine, 2.2 mg/kg IM); TX (Telazol, 4.4 mg/kg IM; and xylazine, 2.2 mg/kg IM); T2X (Telazol, 4.4 mg/kg IM; and xylazine, 4.4 mg/kg IM); and KX (ketamine, 8 mg/kg IM; and xylazine, 4 mg/kg IM). These drug combinations were evaluated for restraint and induction of surgical anesthesia in 40 swine, 10 in each group. All drug combinations were drawn up singularly, mixed in a single syringe, and administered as a single intramuscular injection. All combinations were reportedly safe and satisfactory for anesthesia induction in swine of this age (6 to 8 months). However, the TKX and T2X combinations were preferred.³⁶

Because of the popularity of potbellied pigs as companion animals, practitioners are occasionally asked to perform selected surgical and diagnostic procedures on these swine (e.g., hoof trim, hernia repair, ovariohysterectomy, castration, cesarean section, and ultrasound for pregnancy diagnosis). The potbellied pig's body appears to be sturdily built but is heavily covered with fatty tissue, and drug injection can be problematic. Table 29.2 lists a variety of drugs and combinations used in this breed of swine. For predictable response, care must be taken to ensure the anesthetic drugs are deposited into muscle and not fat when intramuscular injection is attempted.

Guaifenesin-Ketamine-Xylazine (Triple Drip)

This drug combination is prepared by adding 2 mg of ketamine and 1 mg of xylazine to each milliliter of 5% guaifenesin prepared in 5% dextrose in water. The drug combination must be administered IV. This can be a major problem because of the absence of accessible auricular veins in some individuals. The induction dose ranges from 0.67 to 1.0 mL of the mixture per kilogram. The average anesthetic maintenance dose is $2.2 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$. Using a standard intravenous delivery set (15 drops = 1 mL), the maintenance dose is calculated as follows: (kilograms of body weight) \times ($2.2 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$) \times 15 drops/mL divided by 60 = drops/min and when divided again by 60 =

drops/s. In a 150-kg sow, induction would require approximately 100 to 150 mL, depending on the rate of injection. Maintenance would be calculated as follows: $150 \times 2.2 \times 15 = 4950$ drops/h divided by 60 = 83 drops/min, divided by 60 again = approximately 1.4 drops/s. This dosage rate is sufficient for the average sow. Sows that have been in prolonged labor usually require a smaller dose. On the other hand, young, vigorous sows, in labor for only a short time, may require an increased dose. Animal response will serve as a guide to dose requirement. As with any injectable mixture, it should be given to effect as measured by monitoring of vital signs.

Induction and recovery from this anesthetic mixture are rapid (recovery occurring in 30 to 45 min). Recovery time can be decreased by intravenous injection of a specific xylazine antagonist (e.g., yohimbine, 0.06 to 0.1 mg/kg; or tolazoline, 2 to 4 mg/kg). When the α_2 -antagonist is given, postoperative analgesia is diminished. Rapid arousal to the antagonist suggests that xylazine is most likely responsible for residual anesthetic effect during recovery following continuous infusion of triple drip.

Triple drip used for cesarean section provides excellent relaxation and analgesia. Piglets are only minimally depressed. Clearly, neonatal depression is directly related to the total dose of triple drip prior to fetal delivery. Surgical speed is of the essence. Xylazine likely is responsible for neonatal respiratory depression. This speculation is based on clinical observations that piglets will quickly commence breathing after a small dose of an α_2 -antagonist is administered. A minimal dose of doxapram (i.e., 0.25 to 0.5 mg/kg) can also be used to stimulate breathing once the airway is cleared.⁴

Medetomidine-Butorphanol-Ketamine

The intramuscular administration of MBK (atropine, 25 $\mu\text{g}/\text{kg}$, and medetomidine, 80 $\mu\text{g}/\text{kg}$; combined with butorphanol, 200 $\mu\text{g}/\text{kg}$, and ketamine, 10 mg/kg) has also provided appropriate anesthesia and analgesia for short-term surgical procedures in pigs.³⁷ Anesthesia induction is rapid and is sufficient to support surgical procedures for at least 30 to 45 min. Recovery is generally smooth but can be effectively and quickly reversed with atipamezole (240 $\mu\text{g}/\text{kg}$ IM), if necessary. This combination was reportedly less cardiorespiratory depressive and more profoundly analgesic than a combination consisting of xylazine (2 mg/kg), butorphanol (200 $\mu\text{g}/\text{kg}$), and ketamine (10 mg/kg) given IM. The loss of response to painful stimuli was greater with MBK than with XBK. The authors suggest that MBK may be a superior drug combination for brief surgical analgesia/anesthesia. This combination has also been used in potbellied pigs when rapid recovery is desired.

Inhalation Anesthetics

The inhalants are safe anesthetics for swine other than for those individuals susceptible to malignant hyperthermia. Because of the equipment required for administration, inhalants can only be used practically within hospitals. Halothane and isoflurane have been the primary inhalants used in swine. Enflurane, an isomer of isoflurane, is of limited use without appropriate premedica-

Table 29.2. Doses of preanesthetic and anesthetic induction drugs used in potbellied pigs.⁶⁵

Drug	Dose (mg/kg)	Route	Comments
Preanesthetic drugs			
Acepromazine	0.10–0.45	IM	Slow onset of action, 20–30 min to peak effect; no analgesia; maximum dose, 15 mg
Xylazine	1.0–2.0	IM	Minimal sedation; may cause vomiting before surgery or during recovery; administer with atropine to block increased vagal tone; will offset hyperalgesic effect produced by thiobarbiturates
Diazepam	0.5–1.0	IV	Effective central muscle relaxant; high doses produce ataxia and recumbency
Fentanyl citrate and droperidol	1.0 mL/10 kg	IM	Administer with atropine 20–30 min before induction; excitement and goose-stepping may occur
Azaperone	0.23–2.5	IM	Light sedation produced
Induction drugs			
Ketamine	20	IM	Poor analgesia and muscle relaxation
Tiletamine-zolazepam (Telazol)	4.4	IM	Inadequate for intubation; rough recovery, characterized by vocalization, excessive salivation, and paddling motions
Thiobarbiturates			
Thiopental or Thiamylal	10–20	IV	Concentration should be 5% or less; administered one-half as rapid bolus to unpremedicated pigs; supplemental doses prolong recovery
Thiamylal	6–18	IV	
Injectable drug combinations			
Acepromazine plus Ketamine	0.5 15.0 (given 20 min after acepromazine injection)	IM	Onset of recumbency within 5 min; unreliable; recovery in 65 to 80 min
Diazepam plus Ketamine	1.0–2.0 10–18	IM	Analgesia not as profound as with xylazine-ketamine; smooth recovery; mix together in one syringe
Xylazine plus Tiletamine-zolazepam (Telazol)	2.2 4.4	IM	Mix together in one syringe to administer; good induction combination; intubation easily performed; acceptable short-term anesthesia with smooth recovery
Atropine plus Xylazine plus Tiletamine-Zolazepam (Telazol)	0.044 4.4 6.0	IM	Similar to the xylazine-tiletamine-zolazepam combination; smooth recovery in 2 h
Xylazine ^a Ketamine Tiletamine-Zolazepam (Telazol)	1 mL/75 kg	IV	Anesthesia can be maintained with 0.5 mL/75 kg IV; must be given slowly (over 60 s) to minimize respiratory depression
Xylazine ^a Ketamine Tiletamine-Zolazepam (Telazol)	1 mL/25 kg	IM	Good induction combination; intubation possible; recovery smoother than tiletamine-zolazepam alone; 80-min duration
Atropine plus Medetomidine plus Butorphanol plus Ketamine	0.025 0.08 0.2 10.0	IM	Mix together in one syringe; rapid induction of anesthesia and good analgesia; suitable for minor surgery; duration approximately 30–45 min; recovery smooth and rapid but can be reversed with atipamezole (0.24 mg/kg IM)
Xylazine Ketamine Oxymorphone	2.20 2.0 0.075	IV	Mix together in one syringe; suitable for short-term anesthesia and minor surgery; rapid and shallow breathing; duration approximately 20–30 min; smooth, rapid recovery; all doses may be doubled for administration IM
GKX for swine (triple drip) ^b	0.5–1.0 mL/kg (to induce); 2.0 mL/kg/h to maintain anesthesia	IV	Decrease induction dose 50% if tranquilizer or sedative is administered; administer atropine IM before induction; rapid recovery after discontinuing GKX infusion; recovery may be hastened by administration of yohimbine (0.125 mg/kg IV)
Inhalation agents			
Isoflurane	To effect	Inhalation	Recommended for young or sick pigs; recovery rapid
Sevoflurane	To effect	Inhalation	Recommended for young or sick pigs; recovery rapid

IM, intramuscularly; IV, intravenously.

^aMake the combination by reconstituting tiletamine-zolazepam (Telazol) with 2.5 mL of ketamine (100 mg/mL) and 2.5 mL of xylazine (100 mg/mL). Each milliliter of the resultant combination will contain 50 mg of tiletamine, 50 mg of zolazepam, 50 mg of ketamine, and 50 mg of xylazine.

^bThe solution contains 50 mg/mL of glycerol guaiacolate, 2 mg/mL of ketamine, and 1 mg/mL of xylazine. The combination should be mixed in the desired quantity immediately before use, because of the potential diminished potency of the mixture during storage. The concentration of drugs in this mixture varies among species.

From Wertz and Wagnert.⁶⁵

tion. High inspired concentrations of enflurane can cause a seizurelike response.

Desflurane is an isomer of isoflurane and is nonflammable. It is more volatile than either halothane or isoflurane. Because of this physical characteristic, it requires a special vaporizer for its administration. These vaporizers are extremely expensive and limit desflurane's use primarily to people and possibly swine research. Because its solubility in blood is much lower than that of the other halogenated drugs, induction of anesthesia and recovery are very rapid and depth can be readily regulated. In swine, desflurane's minimal alveolar concentration (MAC) is somewhere between 8% and 10%.

Isolated perfused-lung studies have shown that halogenated anesthetics decrease pulmonary vasoconstrictor response to alveolar hypoxia. The results of studies in intact animals have been less convincing. More importantly, sevoflurane at a clinical dose (1 MAC) had no clinically significant effect on hypoxic-pulmonary vasoconstriction in anesthetized piglets.³⁸ This suggests that, at clinical doses, sevoflurane and likely other inhalants are extremely safe to use in healthy swine.

In some circumstances, nitrous oxide (N_2O) can be used to enhance the effects of other inhalants (e.g., halothane and isoflurane). Normobaric extrapolation studies reveal that an inspired concentration of nearly 200% would be required for complete anesthesia in swine.³⁹ The requirement for high concentrations of N_2O to decrease the inhaled concentration of the major anesthetic can aggravate hypoxic conditions. Rapid movement of N_2O from the blood to the alveoli at the termination of anesthesia, when the pig is permitted to breathe ambient air, can also cause diffusion hypoxia. Thus, to avoid this potential complication, pigs should be permitted to breathe a high concentration of oxygen for 5 to 10 min after discontinuing N_2O administration.

Isoflurane has a broad safety margin. It is more insoluble in blood and tissue than is halothane. This physical property is highly desirable because it produces a more rapid induction and recovery. The anesthetic depth is easily regulated. Both inhalants quickly cross the placental barrier and depress the fetus. Isoflurane is more desirable when performing cesarean section. After delivery and once breathing is initiated, piglets rapidly eliminate isoflurane from body tissues. CNS depression disappears rapidly. Although halothane is less expensive, the recovery time of neonates is longer. Because of their high vapor pressures, newer inhalants should be administered only from equipment designed specifically for their use. Their high vapor pressures and relatively small safety margins prohibit use by the open-drop method.

The physical characteristics of halothane and isoflurane are similar enough that they may be administered from the same precision vaporizer designed specifically for either drug. For example, isoflurane can be administered from a properly cleaned and calibrated halothane vaporizer. Regardless of which anesthetic is chosen, for adult swine it should be administered in oxygen from a circle or a to-and-fro rebreathing system. Anesthetic machines and delivery systems designed for people or small animals are adequate for most adult swine weighing up to 150 kg, provided the soda lime is fresh and actively absorbing CO_2 .

In sedated sows, anesthesia may be safely induced with an inhalant and properly fitted nose cone. Generally, the machine is set to deliver 4 to 8 L of oxygen and 3% to 5% isoflurane. When anesthesia has been induced, the trachea should be intubated. Oxygen flow and anesthetic concentration are gradually decreased. For maintenance, oxygen flow ranges from 1 to 3 L/min. Halothane maintenance concentration ranges from 1.5% to 2.5% (mean, 2%), whereas 2% to 3% isoflurane (mean, 2.5%) is usually required to maintain surgical anesthesia.

N_2O can be used to speed induction of anesthesia. When N_2O is part of the anesthetic induction regimen, pigs are permitted to breathe oxygen and either halothane or isoflurane via nose cone. When signs of sedation appear (i.e., usually 3 to 4 min), N_2O is quickly entrained with oxygen so that it contributes 60% to 70% of the fresh gas inflow (e.g., 2 L of oxygen and 4 L of N_2O) into the breathing system. Because of its high concentration gradient, it moves rapidly from the alveoli to the bloodstream. This technique increases the alveolar concentrations of oxygen (i.e., initially, hyperoxic effect) and the primary anesthetic (e.g., halothane or isoflurane). This increase in concentration gradient of the inhalant increases the rapidity of movement from the alveoli to blood and thus increases the induction speed. This phenomenon is referred to as the *second gas effect*. When induction is complete, N_2O delivery is either decreased to less than 70% of total fresh gas flow or discontinued altogether.

Carbon Dioxide in Oxygen

CO_2 in oxygen can be used to induce anesthesia effectively in piglets. However, induction and surgical time should be restricted to 10 min or less. Most veterinarians are concerned about the humane treatment of all animals. For example, the processing of piglets (i.e., castration, tail docking, and ear notching) involves painful procedures. Because processed pigs are generally destined for human consumption, the use of most injectable anesthetics is not approved to relieve pain associated with processing procedures. Thus, when general anesthesia is used for this purpose, it must be safe, simple, economic, effective, and leave no tissue residues. Further, the anesthetic must have a rapid onset and allow rapid recovery. An anesthetic technique using CO_2 (a natural body by-product of metabolism) and oxygen has been developed to meet these requirements: 50% oxygen and 50% CO_2 (2 L/min oxygen and 2 L/min CO_2) administered by nose cone with a simple mechanical device is illustrated in Fig. 29.5. When assessing this device in 34 piglets, the mean time to inducing unconsciousness was approximately 31 s, whereas processing required 33 s. After CO_2 was discontinued, recovery was complete in 28 s. The time for induction processing and recovery was an average of 92 s.⁴⁰ The cost per piglet was less than 4 cents. This same technique has proven effective and safe in other neonatal species (e.g., lambs and kids).

In a later report, inhalation of CO_2 (90%) for 60 s in piglets induced anesthesia rapidly. Muscular response lasts for 13 to 30 s during the induction process. CNS suppression lasts for approximately 1 min after removal from CO_2 inhalation. A study designed to compare halothane 5% in oxygen and 80% CO_2 in 20%

Fig. 29.5. Schematic drawing illustrating a device used to administer a 50:50 carbon dioxide–oxygen mixture to anesthetize piglets. The device uses a combination regulator–flowmeter to deliver gas flows to an anesthetic mask. Line pressures of 50 psi and flow rates of 1 L/min each of oxygen and carbon dioxide are adequate for rapid anesthetization of piglets, relieving pain associated with piglet processing (e.g., castration, tail docking, and ear notching). From Thurmon and Benson.⁴

oxygen revealed that anesthesia with the CO₂-oxygen combination induced surgical anesthesia rapidly and safely. Castration was performed without any reaction.⁴¹ However, the 50:50 combination of CO₂-oxygen each flowing at a rate of 2 L/min delivered via a tightly fitted mask appears to be a more rational and safer use of CO₂ for short-term anesthesia of piglets.

Xenon gas is known to have anesthetic properties in people. To determine its efficacy and safety in swine, nine Pietrain, malignant hyperthermia–sensitive swine, anesthetized with pentobarbital, were mechanically ventilated with 70% xenon for 2 h.⁴² Heart rate, mean arterial pressure, cardiac output, body temperature, arterial and mixed venous blood gases, plasma catecholamines, and lactate were measured at 10-min intervals during xenon-oxygen ventilation after a 30-min xenon-washout period. This study next used halothane (1% inspired) and succinylcholine (3 mg/kg IV). During the xenon phase of the study, no changes characteristic of malignant hyperthermia were observed. In contrast, 20 min after administration of halothane and succinylcholine, all swine developed a fulminating and fatal malignant hyperthermic episode. Clearly, xenon anesthesia does not trigger malignant hyperthermia in susceptible swine. In contrast, desflurane, inhaled in repeatedly increasing concentrations, caused fulminating malignant hyperthermia in large white pigs genetically selected for development of this condition.⁴³

Less Commonly Used Injectable Drugs

Opioids

These have been used in swine as adjuncts with other drugs to induce and maintain surgical anesthesia. They have also been used as constant infusions for maintenance. The first commercially

available opioid drug combination was fentanyl and droperidol in a concentration of 0.4 and 20 mg/mL, respectively (Innovar-Vet). Pigs may become excited after Innovar-Vet injection. Salivation is often excessive unless atropine has been given. A major problem with this combination is the difference in drug half-life between the two drugs. That of fentanyl is quite short, whereas that of droperidol is rather long. Thus, the use of a specific opioid antagonist (e.g., naloxone) is ineffective in shortening a prolonged recovery because deep droperidol tranquilization often remains after the action of fentanyl has waned. In such situations, pigs may respond violently if a high degree of postoperative pain persists. Innovar-Vet (1 mL/13 to 14 kg IM) combined with ketamine (11 mg/kg IM) will induce satisfactory anesthesia for 20 to 30 min in young swine.^{1,2,44}

High-dose opioid infusion is commonly used for anesthesia in cardiovascular research because opioids have minimal effect on cardiovascular function.^{45,46} Fentanyl is most often used for this purpose. In people, fentanyl can be administered IV in a wide range of doses (50 to 150 µg/kg). Even with high doses, the hemodynamic stability is excellent.²⁹ Opioid anesthesia in swine has been maintained with fentanyl at a constant infusion of 45 to 90 µg · kg⁻¹ · h⁻¹. The dose requirement in swine appears to be larger than for humans and most other species.⁴⁷ Fentanyl has been safely administered at a dose as high as 200 µg/kg/h in pigs.

Mild tranquilization will generally prevent muscle rigidity after an intravenous opioid bolus and before infusion is commenced. In people, chest muscle rigidity following fentanyl administration is referred to as *woody chest syndrome*. Clinical experience suggests this may also occur in swine. Severe muscle rigidity can be completely eliminated by the use of a muscle relaxant.

The two opioids most commonly used in swine are buprenorphine and fentanyl. Buprenorphine can be dosed at 0.01 mg/kg IV or IM to provide analgesia for 6 h, whereas a dose of 0.02 mg/kg IV or IM provides analgesia for up to 12 h. Significant analgesia is generally not observed with doses less than 0.01 mg/kg.⁴⁸ Although buprenorphine is effective for controlling pain following surgery, its efficacy in ameliorating pain associated with chronic inflammation, organ failure, or systemic disease is questionable. Transdermal fentanyl patches may also be used for postoperative analgesia in swine. Serum concentrations of fentanyl reach a maximum of 0.5 to 1.5 ng/mL by 36 to 48 h after applying a patch designed to deliver 50 or 100 µg of fentanyl per hour.^{49,50} The 50-µg/h patch (but not the 25-µg/h patch) provided postoperative analgesia comparable to buprenorphine given at 0.01 mg/kg IM for 3 to 4 days.⁵⁰ Buprenorphine is generally recommended when short-term analgesia is needed. Since buprenorphine must be redosed every 8 to 12 h, fentanyl patches are preferred when longer pain control is necessary (e.g., after a thoracotomy).

Generally speaking, an opioid antagonist should be given only when an opioid severely depresses ventilation. In most instances, an agonist-antagonist (e.g., butorphanol or nalbuphine) can be given to restore ventilation while retaining some degree of analgesia.⁵¹ The half-life of nalbuphine in people ranges from 3 to 6 h. However, fentanyl respiratory depression reversed by nalbu-

phine antagonism has been reported to recur in 2 to 3 h.²⁹ A similar situation could be expected in swine following butorphanol administration after long-term fentanyl infusion. Naloxone (0.5 to 2 mg/kg IV or IM) effectively antagonizes the residual effects of fentanyl.

Propofol

This is an isopropylphenol derivative administered only intravenously. This nonbarbiturate is supplied in an aqueous solution of 10% soybean oil, 2.5% glycerol, and 1.2% purified egg phosphatide in a concentration of 10 mg/mL.⁵² The drug is approximately twice as potent as thiopental and perhaps half as potent as methohexital. In people, consciousness returns more rapidly after a single injection or a constant infusion than with either thiamylal or thiopental. The residual CNS effect is less than that of the barbiturates. The clearance from plasma at a rate greater than the hepatic blood flow suggests that tissue sequestration plays an important role in its short duration of action.²⁹ Propofol is often described as a hypnotic offering only minimal analgesia. As a result, it is generally used for anesthesia induction or combined with a strong analgesic (e.g., an opioid or α_2 -adrenoceptor agonist). Propofol has been used in combination with azaperone and thiopental in pigs, but none of these drugs provide good analgesia. When propofol is used alone as an induction agent in dogs, the dose ranges from 6 to 8 mg/kg IV. Rapid injection may cause apnea. In swine, deep sedation can be maintained with a constant infusion of 4 to 10 mg \cdot kg⁻¹ \cdot h⁻¹. Propofol infused at a rate of 12 mg \cdot kg⁻¹ \cdot h⁻¹ did not trigger malignant hyperthermia in susceptible swine.⁵³

Cardiovascular studies have been performed in piglets after the administration of propofol at 7.5, 15, and 30 mg \cdot kg⁻¹ \cdot h⁻¹.⁵⁴ Mean arterial pressure decreases approximately 25% with no dose difference. Heart rate and left ventricular pressure were unchanged from control. Propofol appears to be a relatively safe hypnotic for use in newborn piglets. Because propofol has such a minimal influence on heart function, a combination of low doses of propofol and fentanyl may be a useful anesthetic in neonatal pigs.

Medetomidine (20 to 40 μ g/kg) and propofol (2 to 4 mg/kg) induces a light plane of anesthesia in 30- to 60-kg pigs. Xylazine (1 to 2 mg/kg) appears to be a reasonable substitute for medetomidine. Neither medetomidine nor xylazine are as effective in swine as they are in most other species. When combined with propofol, though, α_2 -agonists provide a degree of analgesia commensurate with a light plane of anesthesia. Because propofol does not have a preservative, the possibility of bacterial contamination is a real threat if the entire vial is not used soon after opening. A scrupulously sterile technique must be used after the heat-sealed vial has been opened. If the drug is to be stored for later use, complete sterility is essential.

Alphaxalone and Alphadalone (Saffan)

Saffan is a neurosteroid anesthetic that has been used in swine for some time in Europe and Canada. Anesthetic response to this drug combination is brief, lasting only 10 to 15 min when a dose of 5 to 6 mg/kg is injected IV. The dose can be decreased by ad-

ministering xylazine (1 to 2 mg/kg IM) or azaperone (4 mg/kg IM). The latter will prolong recovery time. Saffan anesthesia may be prolonged by repeated intravenous injection of doses ranging from 2 to 4 mg/kg. This drug combination has been used without incident in swine susceptible to malignant hyperthermia. Alfaxan-CD (hydroxypropyl- β -cyclodextrin [HPCD]) has recently been introduced in Australia as an anesthetic for use in dogs and cats. This new neurosteroid preparation does not cause histamine release because the carrier solution has been changed from Cremaphor EL (a polyethoxylated castor oil) to a cyclodextrin.⁵⁵

Etomidate

This is a carboxylated imidazole compound unrelated to other injectable anesthetics. It is a relatively poor analgesic and muscle relaxant, and is often classified as a sedative hypnotic when given in low doses (e.g., 2 to 4 mg/kg). Etomidate maintains cardiovascular stability but suppresses adrenocortical activity in people.⁵⁶ It does not trigger malignant hyperthermia in susceptible swine.⁵⁷ Etomidate in clinically recommended doses causes hemolysis in dogs.

When pigs have been sedated with either xylazine (1 to 2 mg/kg IM or IV) or azaperone (2 to 4 mg/kg IM), analgesia and recovery time are prolonged after etomidate administration. Azaperone premedication prolongs recovery more, but the degree of analgesia is less than with the coadministration of xylazine and etomidate. Etomidate induction (0.6 mg/kg IV) followed by ketamine infusion at a rate of 10 mg \cdot kg⁻¹ \cdot h⁻¹ has been used to maintain anesthesia in experimental swine.²⁴

Metomidate

Metomidate (4 mg/kg IV), which is a hypnotic similar to etomidate, provides rather stable cardiovascular function. In Europe, it has often been used in combination with azaperone (2 to 4 mg/kg IM) to anesthetize swine. Azaperone is given as a preanesthetic, and metomidate is used to maintain anesthesia by repeat injection at 15- to 30-min intervals.⁵⁸ The metomidate dose can be doubled to prolong anesthesia. Under such circumstances, it must be administered slowly to prevent apnea. Anesthesia with minimal analgesia has been maintained by continuous infusion of azaperone (2 mg \cdot kg⁻¹ \cdot h⁻¹) and metomidate (8 mg \cdot kg⁻¹ \cdot h⁻¹). Metomidate (15 mg/kg) has also been given by intraperitoneal injection.¹ However, because this route of administration is often accompanied by peritonitis and intra-abdominal adhesions, peritoneal injections are discouraged and should no longer be recommended. Because metomidate provides poor analgesia, a local analgesic (e.g., lidocaine), an α_2 -agonist, or an opioid is often administered concomitantly with metomidate and azaperone.

α -Chloralose

This drug has been used exclusively in the research laboratory. It is a poor analgesic, and hypnosis is usually accompanied by spontaneous leg movement. Blood pressure is unchanged or increased. Heart rate is usually increased, and respiratory depression does not occur until large doses are administered.

α -Chloralose is relatively insoluble, and onset of effect is slow, requiring approximately 15 to 20 min. α -Chloralose (55 to 86 mg/kg) can be combined with morphine (0.3 to 0.9 mg/kg) to improve overall anesthesia. However, continuous limb paddling still often occurs in pigs given this drug combination. Ketamine (5 to 10 mg/kg IV or IM) and butorphanol (0.5 mg/kg IV or IM) can also be combined with α -chloralose in an effort to enhance the overall anesthetic and analgesic actions of this drug.¹

Malignant Hyperthermia

It was not until the early 1970s that E. W. Jones reported the occurrence of an unusual metabolic condition in swine.⁵⁹ Prior to that report, healthy swine leaving the farm for market by truck and arriving dead were diagnosed as having *soft watery pork* (i.e., *pale soft exudative pork*) syndrome. As people and swine with the disease were observed more closely, the condition later became known as *malignant hyperthermia*. The condition is characterized by striated muscle deterioration. Since that time, pigs with this genetic peculiarity have been identified in most swine breeds. Malignant hyperthermia has also been diagnosed in other species, including dogs, horses, cats, birds, deer, and other wild animals. In wild species, the syndrome is frequently referred to as *capture myopathy*. However, of all the mammalian species, malignant hyperthermia is most commonly encountered in swine.

Malignant hyperthermia is most prevalent in individuals of breeds having a high ratio of muscle to total body mass and rapid growth.^{60,61} Breeding for these market characteristics appears to have played a major role in increasing swine's predisposition to developing malignant hyperthermia. The breeds most frequently carrying this genetic alteration are Pietrain, Landrace, spotted swine, large white, and Hampshire (not necessarily in this order). Although malignant hyperthermia may occur in other breeds, the incidence is encountered less frequently in the Duroc breed.⁶² In highly susceptible individuals, malignant hyperthermia may be triggered by the stress of restraint for blood sampling, castration, and other processing procedures in market swine. Malignant hyperthermia has been observed in young boars pursuing gilts that were unreceptive to breeding, particularly under hot summer conditions. Individuals arising from parentage with a strong inherent predisposition to malignant hyperthermia were very common at one time, particularly in the Landrace breed.

Malignant hyperthermia in swine is caused by an inherited autosomal recessive disorder that causes a single amino-acid mutation in the porcine ryanodine receptor 1 gene (*RYR1*). This ryanodine receptor is a calcium-release channel, and susceptible swine are not capable of controlling calcium efflux from inside the sarcoplasmic reticulum.⁶³ With the advent of rapid genetic testing to detect the presence of this gene in swine, the incidence of malignant hyperthermia has declined dramatically, although it is still present in the domestic swine population.

The incidence of malignant hyperthermia in potbellied pigs is unknown. It can be expected to be small or nonexistent because this breed has a high ratio of fat to body mass. Potbellied pig deaths attributed to this condition may actually be caused by the

stress of restraint. Halothane anesthesia in thousands of potbellied pigs over the last 2 decades has not uncovered a single death that could be attributed to malignant hyperthermia. Presently, anesthetic-related deaths attributed to MH in this species of swine appear to be speculative.

The occurrence of malignant hyperthermia is associated with a sudden increase in muscle oxygen requirement and, thus, lactate production. Body temperature increases, as does respiration rate. Metabolic acidosis is accompanied by muscular contraction, sympathetic activation, and increased muscle cellular permeability. Initially, serum magnesium, calcium, phosphorus, and potassium ion concentrations are increased. These changes are followed by a decrease in serum potassium and calcium ion concentrations. Myoglobinuria often appears shortly thereafter if the affected animal does not succumb.

Clinically, the syndrome in swine is characterized by rapid onset of tachycardia, hyperthermia, muscle rigidity (i.e., activation of limb extensor muscles), tachypnea progressing to dyspnea, and finally apnea. A rapidly increasing end-tidal CO₂ concentration is the most revealing clinical sign of impending malignant hyperthermia. In the later stages of the syndrome, tachycardia is accompanied by dysrhythmias that lead to bradycardia and finally cardiac arrest. Current findings indicate that metabolic status during malignant hyperthermia is characterized by an increased oxygen demand ischemia of the heart and skeletal muscle. Insufficient coronary blood flow and increased metabolism as a result of tachycardia and increased concentrations of catecholamines are dominant factors contributing to the dramatic alteration in cardiac performance during porcine malignant hyperthermia.⁶⁴ When tachycardia is accompanied by malignant arrhythmias, treatment success is unlikely. Most patients will die regardless of treatment.

In susceptible swine, clinical signs appear shortly after exposure to halothane. An exception to this occurs when swine have been given a phenothiazine tranquilizer (e.g., acetylpromazine) and anesthesia is induced with a thiobarbiturate (e.g., thiopental). Under such circumstances, the onset is delayed when anesthesia is continued with a halogenated hydrocarbon (e.g., halothane) or a halogenated ether (e.g., isoflurane). However, malignant hyperthermia may occur in susceptible swine when the effects of the tranquilizer and/or the barbiturate have waned. Thus, it is important to understand that time of onset of the syndrome is influenced by drugs used in various anesthetic regimens and is not always an acute response to halothane or succinylcholine administration. Succinylcholine injected into susceptible swine can easily trigger the syndrome, whereas nondepolarizing muscle relaxants (e.g., pancuronium) are less likely to do so.

Prevention and Treatment

The drug used most commonly to prevent and treat malignant hyperthermia in swine is dantrolene (Dantrium, 2 to 5 mg/kg IV). This muscle relaxant is also an antipyretic. It suppresses calcium ion release but does not appear to inhibit uptake of calcium by muscle tissue cells. Even though it acts directly within muscle cells, its depressant effect on respiratory muscle function is minimal. The use of dantrolene has proven to be a valuable prophylactic

lactic treatment for malignant hyperthermia in susceptible swine and people.

Dantrolene is dosed orally (5 mg/kg) 8 to 10 h prior to surgery. There is evidence that the drug should be repeated (3 to 5 mg/kg IV) preoperatively and postoperatively should surgery be prolonged. When a known triggering drug has been used to maintain anesthesia (e.g., halothane or isoflurane), the patient should be monitored closely for 1 day postoperatively.

Symptomatic treatment includes rapid termination of the inhalant, changing of the anesthetic machine rubber goods (i.e., hoses and rebreathing bag), or switching to a clean machine for administering 100% oxygen, procaine (1 to 2 mg/kg IV), intravenous corticosteroids, sodium bicarbonate (2 to 4 mEq/kg IV) if severe metabolic acidosis is present, and body cooling. Whole body cooling may be achieved with an ice water–alcohol mixture and cold fluids IV, orally, or by infusion per rectum.

Anesthetic drugs least likely to trigger malignant hyperthermia in susceptible swine include thiopental, propofol, etomidate, metomidate, and epidural anesthesia. In highly susceptible swine, restraint for intravenous or epidural drug injection can precipitate the syndrome. In susceptible swine, preanesthetic medications (e.g., acetylpromazine) known to inhibit the malignant hyperthermia syndrome should be administered IM prior to anesthesia induction.

Introduction

Anesthesia of laboratory animals provides some unique challenges to veterinary anesthetists. In addition to working with less familiar species, the constraints of particular research projects may limit the anesthetic and analgesic options available. Some of the anesthetic regimens proposed by investigators may be unfamiliar to anesthetists who have worked only in a clinical environment; for example, the use of chloralose or urethane. Finally, the duration of anesthesia required may range from a matter of seconds (e.g., for blood sampling) to several days for some neurophysiological studies. Although these factors may seem daunting, the involvement of veterinary anesthetists in this field is

essential if we are to help promote both high standards of anesthesia and high standards of animal welfare. Many laboratory-animal facilities employ veterinarians specialized in laboratory-animal medicine, and it is always advisable to contact them prior to offering advice or becoming directly involved in providing assistance to a research group.

Selecting an Anesthetic Regimen

In addition to the usual factors to be considered when selecting an anesthetic regimen, a further issue when working with laboratory species is the potential interactions between the anesthetic and the particular research protocol. It is important to discuss the proposed anesthetic regimen with the research group concerned and try to indicate any specific pharmacological properties of the anesthetic that are likely to be relevant. This may require a detailed literature search. A variety of strategies may be needed to identify relevant information—note that some product development work will have been conducted in laboratory species, but that the agent may be referred to by its original manufacturer's drug identifier (e.g., propofol as ICI 35 168). If it is determined that interactions could occur, it is important to place them in the overall context of the research protocol. In addition, do not overlook the importance of high standards of perioperative care and minimizing the general effects of anesthesia. These include respiratory depression, producing hypoxia, hypercapnia, and acidosis; cardiovascular depression with reduction in cardiac output and alterations in organ blood flow; and depression of thermoregulation, causing hypothermia and consequent changes in metabolism and cardiovascular function.

If an animal is undergoing surgical procedures, then the effects of surgical stress are almost unavoidable and will have profound and long-lasting effects on the animal's metabolism and endocrine system.¹

General Considerations

The majority of laboratory animals will be young, healthy adults, although in some circumstances animals with intercurrent disease will be encountered. Laboratory-facility veterinarians should be able to provide information on the health status of the animals and the incidence of clinical and subclinical disease. Most facilities require that animals undergo a period of acclimatization, usually for 1 to 2 weeks, prior to their use in research procedures. This provides an excellent opportunity for habituation to handling and restraint. It also provides time for the anes-

Table 30.1. Physiological data for rodents and rabbits.

	Mouse	Rat	Rabbit	Guinea Pig	Hamster	Gerbil
Adult body weight (g)	25–40	300–500	2000–6000	700–1200	85–150	85–150
Body temperature (°C)	37.5	38	38	38	37.4	39
Respiratory rate (breaths/min)	80–200	70–115	40–60	50–140	80–135	90
Heart rate (beats/min)	350–600	250–350	135–325	150–250	250–500	260–300

thetist and the animal-care staff to assess the behavior and temperament of animals, perform a general clinical examination, and obtain background data such as growth rate and food and water consumption. This information is of considerable value when assessing postoperative recovery. Some basic biological data are provided in Tables 30.1 and 30.2.

Rodents and Rabbits

Small rodents and rabbits do not vomit, so there is generally no need to withhold food or water prior to anesthesia. Withholding food from small rodents for prolonged periods can be detrimental because it can predispose them to hypoglycemia. Rabbits and guinea pigs are more likely to develop postoperative gastrointestinal disturbances if food is withheld. In anesthetized guinea pigs, small quantities of food are often found in the mouth, but this is not prevented by withholding food.

Nonhuman Primates

Both Old World and New World primates may vomit during induction or recovery from anesthesia, so withdrawal of food for 8 h and water for 2 to 3 h preoperatively is advisable. Note that these animals may eat bedding or other material in their cages, so withdrawing food does not guarantee an empty stomach.

Preanesthetic Medication

Rodents and Rabbits

Since anesthesia in rodents is often induced by using an anesthetic chamber, or by using an injection of drugs by the intraperitoneal or subcutaneous routes, preanesthetic medication is not often given. In rabbits, induction with a volatile agent delivered via a face mask may be considered, but a sedative agent (e.g., diazepam or acepromazine) should be administered because animals often find this procedure stressful.^{2,3} Even when volatile agents are not used, since rabbits are easily stressed when handled and restrained, use of sedatives or tranquilizers can have significant benefits. Administration of the drug before removal from the animal's home cage or pen is advisable. Suitable agents are listed in Table 30.3. Preanesthetic sedation may also be considered advisable if isoflurane is to be administered to guinea pigs, because this agent appears to be an irritant in this species.

When only immobilization is required, rather than anesthesia, high doses of some of the agents listed in Table 30.3 may be effective, but often low doses of anesthetic combinations (e.g., ketamine-medetomidine) are more useful.

Preanesthetic medication with an analgesic may be advisable in all of these species, as part of a perioperative pain-management

Table 30.2. Physiological data for nonhuman primates.

	Marmoset	Rhesus Macaque
Average adult body weight	500 g	8–12 kg
Body temperature (°C)	38.5–40.0	39
Respiratory rate (breaths/min)	50–70	35
Heart rate (beats/min)	225	150

regimen (see the section on Effective Pain Control), and dose rates of suitable analgesics are listed in Table 30.4.

As in other species, atropine or glycopyrrolate can be administered to reduce bronchial and salivary secretions, although this is rarely needed in rodents that are free of respiratory infection. However, these agents may be useful in protecting the heart from vagal inhibition caused by some surgical procedures (e.g., handling of the viscera, or carotid cannulation that may involve direct vagal manipulation). It is advisable to use glycopyrrolate in rabbits because atropine is often relatively ineffective in this species.⁴

Nonhuman Primates

The use of preanesthetic medication in Old World primates (macaques and baboons) has been considered essential because of concerns for the safety of the staff involved. However, the change in emphasis in husbandry techniques so that primates are well socialized and may accept intravenous injection increases the anesthetic options that can be selected. If animal-care staff advises that chemical restraint is needed, then ketamine can be administered to immobilize an animal so that it can then be handled safely. Drug administration may be facilitated by use of a cage design that allows the animal to be confined for injection, or the animal can be trained to stand and accept the injection. As an alternative to the dissociative anesthetics, sedatives and tranquilizers can also be used in nonhuman primates, but these are not always effective in preventing aggression. Medetomidine should be used with great care in nonhuman primates because its sedative effects are less predictable and some animals may suddenly become alert and bite their handlers. When combined with ketamine, animals are immobilized and a medium plane of anesthesia is produced.⁵ As in other species, atipamezole can be administered to reverse the effects of medetomidine. Although the effects of ketamine still remain, recovery is generally rapid.

The use of ketamine in New World monkeys such as mar-

Table 30.3. Preanesthetic agents for use in rodents and rabbits.

Drug	Species	Dose Rate	Effect
Acepromazine	Rat, guinea pig	2.5 mg/kg IP or SC	Sedation, but still active
	Mouse, hamster, gerbil	3–5 mg/kg IP or SC	
	Rabbit	1 mg/kg SC or IM	
Acepromazine + butorphanol	Rabbit	0.5 mg/kg + 1.0 mg/kg IM or SC	Sedation, often immobilized, some analgesia
Atropine	Mouse, hamster, gerbil, rat, guinea pig	40 µg/kg SC or IM	Reduced bronchial and salivary secretions, inhibits vagal responses, ineffective in many rabbits
Diazepam	Mouse, hamster, gerbil, guinea pig	5 mg/kg IP	Sedation
	Rat	2.5 mg/kg IP	
	Rabbit	1–2 mg/kg IM	
Glycopyrrolate	Rabbit	0.01 mg/kg IV or 0.1 mg/kg SC or IM	Reduced bronchial and salivary secretions, inhibits vagal responses
Innovar-Vet (fentanyl-droperidol)	Rabbit	0.22 mL/kg IM	Sedation and analgesia; often sufficiently immobilized for minor surgical procedures
Hypnorm (fentanyl-fluanisone)	Mouse	0.5 mL/kg IM	Sedation and analgesia; often sufficiently immobilized for minor surgical procedures
	Hamster	1.5 mL/kg IM	
	Guinea pig	0.4 mL/kg IM	
	Mouse, hamster, gerbil, rat, guinea pig	0.5 mL/kg SC or IP	
Medetomidine	Mouse, hamster, rat	30–100 µg/kg SC or IP	Sedation and some analgesia, immobilized at higher dose rates
	Rabbit	100–500 µg/kg SC or IP	
Midazolam	Mouse, hamster, gerbil, guinea pig	5 mg/kg IP	Sedation
	Rat	2.5 mg/kg IP	
	Rabbit	1–2 mg/kg IM	
Xylazine	Mouse, hamster, rat	5 mg/kg SC or IM	Sedation and some analgesia, immobilized at higher dose rates
	Rabbit	2.5 mg/kg SC or IM	

IM, intramuscularly; IP, intraperitoneally; IV, intravenously; SC, subcutaneously.

Table 30.4. Suggested analgesic dose rates for rodents and rabbits^a.

Analgesic	Mouse	Rat	Rabbit	Guinea Pig	Hamster	Gerbil
Buprenorphine	0.1 mg/kg SC per 6–12 h	0.01–0.05 mg/kg SC per 6–12 h	0.01–0.05 mg/kg SC	0.05 mg/kg SC	0.1 mg/kg SC	0.1 mg/kg SC
Butorphanol	2 mg/kg SC per 4 h	2 mg/kg SC per 4 h	0.1–0.5 mg/kg SC	2 mg/kg SC	?	?
Carprofen	10 mg/kg SC	5 mg/kg SC	4 mg/kg SC once daily or 1.5 mg/kg PO daily	2.5 mg/kg	?	?
Flunixin	2.5 mg/kg SC twice daily	2.5 mg/kg SC twice daily	1.1 mg/kg SC twice daily	?	?	?
Meloxicam	5 mg/kg SC per 4 h	1–2 mg/kg SC or 4 mg/kg PO	0.2 mg/kg SC daily	?	?	?
Morphine	2–5 mg/kg SC	2–5 mg/kg SC per 4 h	2–5 mg/kg SC or IM per 4 h	2–5 mg/kg SC or IM per 4 h	?	?
Oxymorphone	?	0.2–0.3 mg/kg SC	0.1–0.2 mg/kg IM or IV	?	?	?
Pethidine	10–20 mg/kg SC or IM per 2–3 h	10–20 mg/kg SC or IM per 2–3 h	10 mg/kg SC or IM per 2–3 h	10–20 mg/kg SC or IM	?	?

IM, intramuscularly; IV, intravenously; PO, per os (orally); SC, subcutaneously.

^aDose rates are based largely on uncontrolled clinical trials and a limited range of procedures and so are likely to be subject to revision. A “?” indicates that information is insufficient to make a firm recommendation of an appropriate dose.

Table 30.5. Preanesthetic agents for use in nonhuman primates.

Drug	Species	Dose Rate
Alphaxalone-alphadolone	Marmoset	12–18 mg/kg IM
Ketamine	Rhesus macaque	5–25 mg/kg IM

IM, intramuscularly.

Fig. 30.1. Application of local anesthetic cream (EMLA Cream; AstraZeneca, London) to the skin overlying the cephalic vein of a cat. Local anesthetic cream should be applied 45 min to 1 h prior to venipuncture.

mosets has been associated with muscle damage. This is probably related to the low pH of ketamine (3 to 4) and its injection into the relatively small muscle mass of these animals. Similar effects have been seen in small rodents. Although an even larger volume of injectate is required, alphaxalone-alphadolone is well tolerated and appears to be nonirritant. It produces deep sedation, and additional drug can be given intravenously to deepen anesthesia.^{6,7} Dose rates of suitable agents are listed in Table 30.5.

Special Considerations with Other Species in a Research Environment

Cats

Cats should be well socialized and thus easy to restrain for intravenous administration of anesthetic agents. They may resent insertion of over-the-needle catheters and may struggle in response to venipuncture. This can be avoided by using local anesthetic cream as shown in Fig. 30.1.⁸ This mixture of lignocaine and prilocaine produces full-skin-thickness anesthesia, but requires 45 min to 1 h of contact time and needs to be covered with a dressing. An alternative approach is to administer a sedative.

Dogs

Early socialization of laboratory-bred dogs is important, because they will then be easy to handle and restrain for injection of anesthetics. Like cats, they may resent insertion of over-the-needle catheters and may struggle in response to venipuncture. Use of

Fig. 30.2. Placement of an over-the-needle catheter into the ear vein of a pig. A local anesthetic cream may be applied to the ear 4 min to 1 h prior to venipuncture.

EMLA Cream (lidocaine 2.5% and prilocaine 2.5%) can prevent discomfort during venipuncture or catheter placement. Alternatively, a range of different sedatives can be administered as pre-anesthetic medication.

Pigs

Laboratory-bred pigs (usually minipigs) should have been socialized to be accustomed to human contact. They can be readily trained to accept some degree of restraint, enabling intramuscular injection of a sedative combination to immobilize them. If trained to accept restraint in a sling, then the ear can be anesthetized with EMLA Cream and a catheter placed for intravenous induction of anesthesia (Fig. 30.2). Many pigs, particularly those reared under farm conditions, may be apprehensive and difficult to approach. Such animals should be immobilized or heavily sedated. Drug administration is easier if a long needle (3 to 4 cm) is attached using extension tubing to a syringe so that, after the catheter is placed, the drug can be injected without the need for physical restraint of the animal.

Sheep

Few sheep are bred specifically for research purposes; after a few weeks of acclimatization, however, they may become more tractable and approachable than those housed on farms.

Handling, Restraint, and Routes of Drug Administration

Small animals should be handled with care. Habituation to handling during acclimatization will facilitate future restraint and reduce the stress to the animal and operator during the administration of anesthetics. It is important to make animals aware about our intentions before attempting to handle them, especially if they are asleep, in order to minimize stress and also avoid bite injuries.

Fig. 30.3. Rodent restraint tubes. Mice and rats may be placed in these tubes to facilitate venipuncture.

Anesthetics or analgesics may cause discomfort, irritation, and/or ulceration of the skin, mucous membranes, vascular endothelium, or muscles if they are irritant (e.g., low or high pH), cold (straight from the refrigerator) and/or administered by an inappropriate route (e.g., pentobarbital by intramuscular route).

Intravenous injection or placement of intravenous catheters for anesthetic administration in conscious rodents may be challenging even for experienced operators. The use of physical methods (e.g., restraint tubes) or volatile anesthetics for induction may provide the desired restraint to facilitate this task (Fig. 30.3).

Rodents

The intraperitoneal route of administration is the easiest approach for small rodents, because larger amounts of fluids may be administered. However, errors during administration by this route are quite common (e.g., intravisceral, subcutaneous, or administration into the adipose tissue).⁹ Such errors may cause organ damage or delayed onset of action of the anesthetic agent. Injections are usually made into the left lower abdominal quadrant. Rodents are restrained in dorsal recumbency, as shown in Fig. 30.4.

Most of the commercially available analgesic and anesthetic agents are available in high concentrations, so that only very small volumes would be required for injection in small rodents. Precise dosing is easier if insulin syringes (50 IU, 0.5 mL) are used. Alternatively, a commercial preparation can be diluted to provide a more accurately administered volume. For intravenous administration, butterfly needles or over-the-needle catheters with or without extension sets may be used for initial induction and anesthetic maintenance by infusion, as shown in Fig. 30.5.

Hamsters

Animals can be held in both hands, immobilizing the head to avoid being bitten (Fig. 30.6). Alternatively, grasp the loose skin around the neck and back region firmly (Fig. 30.7). The saphenous vein may be used for intravenous administration. For other routes, see Table 30.6.

Fig. 30.4. Intraperitoneal injection of a rat. The rat is restrained in dorsal recumbency by an assistant. An injection is made into its lower left abdominal quadrant.

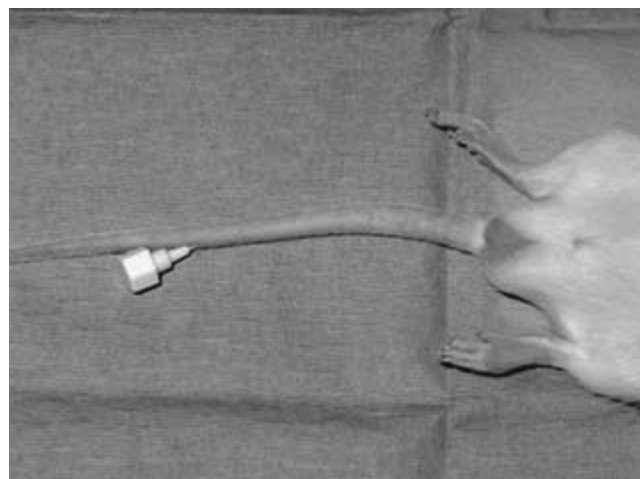

Fig. 30.5. An anesthetized rat with an over-the-needle catheter placed in its lateral tail vein.

Gerbils

Gerbils are generally easy to handle and can be scooped into the palm of a hand. Alternatively, they can be picked up gently at the base of the tail, but grasping the distal end of the tail might detach skin. Gerbils dislike being picked up and turned onto their backs. The lateral tail or saphenous veins may be used for intravenous administration. For other routes of administration, see Table 30.6.

Guinea Pigs

Guinea pigs are easily lifted by grasping them gently around the thorax and shoulders with one hand while supporting the hindquarters with the other hand (Fig. 30.8). Aural, saphenous, or penile veins (only under anesthesia) may be used for intravenous administration. For other routes, see Table 30.6.

Fig. 30.6. Hamster restraint. The hamster is held in both hands with its head immobilized.

Fig. 30.7. Hamster restraint. The hamster is grasped firmly by the loose skin around its neck and back.

Mice

Mice are not as easily habituated to restraint as other rodents, and there are great variations between different strains. Some are relatively docile and easy to catch, whereas others may be extremely active. Mice are usually grasped by the base of the tail and lifted from the cage (Fig. 30.9). When placed on a nonslip surface such as a cage lid or laboratory coat, they can be grasped by the loose skin overlying the animal's back, with the tail restrained between the operator's fingers (Fig. 30.10). This form of restraint is particularly suitable for intraperitoneal, intramuscular, and subcutaneous administration of drugs. For administration details, see Table 30.6.

Rats

The easiest and most humane way to lift a rat is with one hand supporting the hind quarters and the other hand supporting the head, with the thumb under the foreleg and mandible (Fig. 30.11). Rats can be grasped using the loose skin overlying the neck and back, if necessary. For administration details, see Table 30.6.

Rabbits

Gently approach the rabbit in the cage or floor pan and grasp the skin of the neck and back firmly, supporting the abdomen and hind legs with the other hand (Fig. 30.12). When carrying rabbits, the head is kept between the arm and the chest of the handler (Fig. 30.13). Wrapping the rabbit in a towel or a purpose-designed restraint device may facilitate handling and is particularly helpful when performing intravenous injections (Fig. 30.14). For administration details, see Table 30.6.

New World Primates (Marmosets and Tamarins)

If well socialized, these animals can be easily restrained for mask induction of anesthesia or for intramuscular or subcutaneous administration of drugs. Intravenous administration, using the lateral tail vein, requires firm restraint and is often easier after administration of a sedative or tranquilizer. If animals resent restraint, they may bite, so protective gloves may be required to protect the operator (Fig. 30.15).

Table 30.6. Routes of injection for rodents and rabbits.

Injection Site	Species	Location	Needle Size (Gauge)	Precautions
Intramuscular	Rodents	Quadriceps or posterior thigh muscles	25–27	Muscle mass is very small, avoid sciatic nerve
	Rabbits	Quadriceps, dorsal lumbar, or posterior thigh muscles	24–27	Avoid sciatic nerve
Intravenous	Mice and rats	Lateral tail or saphenous vein	24–28	Use a local anesthetic cream (EMLA Cream) prior to injection
	Rabbits	Marginal ear vein, cephalic or saphenous vein	23–25	
Subcutaneous	Rodents	Interscapular or inguinal region	21–25	Highly viscous liquids may cause discomfort and are difficult to inject
	Rabbits	Interscapular or flanks	21–25	

Fig. 30.8. Guinea pig restraint. The guinea pig is grasped gently around its thorax and shoulders with one hand while the other hand supports its hindquarters.

Fig. 30.9. Mouse restraint. The mouse is grasped by the base of its tail.

Old World Primates (Rhesus Macaques and Baboons)

If well socialized, these animals may be restrained by their familiar handler to enable intramuscular injections (into the quadriceps) or intravenous administration (into the saphenous or cephalic veins). Animals that are apprehensive or resent handling should be sedated using ketamine. Face-mask induction of anesthesia or intravenous administration of anesthetics can then be performed more easily.

Inhalational Anesthetic Agents

Diethyl Ether

This anesthetic, which was widely used in laboratory rodents, was delivered in a simple apparatus, with liquid anesthetic placed on a swab in an anesthetic chamber. These delivery systems provided no consistency in terms of induction concentration, and the agent itself has been shown to be irritant and stressful.¹⁰ It has now largely been replaced with other agents that are delivered using more controlled methods. In addition to animal-welfare considerations, ether is explosive when mixed with oxygen or air.

Halothane

This can be used to provide safe and effective anesthesia in most laboratory species. Its effects on the cardiovascular and other body systems are broadly similar to those seen in companion and farm animals. In guinea pigs, it has been reported to cause hepatic injury,¹¹ although it is well tolerated in this species, in contrast to isoflurane and sevoflurane. Halothane is often preferred to isoflurane for neurophysiological studies (e.g., the electroencephalograph) because halothane's effects on some central nervous system activity at comparable planes of anesthesia are less pronounced.¹²

Isoflurane

This is now one of the most widely used inhalational agents for laboratory animals. Its popularity has been enhanced by its relative lack of metabolism. It is therefore thought to be less likely to interfere with drug pharmacokinetic and pharmacodynamic studies in anesthetized animals and less likely to have longer-term effects as a result of induction of liver microsomal enzyme systems. It is important to emphasize to research workers that other factors, such as changes in regional blood flow as a result of

Fig. 30.10. Mouse restraint. The mouse is placed on a cage lid and then grasped by the loose skin overlying its back.

isoflurane administration, also can influence their studies. However, the rapid induction and recovery from anesthesia and ease of change of anesthetic depth make it suitable for both very short term and long term anesthetic protocols in a range of different species. As in companion animals, isoflurane can be combined with other agents (e.g., alfentanil) to provide a balanced anesthetic regimen with reduced nonspecific effects on body systems.

Desflurane

This has not been extensively used in laboratory species, although details of minimum alveolar concentration (MAC) and other characteristics of this agent are available.¹³ It has similar effects in laboratory species as in companion animals and can be used to provide stable anesthesia with rapid induction and recovery. It appears to be better tolerated for anesthetic induction in rabbits than are other volatile agents.³

Sevoflurane

Use of sevoflurane is limited at present, but its popularity is likely to increase as it becomes more widely available in veterinary clinical practice. In addition, the speed and quality of induction and recovery and the ability to rapidly adjust anesthetic depth make it an attractive agent for a range of different studies. In guinea pigs, it appears to have much more variable effects than in other rodents. High concentrations may be required to maintain a surgical plane of anesthesia, and high mortality has been reported.

Nitrous Oxide

As in other animal species, nitrous oxide cannot produce anesthesia when used alone because its MAC value exceeds 100%. It can be used as part of a balanced anesthetic regimen to reduce the concentration of other anesthetic agents required. However, since MAC in small rodents exceeds 200%, the effects are relatively small. Since nitrous oxide is not absorbed by activated charcoal gas-scavenging units, it may be more convenient to avoid its use

Fig. 30.11. Rat restraint. The rat is grasped with one hand supporting its hindquarters and one hand supporting its head, with the thumb under its foreleg and mandible.

Fig. 30.12. Rabbit restraint. The rabbit is initially grasped by the skin of its neck and back.

Fig. 30.13. Rabbit restraint. The rabbit is carried with its head between the handler's arm and chest.

Fig. 30.14. Rabbit restraint. The rabbit is wrapped in a surgical drape to facilitate venipuncture.

altogether. In specific circumstances, for example, during prolonged anesthesia for neurophysiological studies, where the effects of anesthetic agents can be critical, its small contribution to depth of anesthesia and analgesia can be significant.

Delivery Systems

A major advantage of using volatile anesthetics in small mammals is the ease of administration using an anesthetic-induction chamber (Fig. 30.16). Ideally, chambers of different sizes should be available (e.g., for animals weighing less than 100 g and for animals weighing up to 1 kg). To reduce the period of involuntary excitement during induction, the chamber should be filled rapidly, with the maximum safe induction concentration of the agent. Since all anesthetic vapors are heavier than air, the anesthetic gas should be introduced at the bottom of the chamber and

Fig. 30.15. Marmoset restraint. The handler is wearing protective gloves.

Fig. 30.16. Rodent anesthetic chamber (available from Harvard Instruments, South Natick, MA). This particular design enables effective scavenging of waste anesthetic gases.

excess gas ducted from the top. After loss of consciousness, the animal can then be removed from the chamber, and maintained by using a face mask, at a reduced concentration of agent. Providing effective gas scavenging when a face mask is being used

can be difficult, but several systems are available commercially that assist with this, for example, the double-mask system.

Anesthesia can also be induced by face mask, and this can be a rapid and convenient technique when using sevoflurane in rats and mice. As mentioned earlier, volatile anesthetics generally provoke a breath-holding response in rabbits that is often associated with violent struggling unless preanesthetic agents are given. After sedation, the animal should be observed carefully during administration of the anesthetic and the mask removed briefly if breath holding occurs.

Nonhuman primates and other larger animals will generally be heavily sedated or completely immobilized with preanesthetic medication if a volatile agent is to be administered for anesthesia induction.

Some laboratory-animal units are equipped to provide only air as the carrier gas, and this is inadvisable. All of the currently available agents produce some degree of respiratory depression, but hypoxia can be prevented by delivery in oxygen. During recovery from anesthesia, oxygen should continue to be provided until the animal has begun to regain consciousness. If this is not done, then severe hypoxia can occur in some individuals.

Injectable Agents

Rodents and Rabbits

One noteworthy difference relating to the use of injectable anesthetics in small rodents in comparison to companion and farm animals is the difficulty of intravenous access. This results in anesthetic combinations often being administered as single injections by the intraperitoneal, subcutaneous, or intramuscular route, rather than intravenously, to effect. Although this is a simple and rapid means of producing anesthesia, it has inevitable consequences in relation to the safety of certain anesthetic agents, especially those in which the anesthetic dose is close to the lethal dose. Since there is considerable variation between different strains of rodents in their response to anesthetic agents,¹⁴ anesthetic combinations that either have a broad safety margin or are wholly or partially reversible are preferred.

The small body size and high metabolic rate of rodents can result in relatively high dose rates of some anesthetic agents being required to achieve unconsciousness. When coupled with the relative lack of efficacy of agents such as ketamine, this can lead to very high dose rates being administered (e.g., 100 mg/kg ketamine). Since the drug formulations for veterinary use are normally optimized to give convenient volumes for a dog or a cat, the volume per kilogram of drug to be injected into a mouse can be relatively very high, and, if given intramuscularly, can damage tissue and cause pain on initial injection. Anesthetic combinations that are most widely used in rodents and rabbits are discussed below, and suggested dose rates are listed in Table 30.7.

Ketamine cannot be used as the sole anesthetic agent in rodents and rabbits, but when combined with sedatives such as acepromazine, or sedative analgesics such as medetomidine, varying planes of anesthesia can be produced. In small rodents, combinations with tranquilizers often produce only light anesthesia, which is insufficient for surgical procedures, whereas combina-

tions with α_2 -agonists such as medetomidine and xylazine produce surgical planes of anesthesia. In contrast, in rabbits, combinations of ketamine with acepromazine and diazepam often produce surgical planes of anesthesia. The likely effects of these various combinations are also listed in Table 30.7.

The use of medetomidine or xylazine with ketamine has the advantage that the sedative-analgesic component of the combination can be reversed with α_2 -antagonists such as atipamezole. Since this anesthetic combination produces cardiovascular and respiratory depression, in addition to other systemic effects such as hyperglycemia and diuresis, it is strongly advised to administer the antagonist as a routine. Reversing the α_2 -agonist will, of course, reduce the level of postoperative analgesia provided, so that additional agents (e.g., carprofen or buprenorphine) should be administered, if this has not already been done.

In guinea pigs, the effects of ketamine and xylazine and/or medetomidine are more variable, and surgical anesthesia may not be produced.¹⁵ In all species, if the plane of anesthesia is insufficient, then administering additional doses of the combination may have unpredictable effects. It is preferable to administer a low concentration of an inhalant anesthetic (e.g., isoflurane) to deepen anesthesia. This same approach can be used to prolong the period of surgical anesthesia. As an alternative, the surgical field can be infiltrated with local anesthetic. As in other species, it is inadvisable to administer atropine routinely when using high doses of α_2 -agonists. Severe hypertensive effects causing mortality have been reported in rats.

Tiletamine in combination with zolazepam (Telazol) has been recommended as an anesthetic for use in rodents and rabbits. As with ketamine–benzodiazepine combinations, the depth of anesthesia produced is not always sufficient to enable surgical procedures to be undertaken. Combining the mixture with xylazine increases anesthetic depth, but the effects are still variable.

Etorphine-methotrimeprazine (Immobilon), fentanyl-fluanisone (Hypnorm), and fentanyl-droperidol (Innovar-Vet) have all had their use in rodents and rabbits described.^{16,17} All of these agents produce immobility and profound analgesia when used alone, but also cause significant respiratory depression. Fentanyl-fluanisone, when combined with midazolam or diazepam, produces surgical anesthesia in all species. Attempts to develop similar mixtures with the other commercially available neuroleptanalgesic combinations have been less successful.^{18,19}

Fentanyl-fluanisone-midazolam has the advantage that it can be mixed and administered as a single injection, but the active components must be diluted with sterile water before being combined. The mixture is stable for several weeks, but on occasion can crystallize. If this is noted, the mix should be discarded. The fentanyl component can be reversed by using naloxone, but this also reverses all analgesic effects of the combination. It is preferable to reverse the fentanyl with a mixed agonist-antagonist such as butorphanol, nalbuphine, or the partial agonist buprenorphine.²⁰ This reverses any respiratory depression, although full recovery may be prolonged because of the sedative effects of the midazolam and fluanisone. Flumazenil will reverse the midazolam, but its relatively short half-life means that re-sedation can occur.

Table 30.7. Anesthetic and related drugs for use in rodents and rabbits^a.

Drug	Dose Rate	Effect	Anesthesia Duration (min)	Sleep Time (min)
Anesthetic and related drugs for use in mice				
Fentanyl-fluanisone and diazepam	0.3 mL/kg IM + 5 mg/kg IP	Surgical anesthesia	30–40	120–240
Fentanyl-fluanisone and midazolam ^b	10 mL/kg IP	Surgical anesthesia	30–40	120–240
Ketamine and medetomidine	75 mg/kg + 1 mg/kg IP	Surgical anesthesia	20–30	60–120
Ketamine and xylazine	80 mg/kg + 10 mg/kg IP	Surgical anesthesia	20–30	60–120
Tiletamine-zolazepam	80–100 mg/kg IM	Immobilization		60–120
Tribromoethanol	240 mg/kg IP	Surgical anesthesia	15–45	60–120
Anesthetic and related drugs for use in rats				
α-Chloralose	55–65 mg/kg IP	Light anesthesia	480–600	Nonrecovery only
Chloral hydrate	400 mg/kg IP	Light/surgical anesthesia	60–120	120–180
Fentanyl-fluanisone and diazepam	0.3 mL/kg IM + 2.5 mg/kg IP	Surgical anesthesia	20–40	120–240
Fentanyl-fluanisone and midazolam ^b	2.7 mL/kg IP	Surgical anesthesia	20–40	120–240
Ketamine and medetomidine	75 mg/kg + 0.5 mg/kg IP	Surgical anesthesia	20–30	120–240
Ketamine and xylazine	75 mg/kg + 10 mg/kg IP	Surgical anesthesia	20–30	120–240
Tiletamine-zolazepam	40–50 mg/kg IP	Light anesthesia	15–25	60–120
Urethane	1000 mg/kg IP	Surgical anesthesia	360–480	Nonrecovery only
Anesthetic and related drugs for use in rabbits				
Alphaxalone-alphadolone	6–9 mg/kg IV	Light anesthesia	5–10	10–20
Fentanyl-fluanisone and diazepam	0.3 mL/kg IM + 2 mg/kg IP or IV	Surgical anesthesia	20–40	60–120
Fentanyl-fluanisone and midazolam ^b	0.3 mL/kg IM + 2 mg/kg IM or IV	Surgical anesthesia	20–40	60–120
Ketamine and acepromazine	50 mg/kg IM + 1 mg/kg IM	Surgical anesthesia	20–30	60–120
Ketamine and medetomidine	15 mg/kg SC + 0.25 mg/kg SC	Surgical anesthesia	20–30	90–180
Ketamine and xylazine	35 mg/kg IM + 5 mg/kg IM	Surgical anesthesia	20–30	60–120
Propofol	10 mg/kg IV	Light anesthesia	5–10	10–15
Thiopentone	30 mg/kg IV	Surgical anesthesia	5–10	10–15
Anesthetic and related drugs for use in guinea pigs				
Alphaxalone-alphadolone	40 mg/kg IP	Immobilization		90–120
Fentanyl-fluanisone and diazepam	1 mL/kg IM + 2.5 mg/kg IP	Surgical anesthesia	45–60	120–180
Fentanyl-fluanisone and midazolam ^b	8 mL/kg IP	Surgical anesthesia	45–60	120–180
Ketamine and medetomidine	40 mg/kg + 0.5 mg/kg IP	Moderate anesthesia	30–40	90–120
Ketamine and xylazine	40 mg/kg + 5 mg/kg IP	Surgical anesthesia	30	90–120
Anesthetic and related drugs for use in hamsters				
Fentanyl-fluanisone and midazolam ^b	4 mL/kg	Surgical anesthesia	20–40	60–90
Ketamine and medetomidine	100 mg/kg + 0.25 mg/kg IP	Surgical anesthesia	30–60	60–120
Ketamine and xylazine	100–200 mg/kg + 10 mg/kg IP	Surgical anesthesia	30–60	90–150
Anesthetic and related drugs for use in gerbils				
Fentanyl-fluanisone and midazolam ^b	8 mL/kg	Surgical anesthesia	20	60–90
Ketamine and medetomidine	75 mg/kg + 0.5 mg/kg IP	Medium anesthesia	20–30	90–120
Ketamine and xylazine	50 mg/kg + 2 mg/kg IP	Immobilization		20–60

IM, intramuscularly; IP, intraperitoneally; IV, intravenously; SC, subcutaneously.

^aNote that considerable between-strain variation occurs, so dose rates should be taken only as a general guide.

^bDose (mL/kg) of a mixture of 1 part Hypnorm (fentanyl-fluanisone) plus 2 parts water for injection, and 1 part midazolam (5-mg/mL initial concentration).

In rabbits, the combination is best administered separately—fentanyl-fluanisone initially to produce sedation, analgesia, and peripheral vasodilation. This makes placement of an intravenous catheter, for example, in the marginal ear vein, simple and enables slow intravenous administration of the midazolam to produce the desired effects.

In rats, rabbits, and guinea pigs, mixtures of potent opioids (e.g., fentanyl or sufentanil) can be combined with medetomidine or other α_2 -agonists to produce surgical anesthesia. In some instances, the addition of a benzodiazepine improves the degree of muscle relaxation.²⁰ These combinations have the advantage that they can be completely reversed by using specific antagonists.

Thiobarbitals (Inactin) has been extensively used to provide medium-term to long-term anesthesia in rats. It is considered to have minimal effects on the cardiovascular system; in many respects, however, it resembles other barbiturates, producing reduction in cardiac output and organ blood flows.²¹

Urethane is a hypnotic agent that produces long-lasting and stable anesthesia with minimal cardiovascular and respiratory system depression. Urethane provides good narcosis and muscle relaxation, but the analgesic component may not be adequate. It is commonly used in terminal experiments for central and peripheral neural function studies where reflex responses should be preserved. When administered intraperitoneally, the most common route used, it has profound endocrine and metabolic effects, producing superficial damage and necrosis of intra-abdominal organs and massive leakage of plasma into the peritoneal cavity.²² The onset of the aforementioned effects is rapid. Similar effects have not been observed when urethane was administered by subcutaneously, intravenously, or intra-arterially. Urethane is a carcinogenic and potentially mutagenic anesthetic agent therefore it should only be used if other suitable alternatives are not available and only for terminal (non recovery) studies.

Chloralose is used to provide long-lasting anesthesia, particularly in studies in which maintenance of cardiovascular responses is required. α -Chloralose is a hypnotic, and the anesthesia depth produced may be insufficient to enable surgical procedures to be undertaken. Induction and recovery from chloralose are very prolonged, so the agent is normally used only for terminal procedures. To avoid problems associated with a prolonged onset of action, anesthesia is often induced using another agent (e.g., isoflurane). Following intravenous cannulation and any other surgical procedures, chloralose is then administered.

Although now rarely used in farm-animal anesthesia, chloral hydrate, because of its minimal effects on the cardiovascular system, is still used to anesthetize laboratory animals. It is also used in neuropharmacology studies, because it is thought to have a reduced likelihood of interacting with other compounds. It produces medium-duration anesthesia. The anesthesia depth varies between different strains of rodent and can be sufficient for surgical procedures to be undertaken.^{23,24} In some strains of rat, chloral hydrate can cause postanesthetic ileus, which can be fatal.²⁵ Using a dilute solution of chloral hydrate (36 mg/mL) can reduce the incidence of ileus.

Tribromoethanol (Avertin) is a hypnotic that produces surgical anesthesia in rats and mice that lasts approximately 15 to 20 min.

It has become extremely popular for anesthesia of mice for embryo transfer and for the production of transgenic animals, and has been reported to be safe and effective.²⁶ However, if improperly prepared or poorly stored, tribromoethanol can cause gastrointestinal disturbances. More recently, it has been reported that tribromoethanol can cause low-grade peritoneal irritation, even when correctly prepared and stored.^{27,28} In view of these potential adverse effects, tribromoethanol is better replaced with other anesthetic combinations.

Nonhuman Primates

A very extensive range of anesthetic agents can be used in these species (Table 30.8). In most Old World primates, ketamine is administered initially to provide restraint. It is then possible to place an intravenous catheter and use an intravenous induction agent such as propofol, thiopental, or alphaxalone-alphadolone. Alternatively, anesthesia can be induced by using an inhalant anesthetic delivered via face mask. All of the currently used inhalant agents can be used safely and effectively in primate species.

As with other species, balanced anesthetic regimens—for example, ketamine as a preanesthetic medication, induction with propofol, followed by maintenance with sevoflurane, perhaps together with an opioid infusion—can provide stable anesthesia for many hours. However, body systems should be monitored carefully, and it is often advisable to intubate and assist ventilation if opioid infusions are used.

As mentioned earlier, ketamine has been reported to cause muscle necrosis in New World primates, so alphaxalone-alphadolone can be used as an alternative. Anesthesia can be deepened by further doses administered intravenously.⁷ Alternatively inhalational agents can be used or propofol by continuous infusion.

Monitoring and Intraoperative Care

It is particularly important to provide high standards of perioperative care with laboratory animals, since not only can problems such as hypothermia prolong recovery, they cause widespread physiological effects that may interfere with particular research objectives. As in veterinary clinical practice, one staff member may need to act as both anesthetist and surgeon, so detailed clinical monitoring may be lacking. Use of electronic monitoring devices can therefore be of considerable value. The type of monitoring used should be selected based on the species, duration of anesthesia, type of surgery, and assessment of the degree of risk of complications or emergencies. Use of such devices is straightforward in Old World nonhuman primates, rabbits, and other large species, but is complicated by the small body size of other laboratory species. Small size is associated with a rapid heart rate (>300 beats/min) that may exceed the upper limits of some monitors, and the low signal strength may not be detectable. In addition, small body size limits such procedures as invasive blood-pressure monitoring and makes most noninvasive devices ineffective. Some equipment is now available that can function despite these problems, and routine electronic monitoring is becoming increasingly commonplace.

Table 30.8. Anesthetics and related drugs for use in nonhuman primates^a.

Anesthetic and Related Agents	Dose Rate	Effect
Alphaxalone-alphadolone	10–12 mg/kg IV 12–18 mg/kg IM	Surgical anesthesia Immobilization, anesthesia
Ketamine/diazepam	15 mg/kg IM + 1 mg/kg IM	Surgical anesthesia
Ketamine/xylazine	10 mg/kg IM + 0.5 mg/kg IM	Surgical anesthesia
Propofol	7.5–12.5 mg/kg IV	Surgical anesthesia

IM, intramuscularly; IV, intravenously.

^aNote that considerable between-animals and between-species variation occurs so dose rates should only be taken as a general guide.

Assessment of Respiratory Function

Clinical observation of respiratory rate and pattern is relatively straightforward, but can be complicated by placement of surgical drapes, especially in small rodents. In these smaller species, the anesthetic circuit will not normally contain a reservoir bag, so observation of bag movements cannot be used to monitor respiration. Unfortunately, many electronic monitors do not respond to the relatively small respiratory movements and low tidal volumes, especially when used with animals weighing less than 200 g. In these small mammals, direct observation of respiratory rate and pattern may be the only option available.

In common with other species, the pattern, rate, and depth of anesthesia vary both with anesthetic depth and with the anesthetic regimen used. With inhalant anesthetics and the majority of injectable regimens, respiratory rate falls. Typical respiratory rates during anesthesia are 50 to 100 breaths/min for small rodents and 30 to 60 breaths/min for rabbits. Since many of these animals show a very marked stress-related tachypnea prior to induction, assessment of the degree of respiratory depression should either be based on estimates of normal resting rate (Table 30.1) or established by observing the animals preoperatively when undisturbed. A reduction to less than 50% of the estimated normal respiratory rate should cause concern. Gradual changes in rate, rather than a sudden reduction, are more usual, so keeping an anesthetic record is advisable.

The adequacy of oxygenation and heart rate can be assessed by using a pulse oximeter, but the high heart rates in rodents may exceed the upper limits of the monitor. A monitor with an upper limit of at least 350 beats/min is needed, and successful operation may also depend on the type of probe used. It is advisable to try several instruments, probes, and probe positions to find the most reliable combination. In the authors' experience, a signal can usually be obtained from across the hind foot in rodents or across the base of the tail. In rabbits, the toe, tail, tongue, and ear are also useful. In particular, the use of an angled probe placed in the mouth has proven particularly reliable.

End-tidal carbon dioxide is difficult to measure in small mammals. The gas volume sampled by side-stream capnographs may be very large in relation to the animal's tidal volume, and main-stream capnographs introduce too much equipment dead space into the anesthetic-breathing circuit. In rabbits and Old World primates, equipment designed for pediatric use in people usually functions well (Fig. 30.17).

Fig. 30.17. An anesthetized rabbit. There is a low dead-space connector (Portex; Smiths Medical, Hythe, Kent, England) on the end of the endotracheal tube, with a side-port connector for capnograph connection.

Maintenance of a patent airway may be assisted by placement of an endotracheal tube, but the small size of many laboratory species makes this technically difficult. Intubation of nonhuman primates is relatively straightforward when using a small Macintosh blade or other curved design. Alternatively, a Soper or Wisconsin blade can be used to visualize the larynx (Fig. 30.18). The animal can be positioned either in sternal recumbency or on its back, depending on the preferences of the anesthetist. A cuffed 4-mm tube can be placed in a 7- to 8-kg Rhesus monkey. An introducer can be used to help pass the tube through the vocal cords, and laryngospasm can be prevented by spraying the cords with lidocaine. Stimulation of the larynx in a lightly anesthetized animal can provoke violent coughing and occasionally vomiting, so it is important to ensure that the animal is sufficiently deeply anesthetized before intubation is attempted.

Rabbits can also be intubated relatively easily by using either an otoscope to visualize the larynx or a blind technique. Prior to intubation, the animal should breathe 100% oxygen for 1 to 2 min. Uncuffed endotracheal tubes should be used to maximize the airway diameter; a 3- to 3.5-mm-diameter tube is usually suitable for a 3- to 4-kg rabbit. Tubes with a diameter of less than

Fig. 30.18. An immobilized squirrel monkey with a view of its larynx prior to intubation.

2.5 mm are required for very small rabbits (<800 g), and these should be purchased from specialist suppliers.

When an otoscope is used, the rabbit is positioned on its back, its mouth opened, and its tongue pulled forward into the gap between the incisors and premolars, taking care not to injure the tongue on the edges of the incisors (Fig. 30.19). The otoscope speculum should be inserted into the gap between teeth on the opposite side of the mouth to the tongue and advanced until the end of the soft palate or the larynx is visible. In some animals, the epiglottis will be positioned behind the soft palate, hiding the larynx from view. To expose the larynx, the introducer is used to reposition the epiglottis and soft palate. The larynx should then be sprayed with local anesthetic. The introducer is then advanced through the otoscope speculum, through the larynx, and into the trachea. The otoscope is removed and the endotracheal tube threaded onto the introducer and into the trachea. The introducer is then withdrawn.

To place a tube using the blind technique, the rabbit is positioned on its chest, with its head and neck extended upward (Fig. 30.20). The endotracheal tube is introduced into the gap between the incisors and premolars and advanced into the pharynx. When the larynx is reached, some increase in resistance is felt. The tube

Fig. 30.19. Intubation of a rabbit's larynx by using an otoscope. The rabbit is in dorsal recumbency, and oxygen is administered for at least 2 min through a face mask prior to intubation.

Fig. 30.20. Intubation of a rabbit by using the “blind technique.” The rabbit is in ventral recumbency, and oxygen is administered for at least 2 min prior to intubation. To intubate, the endotracheal tube is placed in the rabbit's mouth to the level of its larynx. On inspiration, the endotracheal tube is gently advanced into the larynx in the direction of the loudest breath sounds.

can then be advanced into the larynx and trachea—this is usually accompanied by a slight cough. In some cases, the tube passes into the esophagus and will need to be withdrawn and repositioned. Passage of the tube is often assisted by gently rotating it through 45° as it is advanced into the larynx. The tube position can be monitored by listening at the end of the tube—if breath sounds can be heard, the tube is in the pharynx or the trachea. As an alternative to intubation, a laryngeal mask can be used.²⁹ This technique is easier to master than endotracheal intubation, but assisted ventilation may not be effective. If only oxygen supplementation is required, a nasal catheter can be passed and positioned in the back of the pharynx.

Fig. 30.21. A rodent workstand (available from Hallowell EMC, Pittsfield, MA) designed to facilitate endotracheal intubation in mice and rats.

Intubation of small rodents is made easier if a specialized apparatus is used. A technique using a modified otoscope speculum to visualize the larynx and an over-the-needle catheter as the endotracheal tube is relatively easy to master. Although a variety of other methods have been described, the modified otoscope (Fig. 30.21) enables rapid, atraumatic intubation and is supplied together with an instructional video.

After intubation, animals can be maintained on an appropriate anesthetic circuit; for example, a purpose-made low-dead-space T piece for small rodents, or a pediatric T piece or unmodified Bain's circuit for rabbits or nonhuman primates.

Assessment of Cardiovascular Function

Clinical monitoring of the cardiovascular system is difficult in small rodents because of their size. Peripheral pulse is difficult or impossible to palpate, and even when the thorax is palpated, since heart rate is frequently greater than 250 beats/min, accurate heart rate cannot be assessed. In rabbits and guinea pigs, the chest can be auscultated, but this is difficult in smaller rodents. An esophageal stethoscope can be used in rabbits. When using electronic monitoring equipment, the upper rate limits (often 250 or 300 beats/min) are often exceeded, and some instruments will not detect the low-amplitude electrocardiographic signal.

Other clinical assessments, such as use of capillary refill time, are practicable and useful in rabbits and primates. In all species, assessment of the color of the mucous membranes enables some assessment of peripheral perfusion. Arterial blood pressure can be measured by using noninvasive systems in nonhuman primates and larger rabbits or by using pediatric-sized cuffs or specially designed veterinary equipment. Blood pressure can be measured in this way in rats, using a tail cuff, but special apparatus is required. Invasive blood-pressure monitoring is possible in all species, but surgical exposure of the vessel is needed in rodents, which tends to limit use of this technique to nonrecovery procedures. In rabbits, an over-the-needle catheter can be placed

in the central ear artery, and, in primates, the femoral artery can be catheterized by using a Seldinger technique.

Blood volume in all of these species is approximately 70 mL/kg of body weight, so small rodents will have very low total blood volumes (e.g., 2 mL for a 30-g mouse). It is therefore critically important to minimize blood loss by careful surgical technique and to monitor blood loss by accurate weighing of swabs and assessing other losses at the surgical site.

Thermoregulation

Small mammals have an increased surface area to body weight ratio that results in rapid cooling during anesthesia. Maintaining body temperature and careful monitoring to ensure this is being achieved effectively are therefore critically important. Hypothermia can cause much delayed recovery from anesthesia and, if severe, can cause cardiac arrest. Rectal temperature should be monitored with an electronic thermometer. The probe size of less expensive instruments is usually appropriate for animals weighing 250 g or more, but specialist instruments are needed for very small rodents (e.g., mice and hamsters). To reduce loss, the area of fur shaved during preparation of the surgical site should be minimized, and use of skin disinfectants should be limited to the minimum necessary to maintain asepsis. Animals should be placed on a heating pad maintained at 37° to 39°C. It is important that measures to maintain body temperature are continued into the postoperative period.

Emergencies

All of the measures for coping with anesthetic emergencies applicable to companion animals can be used in laboratory species, but as with many other techniques, small body size can limit or complicate some of these procedures. To assist ventilation if an animal has not been intubated, its head and neck should be extended, its tongue pulled forward, and its chest squeezed between the anesthetist's thumb and forefinger. If the tongue is difficult to grasp, it can be rolled forward using a cotton-wool bud (Q-tip). When an animal has been intubated, respiration can be assisted relatively easily. Attempting to assist ventilation by using a face mask is usually unsuccessful, but in small rodents a soft piece of rubber tubing can be placed over the nose and mouth, and the lungs inflated by gently blowing down the tube. Doxapram (5 to 10 mg/kg intravenously, intramuscularly, or subcutaneously) can also be administered to stimulate ventilation. Oxygen should always be administered with doxapram administration if this is not already being provided.

As mentioned earlier, since total blood volume is low in small rodents, every effort should be made to minimize blood loss. If fluid therapy is required, this can be delivered via an over-the-needle catheter in the tail vein of rats, the medial tarsal vein in guinea pigs, or the marginal ear vein, cephalic vein, or jugular vein in rabbits. The cephalic or saphenous veins can be used in nonhuman primates, and the lateral tail vein can be used in marmosets. If whole blood is required, then a suitable donor may be available in the research facility. All of the commonly available fluid products can be administered safely to small mammals and other laboratory species. In smaller rodents in which intravenous

access is not practicable, intraperitoneal or subcutaneous administration of warmed electrolyte solutions can slowly replace fluid deficits, but will be of minimal benefit if rapid hemorrhage is occurring. In these smaller species, placement of an intraosseous catheter can provide an alternative route for fluid replacement. If cardiac arrest occurs, external cardiac massage and emergency drugs such as epinephrine can be used when attempting resuscitation.

Postoperative Care

If possible, a separate recovery area should be provided, because this makes it easier to provide an optimal environment during this period. It also encourages individual attention and special nursing, if those are required.

Most of the commonly used anesthetics will continue to cause some degree of respiratory depression in the immediate postoperative period. In addition to continuing to monitor respiratory function, care must be taken that respiratory obstruction does not occur. Small rodents and rabbits may attempt to hide and push into the corner of a recovery cage, and this can result in airway obstruction. Also, when allowed to recover in a group, rodents may huddle together, which can decrease oxygen availability for the animals at the bottom of the group. Although recovery is often more rapid after use of inhalational agents, significant hypoxia (oxygen saturation of less than 70%) can occur, and this should be prevented by maintaining the animal in an oxygen-enriched environment, either by using a face mask or by delivering oxygen into the incubator until respiratory function is judged to be normal.

It is also important that measures to maintain normal body temperature are continued in the recovery period. This can often be achieved by allowing small animals to recover in a pen or cage in a recovery room (maintained at a high ambient temperature, with supplemental heating of the cage as necessary) or inside an incubator. A temperature of 25° to 30°C is needed for adult animals and 35° to 37°C for neonates. If an incubator is unavailable, heating pads and lamps should be provided. Care must be taken not to overheat the patient, and a thermometer should be placed next to the animal to monitor the temperature in its immediate environment.

During recovery from anesthesia, animals should be provided with bedding, such as synthetic sheepskin (Fig. 30.22). If this is not available, then toweling or a blanket should be used. Sawdust or wood shavings are unsuitable because this type of bedding will often stick to an animal's eyes, nose, and mouth. Tissue paper is often provided as bedding for small rodents, but it is relatively ineffective because animals usually push it aside during recovery from anesthesia and end up lying in the bottom of a plastic cage soiled with urine and feces.

Drinking water should be available, but care must be taken that this not be spilled, because, if the animal's skin becomes wet, it will lose heat rapidly. Small rodents are usually accustomed to using water bottles, so this is rarely a problem, but it can present difficulties with rabbits, guinea pigs, ferrets, and larger species.

It may also be judged necessary to provide fluid therapy post-

Fig. 30.22. Rats recovering from anesthesia in an incubator. Rats are provided with dry synthetic bedding.

operatively. This can be given by intravenous infusion in larger animals, but it is most convenient in small rodents to give warmed (37°C) subcutaneous or intraperitoneal dextrose-saline at the end of surgery (Table 30.9).

Food should be provided for most laboratory species immediately after they regain consciousness. Animals should be encouraged to eat as soon as possible, and this can often be achieved by providing highly palatable foods. A mash made by soaking pelleted diet in warm water is often rapidly consumed by small rodents, providing both additional fluid as well as food intake.

When monitoring the recovery of nonhuman primates, an additional concern is ensuring the safety of staff because of the potentially serious consequences of being bitten by a primate. The use of propofol sedation during recovery, so that animals can be allowed to regain consciousness in a controlled manner, can be helpful. After completion of surgery, the anesthetic (e.g., isoflurane) is discontinued and recovery of reflexes monitored. After return of the pedal withdrawal response and increase in jaw tone, propofol can be administered intravenously to deepen anesthesia slightly. Having produced a stable plane of light anesthesia, the animal either can be extubated when jaw tone returns or moved from the operating area to its recovery cage. Deep sedation or light anesthesia can be continued with incremental doses of propofol. The intravenous catheter can then be removed and the animal allowed to recover completely. Recovery from propofol is normally smooth, rapid, and associated with a less prolonged period of ataxia than is, for example, isoflurane. An alternative is either to maintain the primate on sevoflurane or to switch to this agent at the end of surgery. In our experience, recovery from this agent is smooth and rapid.

Pain Assessment

If analgesics are to be administered appropriately, then it is essential that attempts are made to assess the severity of postoperative pain. Only when this is done can one determine whether an

Table 30.9. Volumes of fluid for administration to rodents and rabbits^a.

Route	Mouse	Rat	Rabbit	Guinea Pig	Hamster	Gerbil
Intraperitoneal (mL)	2	5	50	20	3	2–3
Subcutaneous (mL)	1–2	5	30–50	10–20	3	1–2

^aVolumes are suggested rates for adult animals. All fluids should be warmed to body temperature prior to administration.

appropriate dose of analgesic has been administered. Pain assessment is also essential to judge whether an appropriate type of analgesic has been selected, when to repeat dosing, and when to discontinue therapy.

Unfortunately, assessing pain in laboratory species is difficult. At present, the only practical option may be to judge the likely pain intensity based on the type of surgery and skill of the surgeon and use this to formulate an analgesic protocol. As with anesthesia selection, the aims of the particular research project should be considered when selecting the analgesic. Attempts should still be made to assess pain, and, since this is a rapidly developing field, it is important to continue to monitor the scientific literature for new information. Analgesic efficacy clearly varies considerably between different strains of rodents,³⁰ and this reinforces the need for pain-scoring systems.

At the time of writing, pain-scoring schemes have been developed for rats, following abdominal surgery.³¹ In this species, back arching, contraction of the abdominal muscles, staggering and falling (not related to anesthetic recovery), and twitching of the skin overlying the back and abdomen all appear to be pain related. If more than one or two back arches, abdominal contractions, or staggers are seen in a 5-min period, then additional analgesia may be required. Illustrative material is available from www.digires.co.uk. In mice, similar behaviors have been noted (S. Wright-Williams, personal communication), as has a reduction in normal activities such as climbing (A. Karas, personal communication), but these behaviors have not yet been developed into a formal pain-scoring system. Some rabbits also show abdominal contractions after laparotomy, but changes in postoperative behavior in this species appear to be much more variable and to be markedly inhibited in some animals by the presence of an observer. Virtually no information is available regarding pain-related behavior in guinea pigs, hamsters or gerbils, or nonhuman primates.

In rats and probably other small rodents, analgesic efficacy can be assessed retrospectively by evaluating food and water intake and body weight. Body weight, food intake, and water intake decreases after many types of surgery in several different strains of rat, and administration of analgesics reduces this effect.^{32,33} However, changes are not always consistent, particularly in juvenile animals.³⁴

Pain Alleviation

Since all of the analgesic agents available for use in animals and people have been developed and tested for safety and efficacy in laboratory animals, likely effective doses can be suggested for

Table 30.10. Suggested analgesic dose rates for nonhuman primates (marmosets and rhesus macaques)^a.

Analgesic	Dose Rate
Buprenorphine	0.005–0.01 mg/kg IM or IV, per 6–12 h
Carprofen	2–4 mg/kg SC per 24 h
Meloxicam	0.1 mg/kg PO per 24 h

IM, intramuscularly; IP, intraperitoneally; IV, intravenously; SC, subcutaneously.

^aDose rates are based largely on uncontrolled clinical trials and a limited range of procedures and so are likely to be subject to revision.

most agents. However, the assessments of efficacy made during drug development are often based on tests that rely on acute painful stimuli (e.g., brief noxious heat or pressure). These differ from clinical pain. The dose rates suggested in Tables 30.4 and 30.10 are based on clinical experience, published data that incorporated a means of assessing postoperative pain, or data from analgesimetric assays, such as the late-phase formalin test, that are believed to be more relevant to clinical pain.³⁵

Nonsteroidal Anti-inflammatory Drugs

All of the nonsteroidal anti-inflammatory drugs (NSAIDs) available for use in animals or people can be administered to laboratory species. The general considerations related to their use in other species apply equally to laboratory species; however, since most laboratory animals undergoing surgery are young, healthy adults, concerns related to preexisting disease are often minimal. Of the agents available, the oral preparation of meloxicam is of particular value because it is highly palatable to many small rodents and to nonhuman primates, particularly if added to a favorite foodstuff. The duration of action of NSAIDs in rodents and rabbits is uncertain, but carprofen and meloxicam appear to have duration of at least 8 and possibly 24 h.

Opioids

These are effective at alleviating postoperative pain, but some species-specific side effects have been reported. In nonhuman primates, butorphanol has been reported to cause a relatively greater degree of respiratory depression than occurs in other species.⁵ Buprenorphine causes very little depression of respiration at clinically relevant dose rates, so is recommended as the partial agonist of choice in nonhuman primates. Opioids may also cause sedation or excitement, with their effects varying con-

siderably in different animal species. The effects on behavior also depend on the drug dose that has been administered. Morphine sedates rats, but produces excitement in mice and, at high doses, a characteristic elevated and rigid tail (the Straub tail response). Although an effective analgesic, buprenorphine use in some strains of rat in some research institutes has been reported to cause pica, manifested as compulsive eating of bedding material. This is most severe when inappropriately high drug doses are administered,³⁶ but can also be seen at lower dose rates. Although the problem can be prevented by housing the animals on grid floors,³⁷ it may represent abdominal discomfort or nausea, so, if seen, an alternative analgesic should be used for that particular strain of animal. This side effect does not occur consistently, and, in view of the prolonged duration of action and safety of buprenorphine, this analgesic is often considered the opioid analgesic of choice in rats and other laboratory species.³⁵ A suggested analgesic dose of buprenorphine for use in nonhuman primates is listed in Table 30.10.

Effective Pain Control

Whatever the choice of analgesic regimen, it is important to administer sufficient drug to relieve pain effectively. If pain is not controlled effectively as rapidly as possible, such control can become progressively more difficult to achieve. This is one reason why preoperative administration of analgesics before elective surgery is advocated. In addition to providing more effective pain relief, it also may reduce the dose of anesthetic required. Experience with small rodents and rabbits has shown that the use of buprenorphine in this way enables the concentration of isoflurane or halothane needed for surgical anesthesia to be reduced by 25% to 50%. Care should be taken when using injectable anesthetics administered intraperitoneally or intramuscularly. As discussed earlier, in these circumstances the dose of anesthetic cannot be adjusted to meet individual requirements, and it is clear that opioids can potentiate the effects of anesthesia.³⁸ In view of the difficulty of adjusting the dose of injectable anesthetic, it is probably better to administer opioid analgesics postoperatively. When using neuroleptanalgesics, the opioid component will provide analgesia that can conveniently be partially reversed with the administration of buprenorphine or butorphanol. The latter opioid provides better reversal, but has a short duration of action, so either an additional dose should be given, or it should be combined with a NSAID.

As in other species, in many circumstances combinations of different agents can be particularly effective: for example, local nerve block at the time of repair of a thoracotomy, coupled with the administration of systemic opioids and NSAIDs, followed by repeated administration of opioids and NSAIDs, as required.³⁹ As the degree of pain subsides, the opioids can be reduced and pain controlled solely with NSAIDs. Suggested NSAID dosages for use in nonhuman primates are listed in Table 30.10.

Anesthesia of Neonatal Rodents

Neonatal rodents can be safely and effectively anesthetized with inhalant anesthetics, such as isoflurane.⁴⁰ The majority of in-

Fig. 30.23. A rat pup placed on a gauze swab with crushed ice.

jectable anesthetics may be associated with a high mortality, but fentanyl-fluanisone can be used in neonatal and juvenile rats.⁴¹ Hypothermia is still used as an anesthetic technique in some research laboratories. Reducing body temperature to around 4° to 5°C by placing newborn rodents in a refrigerator or on crushed ice immobilizes them and slows their cardiac and respiratory function to virtually undetectable levels (Fig. 30.23). At these temperatures, nerve conduction is slowed or completely blocked, so that it is assumed that surgery can be performed without the animals experiencing pain or distress.⁴² The technique remains controversial, but mortality is low when this approach is used. In the authors' opinion, this approach should be used only when alternative methods have been shown to be unsuitable.

Fetal Surgery

The majority of descriptions of fetal surgery rely on anesthesia of the mother to produce sufficient anesthesia in the fetus, although

it may also be useful to infiltrate the surgical site in the fetus with local anesthetic to prevent movement in response to surgery. The fetus probably cannot perceive pain,⁴³ but nociceptor activation may produce changes in the central nervous system that can alter pain perception after birth or otherwise alter development.⁴⁴ It is therefore recommended that local anesthesia be used in the fetus, and that anesthetic regimens that cross the placenta be used in the mother.

Introduction

This chapter reviews anesthesia and immobilization of a wide array of selected species commonly found in zoos and wildlife parks, as well as a number of exotic species that have a special role in either animal agriculture or as companion animals. In some instances, species have been included in this chapter because of the unique challenges they present when endeavoring to capture or anesthetize them either in the wild or captured environment.

Flying Mammals: Bats

Bats should be handled with thick leather gloves to prevent one from being bitten.¹ Bats harbor a number of viruses that can cause human illnesses and even death. Therefore, sedation and anesthesia are recommended if extensive handling is necessary. Fruit bats (*Eidolon helvum*) have been sedated with a phenothiazine tranquilizer (intramuscular [IM] chlorpromazine, 2.5 mg/100 g). After the tranquilizer has taken effect, the bat can be mounted on a restraining board with wings extended and an inhalant anesthetic administered by mask. Other methods of chemical restraint include IM xylazine (2 to 3 mg/kg) administration, which will provide 30 to 40 min of sedation. Ketamine can be given IM at a dose of 10 to 20 mg/kg along with this dose of xy-

lazine to provide more complete immobilization with muscle relaxation and a quiet recovery. Medetomidine (50 µg/kg IM) has also been combined with ketamine (5 mg/kg IM) for short-term immobilization. Telazol (tiletamine-zolazepam) may be a good alternative for injectable immobilization at an IM dose of 8 to 10 mg/kg.² Intraperitoneal (IP) pentobarbital injection at a dose of 0.05 mg/g of body weight has been used in a number of genera of bats (*Rhinolophus*, *Hipposideros*, *Tadarida*, *Molossus*, *Eptesicus*, *Chilonycteris*, and *Artibeus*) to implant electrodes surgically on the round window of the cochlea or in the brain. Smaller doses (0.03 to 0.045 mg/g) have been used for *Myotis lucifugus* and *Pleocotus townsendii*.^{3,4}

Isoflurane or sevoflurane delivered by mask or into an induction chamber can be safely used to anesthetize bats. Following mask induction, megachiropterous can be intubated (2- to 3-mm internal diameter [ID]) to maintain anesthesia. When intubating bats, care must be taken to avoid lacerations from teeth and direct contact with saliva. Intravenous (IV) access is feasible via the brachial vessels overlying the distal humerus.²

Terrestrial Mammals

Armadillos

There are ten living genera of armadillos. *Dasyurus novemcinctus*, the most common, weighs 4 to 5 kg as an adult. Armadillos should be caught close to the base of the tail to avoid the hind claws. Because armadillos can incur a large oxygen debt, they may lie completely still without breathing for long periods. Armadillos also have the ability to recover spontaneously from repeated episodes of ventricular fibrillation.⁵ Anesthetics may be administered into the subcarpal tissues or the spinal muscles by inserting a needle between two bands slightly to one side of the midline. The site should be thoroughly cleansed to avoid danger of abscess formation.

Neuroleptanalgesic combinations (e.g., fentanyl-droperidol, 0.20 to 0.25 mL/kg IM) appear to produce sufficient depression and analgesia for surgery.⁶ Longer procedures have been performed with slow IV infusion of thiopental.⁷ Infused over a period of 1 h, 5 mL of 0.5% solution is adequate and safe for most adults. The usual dosage is 5 to 6 mg · kg⁻¹ · h⁻¹. Alternatively, pentobarbital (25 mg/kg IV) has been administered via the superficial femoral vein.⁸ Half the dose is given rapidly, followed by the remainder to effect. Apnea and breath holding are not reported to be a problem with this technique. Injections can be made into the two prominent superficial femoral veins. The

femoral vein is the only accessible superficial vein that can be easily catheterized. Midline cesarean section has been performed with local infiltration of lidocaine.

Telazol (8.5 mg/kg IM), xylazine (1 mg/kg) with ketamine (7.5 mg/kg), and medetomidine (75 µg/kg) with ketamine (7.5 mg/kg) have been evaluated for their anesthetic actions following IM administration. All three combinations induced anesthesia within 5 min.⁹ Armadillos were immobilized for approximately 45 min, with recovery requiring 2 to 3 h. When atipamezole was used to antagonize medetomidine, recovery was shortened to 15 min or less.⁹

Inhalation anesthesia with isoflurane or sevoflurane is easily achieved with a closed induction chamber. Premedication with IM atropine sulfate (total dose, 0.1 mg) can be used to diminish secretions. A soft polyethylene endotracheal tube 4- to 8-mm ID is easily placed through the laryngeal opening with the use of a laryngoscope. Following intubation, anesthesia may be maintained with isoflurane concentrations in the range of 1.5% to 2.5% delivered via a rebreathing system using a precision vaporizer.

Wild Rodents

Chinchillas are easily removed from their cages by grasping them by the base of the tail and lifting them off their feet. Anesthesia can be induced with either 1.5% to 2.5% halothane or isoflurane or 2.5% to 4.0% sevoflurane. Old reports indicate that the IM administration of 15 mg of meperidine approximately 30 min prior to surgery, followed by 1% subcutaneous (SC) lidocaine solution injected along the proposed line of incision, provides adequate analgesia and sedation for cesarean section in chinchillas.¹⁰ Recovery is rapid, and the young suckle within minutes after delivery. Midazolam or diazepam (5 mg/kg) plus ketamine (15 to 20 mg/kg) administered IM also produces relaxation and analgesia for up to 2 h. Thiopental sodium in dilute solution can also be administered IV to effect for minor surgical procedures. Epidural anesthesia has been used for cesarean section because the lumbosacral fossa is easily located and is comparatively large.¹¹ Epidural anesthesia techniques are similar to those used for dogs and cats and can be achieved with local anesthetics such as lidocaine. In a 2004 study, an IM combination of midazolam (1.0 mg/kg), medetomidine (0.05 mg/kg), and fentanyl (0.02 mg/kg) was compared with the IM injection of either xylazine (2.0 mg/kg) with ketamine (40.0 mg/kg) or medetomidine (0.06 mg/kg) with ketamine (5.0 mg/kg) to assess combination anesthetic actions in chinchillas. The xylazine-ketamine and medetomidine-ketamine combinations provided longer surgical tolerance, but overall the midazolam-medetomidine-fentanyl combination was preferred because it induced less cardiopulmonary depression and achieved good anesthesia with the potential for complete reversal.¹²

Squirrels are best anesthetized with isoflurane or sevoflurane administered into an induction chamber. Ketamine (10 to 20 mg/kg) is the most commonly used injectable anesthetic in gray and fox squirrels. It provides adequate immobilization for physical examination and diagnostic procedures. A combination of medetomidine and ketamine has also been used to immobilize squirrels (Table 31.1).

In prairie dogs, ketamine (100 to 150 mg/kg) plus xylazine (20 mg/kg) administered IV produces 1.5 to 2.0 h of satisfactory surgical anesthesia.¹³ Xylazine can be administered 10 min prior to ketamine or may be given in the same syringe at the same time. For longer periods of anesthesia, inhalant anesthetics can also be administered via a mask or following endotracheal intubation. Because prairie dogs are obligate nasal breathers, they need to only have their nose in the mask for induction and maintenance of inhalant anesthesia. Visualization of the larynx is difficult without the use of a modified otoscope or laryngoscope. If all that is required is a short period of sedation, a lower dose of ketamine (40 mg/kg) can be combined with acepromazine (0.4 mg/kg) and administered IM.¹⁴ Butorphanol (2 mg/kg subcutaneously) or buprenorphine (0.02 mg/kg SC) may be used to produce analgesic effects in prairie dogs. Marmots are similar to prairie dogs and have been successfully anesthetized with combinations of xylazine-ketamine, medetomidine-ketamine, and xylazine-Telazol.¹⁵

Agoutis are large, excitable, agile rodents that can injure themselves or handlers if not carefully restrained. Ketamine alone (25 to 35 mg/kg) has been used to immobilize agoutis.¹⁶ Ketamine can be coadministered with analgesics or sedative-analgesics for painful procedures. As might be expected, xylazine, phenothiazine tranquilizers, and fentanyl-droperidol alone are not as effective. Inhalant anesthetics (isoflurane or sevoflurane) delivered via a face mask or by endotracheal tube produce good surgical anesthesia following ketamine immobilization.

The coypu (nutria) is difficult to restrain for IV injection. They have no readily accessible superficial veins. Endotracheal intubation can be performed in anesthetized animals with a slightly flexible tube containing a curved stylet. Intubation can be performed without visualization of the laryngeal opening. Animals weighing 3 to 5 kg require a 5-mm-ID endotracheal tube. Upon insertion, apnea may occur. Following intubation, anesthesia can be maintained with any inhaled anesthetic. In early investigations, chloralose (80 mg/kg) and pentobarbital (40 mg/kg) were administered IP for sedation but did not provide adequate surgical anesthesia at these dosages. Ketamine (10 to 20 mg/kg) plus 2 mg of xylazine have been assessed together in 4- to 5-kg nutria for tail amputation surgery. Prolonged anesthesia was produced by 20 mg/kg of ketamine, whereas 10 mg/kg was insufficient for surgery.¹⁷ Administration of medetomidine (0.1 mg/kg IM) plus ketamine (5 mg/kg IM) induces rapid anesthesia in nutria (Table 31.1). Immobilization lasts for approximately 40 to 60 min. Atipamezole (0.5 to 0.7 mg/kg IM) will awaken animals within 5 to 10 min of administration. The atipamezole dose should be four- to fivefold the dose of medetomidine. Atropine (0.1 mg/kg) is effective as a preanesthetic to decrease salivary secretions.

Voies have been anesthetized for nearly 3 h with pentobarbital at an IP dose of 0.06 mg/g of body weight. Surgical anesthesia can be induced for 15 to 20 min in meadow voles with a 0.06- to 0.09-mg/g dose of pentobarbital injected IM. In recent years, the use of IM or IP pentobarbital for anesthesia has been supplanted with injectable combinations and the use of inhalant anesthetics in most rodent species. Additional information on the dosing of ketamine-medetomidine combinations in wild rodents (e.g., squirrels) is listed in Table 31.1.

^a(1) Insufficient, animal sedated but able to struggle considerably or get up; (2) moderate, deep sedation but occasional muscle tension or mild struggling when handled; and (3) complete immobilization, good muscle relaxation and no arousal after handling or nociceptive stimuli.

^bSubjective evaluation of how reliable the given recommendations are, ranging from + (least reliable) to +++ (most reliable).

Modified from Jalanka and Koeken.¹³⁵

Mustelids

A metal or Plexiglas tube is convenient for restraining mink. The dimensions of the tubes will vary according to the size of the mink being restrained.¹⁸ One end of the tube is covered with hardware cloth, with the other remaining open. The mink is inserted headfirst into the tube. Vaccinations or other injections can be administered SC or IM on the inner surface of the hind leg while the animal is restrained. Anesthesia has been induced with carbon dioxide–oxygen mixtures (1:1), but isoflurane or sevoflurane administration is obviously preferable for chamber inductions. Maintenance of anesthesia with halothane or isoflurane by use of rebreathing or non-rebreathing delivery systems is preferred. In field situations, mink and polecats have been successfully immobilized and anesthetized with a combination of ketamine (10 mg/kg IM) and medetomidine (0.20 mg/kg IM) for radio-transmitter implantation. Induction was achieved in less than 4 min, and immobilization lasted from 28 to 54 min.¹⁹ Older reports indicate that reserpine (0.036 to 0.05 mg) can be administered orally in feed to render mink less nervous and excitable.²⁰ Apparently, there is a wide margin of safety with few cumulative toxic effects.

For ferrets, anesthesia is commonly induced with sevoflurane or isoflurane in an induction chamber. Atropine (0.04 mg/kg) can be administered either SC or IM prior to induction. To maintain anesthesia, inhalants are then delivered via a mask or through an endotracheal tube. Injectable mixtures for producing short periods of anesthesia in ferrets include ketamine (26 mg/kg IM) plus acepromazine (0.22 mg/kg IM), ketamine alone (20 to 30 mg/kg IM) to produce light surgical anesthesia for 40 to 60 min, Althesin (12 to 15 mg of total steroid/kg IM), which is a 3:1 mixture of alphaxalone with alphadolone acetate, to produce 15 to 30 min of light anesthesia, and Telazol at a dose of 5 to 10 mg/kg IM. A mixture of Telazol (250 mg tiletamine and 250 mg zolazepam) solubilized in 4 mL of ketamine (400 mg) and 1 mL of 10% xylazine (100 mg/mL) designed for use in exotic cats can be used in ferrets and feral cats at a dose of 0.03 to 0.04 mL/kg IM.

This mixture has been used for castrations, declawing, and intra-abdominal surgery.^{21,22} Medetomidine (0.1 mg/kg IM) can also be combined with ketamine (5 mg/kg IM) to induce a short period of anesthesia in ferrets (Table 31.1).

In general, rapid-acting volatile anesthetics such as isoflurane or sevoflurane are preferred for anesthetizing skunks. For small skunks, a transparent plastic disposable bag is an ideal container for induction with sevoflurane or isoflurane. Anesthesia is induced while the skunk is in the bag, and the surgery is performed through a small opening cut in the bag. Once immobilized, the skunk is removed and the bag is discarded. This procedure should be performed in a well-ventilated room to minimize human exposure to anesthetic gases and skunk musk. The best age for removal of the scent glands in skunks appears to be 5 to 6 weeks of age, when the skunk's weight is about 2 pounds.²³ If inhalant anesthesia is not feasible, pentobarbital can be administered IP to induce anesthesia by using a 2-mL syringe and 25-gauge needle; the usual dose ranges for adult skunks are 15 to 30 mg/kg.

An anesthetic technique for wild skunks caught in traps using a 9-foot pole syringe has been described.²⁴ The operator stands at a distance while making an IM injection and thus facilitates handling without exposure to musk or possibly being bitten. With this technique, pentobarbital solution has been administered IM at the rate of 20 mg/kg of body weight. Skunks are less likely to expel musk if the operator is slow and deliberate. Skunks that expel musk usually direct it at the pole syringe when the drug is injected. The immobilizing combination of ketamine (16 mg/kg IM) plus xylazine (8 mg/kg IM) has also been effective in skunks. Anesthesia is usually induced in less than 3 min with immobilization lasting approximately 30 min.²⁵

Stoat (*Mustela erminea*) and weasel (*Mustela nivalis*) are extremely fierce and difficult to handle. They will bite through thick leather gloves and, if held tightly, may be asphyxiated.²⁶ A satisfactory and nontraumatic method of inducing anesthesia is to place these animals in a Plexiglas induction chamber (10 × 4

× 4 inches) attached to the end of the cage by means of a removable slide. A 2¹/₂-inch-diameter hole connects the box to the cage. The animal is easily coaxed into this box. Isoflurane or sevoflurane is then introduced into the box via the fresh gas line from the vaporizer. Safe induction concentrations range from 2.5% to 4.0%. Once the animal is unable to right itself, it can be removed from the chamber and inhalant anesthesia maintained at lower concentrations by using a face mask or via delivery through an endotracheal tube. The intubation technique is similar to that used for ferrets. Light surgical anesthesia can be maintained with 1.5% to 2.0% concentrations of isoflurane or 2% to 3% sevoflurane. Alternately, medetomidine (0.1 mg/kg IM) plus ketamine (5 mg/kg IM) has been used to immobilize stoats with variable success (Table 31.1).

Badgers (*Taxidea taxus*), which have a ferocious disposition, have been successfully immobilized with phencyclidine, acepromazine, chlorpromazine, or succinylcholine administration. Ketamine appears to be the most satisfactory drug for immobilizing the European badger (*Meles meles*).²⁷ The average effective dose is 20 mg/kg IM, and repeated smaller doses are sometimes administered. Complete recovery occurs in 90 to 180 min, depending on the total dose administered. A number of studies have evaluated anesthetic combinations in badgers in comparison with ketamine alone (20 mg/kg). The addition of midazolam with lower doses of ketamine (10 to 15 mg/kg) did not improve anesthesia, nor did the combination of medetomidine (80 µg/kg) with only 5 mg/kg of ketamine.²⁸ The combination of butorphanol, medetomidine and ketamine appeared to improve overall muscle relaxation and anesthesia, however.²⁹ Following immobilization with either IM administered ketamine (15 to 25 mg/kg) plus xylazine (0.5 to 1.0 mg/kg) or Telazol (8 to 12 mg/kg) plus xylazine (0.5 to 1.0 mg/kg), anesthesia can be maintained with isoflurane or sevoflurane delivered through a mask or endotracheal tube.

Wild Procyonids

Members of this family include the ring-tailed cat, raccoon, coatiundi, mountain coati, lesser panda, and giant panda. Anesthetic techniques used in these species are primarily based on experience gained in the immobilization and anesthesia of raccoons. These anesthetic techniques would appear applicable for most procyonids. Intravenous anesthesia is not practical because of difficulty in restraining these species. Ketamine or Telazol have been used extensively and are made more efficacious when supplemented with an α_2 -agonist (e.g., xylazine or medetomidine). A phenothiazine (acepromazine) or benzodiazepine (diazepam) tranquilizer can also be combined with ketamine. When ketamine has been used alone at a dose of 20 to 30 mg/kg IM, induction takes 3 to 7 min, and recovery can be expected to occur in 45 to 90 min. A combination of a lower dose of ketamine (10 mg/kg IM) with xylazine (2 mg/kg IM) or other α_2 -agonist is more often used to immobilize wild procyonids today. Induction occurs in 3 to 5 min after IM injection. Anesthesia appears adequate, lasts for 15 to 20 min, and can be prolonged by administering one-quarter to one-half of the original combination dose IM or by the administration of isoflurane or sevoflurane via a face mask or an endotracheal tube. Medeto-

midine (0.1 mg/kg IM) can also be combined with ketamine (4 mg/kg IM) to immobilize wild red pandas.

Telazol has been used in a variety of procyonids for chemical restraint and short, minor surgical procedures. A dose of 10 mg/kg IM induces anesthesia lasting for 20 to 60 min. With this dose, reflexes (including the palpebral, corneal, pinnal, pharyngeal, and laryngeal) should persist.³⁰

Wild and Feral Canids

In the mid-20th century, these species were usually immobilized by using dart guns with drugs such as nicotine, phencyclidine, etorphine, or succinylcholine. These drugs are rarely used today, having been replaced with various dose combinations of ketamine (e.g., 10 mg/kg IM) plus xylazine (e.g., 2 mg/kg IM) or plus medetomidine (0.1 mg/kg IM) (Table 31.1). With these dosages of ketamine and α_2 -agonists, induction time averages 5 to 10 min. Anesthesia usually lasts 15 to 20 min, and recovery is complete in approximately 30 min. Medetomidine alone (0.025 to 0.1 mg/kg IM) can be used to produce dose-dependent sedation and immobilization of many wild canids. Nevertheless, for safety reasons, ketamine is commonly administered with medetomidine to ensure immobilization. The dose of ketamine used should never be less than 2.5 mg/kg IM for immobilizing any wild carnivore. Once captured, wild canids can be anesthetized with inhalants in the same manner as domesticated dogs. Anesthesia is commonly induced with the animal in a squeeze cage. An injectable tranquilizer, narcotic, and/or ketamine or Telazol is administered, followed by administration of an inhalant such as isoflurane or sevoflurane. Coyotes and other wild carnivores caught in steel traps often injure themselves struggling. A cloth-covered diazepam tablet was described in the 1960s for attachment to the trap. The tablet would hopefully be ingested by the coyote after capture, with the intent of calming the animal and preventing additional self-inflicted harm.³¹

Wild Felids

Throughout the latter half of the 20th century, many species of nondomesticated cats have been immobilized with high doses of ketamine alone (Table 31.2).³² However, salivation, muscle rigidity, and convulsions can occur with ketamine immobilization alone. Combinations of ketamine (10 to 20 mg/kg IM) and xylazine (2 mg/kg IM) can be used to induce short periods of anesthesia (i.e., 5 to 20 min) in most wild felids. Additional doses can be given when necessary to prolong anesthesia. Xylazine alone has been used to immobilize wild cats at a dose ranging from 1 to 3 mg/kg of body weight, but it should be understood that large felids immobilized with xylazine alone can be easily aroused by auditory, visual, and physical stimuli. Medetomidine in combination with ketamine has also been used to immobilize a variety of wild felids (Table 31.1). For many decades now etorphine (M-99) has also been used successfully to immobilize African lions and other wild cats.³³ For a 100-kg lion, the suggested total dose of M-99 is approximately 0.5 mg. In adult lions, tremors associated with M-99 injection can be controlled with acepromazine administration (total dose, 25 to 30 mg). Appropriate doses of Telazol (1.5 to 5.0 mg/kg IM) will usually induce anesthesia in large fe-

lids within 2 to 5 min, providing 15 to 30 min of immobilization and analgesia. The coadministration of atropine with dissociative anesthetics generally prevents excessive salivation. Some tigers may be more sensitive to Telazol than others. Reported adverse reactions to Telazol in tigers and other large cats include prolonged muscle rigidity and an inability to stand for several days after recovery.

Historically (mid-20th century), succinylcholine chloride had been used for immobilization of a large variety of wild species, including large cats such as African and North American mountain lions (*Felis concolor*).³⁴ With the availability of newer drugs

and combinations for immobilization of wild and feral animals, succinylcholine alone is no longer considered an acceptable immobilizing drug.

Relatively high doses of meperidine and promazine have been used as preanesthetics in some large cats, such as ocelots, leopards, and lions. In lions, 11 mg/kg of meperidine or 4.4 to 9.0 mg/kg of promazine has been used to achieve sedation.^{35,36} SC and IM injections are facilitated by use of a squeeze cage. Once sedation is evident, a tourniquet can be applied to the tail to help locate the caudal vein for IV injection of the injectable anesthetic.

When compared with smaller domestic cats, big cats appear to

Fig. 31.1. Adult male lion anesthetized with isoflurane. Indirect blood pressure was measured at 5-min intervals by using an oscillometric device and cuff placement around the metatarsal artery. Fluid administration is important during long procedures and will assure a ready venous access for drug administration.

require less anesthetic per kilogram to produce surgical anesthesia. For example, when combined with medetomidine (0.03 mg/kg IM), the required dose of ketamine is reportedly only 2.5 mg/kg IM for immobilization of tigers and lions (Table 31.1). Certain reflexes may persist, and the recovery period is usually longer for larger cats. The rate and character of ventilation are important criteria for assessing depth of anesthesia. Fewer than 10 breaths per minute is cause for concern. To avoid the need to use larger doses of general anesthetic in large undomesticated cats, it is suggested that local anesthetics be employed, whenever possible, to desensitize tissues and structures prior to surgical manipulation. Additional information on various injectable drug combinations in large cats, including propofol IV administration, has been published.^{37–39}

Whenever possible, inhalational anesthesia with isoflurane or sevoflurane is preferred for longer periods of general anesthesia of large felids. A more precise control of anesthesia depth is provided, and the animal will have a more rapid emergence upon completion of the procedure (Fig. 31.1). If the procedure is expected to be of considerable duration, endotracheal intubation is preferable to mask delivery of the inhalant. Tracheal intubation in large cats can be achieved with or without a laryngoscope (Fig. 31.2). Large lions and tigers require a medium Cole tapered tube or an 18- to 24-mm-ID cuffed tube commonly used in small adult horses. Before the endotracheal tube is positioned in the trachea, the larynx should be sprayed with lidocaine to decrease the likelihood of laryngeal spasms.

Wild and Feral Swine

Wild and feral hogs have been captured by placing α -chloralose on corn or in mixtures of flour, peanut butter, sardines, and syrup. The feeding site should be baited for several days prior to using the drugged bait. When one teaspoonful of methocel per cup is added to dampened shelled corn, it causes the relatively insoluble

Fig. 31.2. Large animal cuffed endotracheal tube is passed into the trachea for delivery of inhalation anesthetic to an adult tiger. Flow rates of 5 to 6 L/min are recommended. The tube should be secured in place to prevent movement and laryngeal trauma.

α -chloralose to adhere to the corn. The maximum safe dosage for feral hogs is about 2.2 g/10 kg of body weight, and the minimum effective dose is about 2.2 g/40 kg. One cup of bait with 2 g of α -chloralose appears to be effective.⁴⁰ Bait should be removed after the trapping operation, because the bait is potentially dangerous to other wildlife. Once captured and restrained, wild swine and javelinas can be anesthetized with a dissociative such as ketamine or a barbiturate such as thiopental (10 mg/kg IV). Adult peccaries and feral hogs have been successfully immobilized with a 1:1 mg mixture of Telazol (100 mg) and xylazine (100 mg). This mixture has provided adequate anesthesia and analgesia to perform short surgical procedures.⁴¹ Once adequate restraint or immobilization has been achieved, anesthetic techniques used in domestic breeds of pigs are effective in wild and feral swine.

Wild Ruminants

Bovidae Species

Prior to the availability of modern immobilizing drugs, Beale and Smith⁴² reported on the use of 6 to 10 mg/45 kg of succinylcholine chloride to immobilize pronghorn antelope. Xylazine (1 to 3 mg/kg) or carfentanil was also commonly employed for sedation and capture of antelope and other wild ruminants in the latter half of the 20th century.⁴³ Carfentanil has often been combined with a tranquilizer, as was reported for its use in roan antelope immobilized with 11 to 13 μ g/kg when combined with 0.75 mg/kg of azaperone.⁴⁴ Intramuscular immobilizing doses of fentanyl, etorphine, and xylazine employed in African antelopes and other wild Bovidae species are listed in Table 31.3. Xylazine alone and in combination with ketamine has also been used extensively for the immobilization of many captive and free-ranging Bovidae ruminants. For example, in the 1980s, captive dorcas gazelles were immobilized by using xylazine (0.25 mg/kg IM) and ketamine (12 mg/kg IM) prior to electroejaculation and

sperm collection.⁴⁵ More recently, a number of wild Bovidae species have been successfully immobilized and/or anesthetized with combinations incorporating medetomidine and ketamine with an opioid in an effort to further enhance the analgesic and anesthetic actions of this combination.^{46,47} When necessary, atipamezole can be administered at a ratio fivefold the medetomidine dose to help prevent resedation in the field and possible predation.⁴⁸

To capture bighorn sheep, etorphine has been used at a dose of approximately 22 µg/kg IM.⁴⁹ The IM injection of acepromazine (total dose, 15 mg in adults) after capture prolongs the effect of etorphine and facilitates handling. Injection of cyprenorphine effects rapid recovery from the effects of etorphine. It is recommended that cyprenorphine or diprenorphine be administered in a dose 2½ times the amount of etorphine and that half be administered IV and half IM to smooth recovery and decrease the likelihood of renarcotization. Xylazine has been used alone to immobilize bighorn sheep, with total effective dosages ranging from 350 mg for adult males to 250 mg for adult females. Long recoveries resulted in some deaths before the procedure was shortened and the anesthesia made safer by reversal with the administration of idazoxan, an α₂-antagonist.⁵⁰ To tranquilize bighorn sheep in a captive environment, diazepam can be mixed at a dose of approximately 13 mg per each kilogram of feed fed to the sheep.

The domestic buffalo (*Bubalus bubalis*) is raised mainly in Asia as a producer of meat and milk. It is only distantly related to the American bison (*Bison bison*). Most anesthetic techniques for the buffalo have been inferred from work with cattle. Several studies have shown considerable variation between species, however. The effects of xylazine on water buffalo calves at doses of 0.22 and 0.44 mg/kg IV and 0.44 mg/kg IM were assessed in the late 1970s.⁵¹ Recovery times were dose related and varied from 65 to 130 min for the IV doses, whereas the IM dose produced an average of 150 min of recumbency. Administration of 0.04 mg/kg of atropine IM reduces salivary secretions and bradycardia observed with xylazine administration. Ketamine (2.0 mg/kg IV) has been combined with chlorpromazine (2.0 mg/kg IM) to anesthetize water buffalo calves. Pretreatment with chlorpromazine increases the duration of analgesia and recovery time beyond that achieved with ketamine alone. Short-term surgical procedures (5 to 10 min) with this drug combination have been performed in calves.⁵²

The use of guaifenesin (165 mg/kg IV) alone in water buffalo calves to produce complete immobilization causes significant hypotension. Cardiovascular and respiratory effects produced by high doses of guaifenesin are generally undesirable.⁵³ An anesthetic mixture used as early as the 1960s consisted of chloral hydrate (30 g), magnesium sulfate (15 g), and thiopental (2.5 g) in 1000 mL of distilled water.⁵⁴ Thirty minutes after the SC administration of atropine, the mixture was administered IV at approximately 2.0 mL/kg. Anesthesia was deemed adequate for 15 to 25 min following the initial injection and could be prolonged by additional injections. Newer methods of providing short periods of injectable anesthesia rely on the combination of ketamine with α₂-agonists and other tranquilizers, such as diazepam and triflupromazine, to enhance muscle relaxation and improve overall

safety.⁵⁵ In one study, a 0.1-mg/kg IV dose of detomidine was combined with 0.1 mg/kg dose of diazepam IV and 3 mg/kg of ketamine IV for 15 min of excellent anesthesia.⁵⁶ Inhalant anesthesia has also proven satisfactory in water buffalo and is preferred for longer-lasting anesthesia when the appropriate facilities and delivery equipment are available at the zoo facility or wildlife park.

Bison (*Bison bison*) are generally dangerous and difficult to handle, and heavy equipment is required in order to restrain mature animals. Capture equipment is necessary to catch free-roaming animals. Early reports (1960s) indicate captured bison being administered chloral hydrate (250 mg/kg) to achieve deep surgical anesthesia. More recently, reports of bison immobilization have emphasized the IM use of α₂-agonist agents (e.g., xylazine or medetomidine) with either potent opioids (e.g., carfentanil) or Telazol, a dissociative and benzodiazepine proprietary mixture.^{57,58} The use of combinations incorporating xylazine or medetomidine with Telazol has caused some concerns regarding ruminal tympany. The anesthetic and physiological effects of these combinations have been effectively antagonized with the administration of α₂-antagonists: tolazoline (for xylazine) and atipamezole (for medetomidine).⁵⁸ Once bison have been restrained and/or immobilized by physical or chemical methods, IV and inhalant techniques commonly used in large domestic cattle can be effective in providing short periods of general anesthesia.

Cervidae Species

Over three decades ago, reports on the effects of IM injections of 0.3 mg/kg up to 9 mg/kg of xylazine in red, fallow, and spotted deer were published.^{59–61} With clinically effective doses of xylazine, sedation begins within 3 to 10 min and usually lasts 1 to 2 h. A degree of analgesia is produced, but supplementation with a local or regional anesthetic was required for surgery. During the onset of sedation, there is some salivation, but regurgitation of ruminal contents or ruminal tympany has been rare. Alterations in respiratory rhythm, ranging from transient apnea to a Cheyne-Stokes respiration, are typically observed with the higher doses of xylazine and have been frequently encountered in red deer, moose, sitatunga (marshbuck), and Barbary sheep. Xylazine had also been used alone to immobilize captive white-tailed deer in the 1970s.⁶² Induction times were shorter in fawns and freshly trapped deer. Immobilization was prolonged with doses above 3 mg/kg, and it was recommended that higher doses than this should not be used. In general, xylazine alone produces good sedation and analgesia in wild Cervidae species, but, with lower doses, immobilization and muscle relaxation are sometimes insufficient for handling.

When given alone, the dose of ketamine for most deer species ranges from 10 to 20 mg/kg IM. More recently, two of the more common drug mixtures for immobilizing wild deer are ketamine-xylazine and Telazol-xylazine. Medetomidine has also been combined with ketamine at varying doses to immobilize several species of deer and other Cervidae species (Table 31.1). Atipamezole can be used to antagonize medetomidine-ketamine-induced immobilization of captive and wild deer at approximately fivefold the administered dose of medetomidine (Table 31.4).

Table 31.4. Total atipamezole intramuscular doses and atipamezole-medetomidine ratios (wt/wt) in selected ruminant species to reverse medetomidine-ketamine-induced immobilization

Species	n	Atipamezole ($\mu\text{g}/\text{kg}$)		Atipamezole-Medetomidine Ratio (wt/wt)

From Jalanka and Koeken.¹³⁵

Potent opioids can also be used to immobilize many species of captive wild deer and other wild ruminants. In the 1970s, for fallow and other species of deer, IM administered mixtures of etorphine (2 mg/100 kg) with xylazine (30 mg/100 kg) or fentanyl (0.3 to 0.66 mg/kg) with xylazine (0.5 to 1.3 mg/kg) were proven to be quite reliable and effective.^{63,64}

For tranquilization of deer prior to transportation, chlorpromazine can be administered IM at a dose of 4.4 mg/kg. Good results have also been obtained in elk with this dose. Full effect occurs in about 1 h and lasts for 16 to 24 h. When used as preanesthetics prior to injectable or inhalant anesthetics, phenothiazine tranquilizers should be injected IM at least 1 h in advance. In the 1990s, longer-lasting neuroleptics began to be administered IM in wild ruminants to provide days or even weeks of taming effects.⁶⁵ Zuclopenthixol acetate (1 mg/kg) and decanoate (10 mg/kg) provide 3 to 4 days and 10 to 20 days of calming effect, respectively. The action of perphenazine enanthate (1 mg/kg) typically lasts 7 to 10 days, whereas pipothiazine palmitate (5 mg/kg) reportedly provides 2 to 4 weeks of calming action.

The reaction of deer to IV barbiturate anesthesia varies greatly. Deer must be watched closely during the recovery period. Salivation and bloating are common problems. If pentobarbital is to be used, it should be preceded by atropine administration, and the animal should be deprived of feed and water for 1 day prior to induction. In a series of approximately 50 deer anesthetized with pentobarbital, one death and several cases of postoperative pneumonia, caused by regurgitation of rumen contents, occurred.⁶⁶ To eliminate such complications, endotracheal intubation is recommended during general anesthesia of deer, as in other ruminants. In general, high-dose barbiturate anesthesia alone cannot be recommended for most wild ruminant species.

As with Bovidae species, the oral ingestion of diazepam alone has been used to produce sedation and muscle relaxation for capture of wild Cervidae.⁶⁷ The dose ranges from 125 to 250 g/10 kg of feed. The effects vary depending on the amount ingested but may persist for several days. Maximum effect occurs 4 to 8 h

after ingestion. Sedated individuals should be separated from nontranquilized animals if possible, because the latter may injure less alert deer. As tranquilization deepens, animals eat less, making this sedation technique somewhat self-limiting.

Succinylcholine chloride or gallamine has been used to immobilize North American elk (*Cervus canadensis*), but these muscle relaxants may cause bloating and severe respiratory depression and can no longer be recommended. Newer methods include the use of potent opioids, such as carfentanil, or the use of α_2 -agonist plus ketamine combinations to immobilize or anesthetize elk.⁶⁸ Intranasal xylazine administration as a novel method of calming and reducing stress in captured elk appears promising, as well.⁶⁹

A number of drugs have been used to immobilize and anesthetize caribou, including fentanyl (0.3 to 0.6 mg/kg IM), xylazine (0.25 to 0.5 mg/kg IM), and azaperone (0.5 to 1.2 mg/kg IM).⁷⁰ Etorphine (0.02 to 0.1 mg/kg IM) has also proven effective in caribou when combined with acepromazine (0.02 to 0.1 mg/kg IM). Xylazine alone produces long-lasting immobility in moose. Sedate animals require constant supervision. A mixture of xylazine (0.15 to 0.5 mg/kg) and fentanyl (0.15 to 0.5 mg/kg) delivered by dart syringe has proven effective in the helicopter-assisted capture of moose.⁶⁴ Hyaluronidase (150 to 300 NF units) added to the IM anesthetic mixture decreases the induction times by 36% to 45%.

Camelids

Large Camelidae can be reliably sedated with xylazine. IM doses ranging from 0.4 to 0.9 mg/kg have been used in Arabian and Bactrian camels. In most instances, once sedation is evident, there is no resistance to positioning and manipulation of feet. Sedation usually begins within 10 min and can vary in duration from 45 min to 5 h. Larger doses produce sedation for as long as 1 day. Regurgitation of rumen contents and ruminal tympany are not common, and recovery is unaccompanied by struggling and excitement.⁷¹ Sedation in Bactrian camels that is achieved with xylazine doses of 0.25 to 0.50 mg/kg IM has been antagonized

with doxapram administration (0.05 to 0.13 mg/kg IV).⁷² In earlier reports (1960s) of camel anesthesia, premedication with IM chlorpromazine (1 mg/kg) reportedly decreased the dose of chloral hydrate or pentobarbital sodium necessary to induce anesthesia while prolonging its duration.⁷² Satisfactory IV anesthesia has been achieved in adult camels with a combination of chlorpromazine (0.5 mg/kg IM), pentobarbital (total dose, 2.0 g IV), and 2.5 g/50 kg of body weight of chloral hydrate administered IV. Anesthesia can be prolonged with supplemental IV doses of pentobarbital when using this combination. In recent years, camels are more typically immobilized with xylazine (e.g., 0.15 mg/kg IM) plus ketamine (e.g., 2.5 mg/kg IM) combinations.⁷³

For laparotomy and rumenotomy procedures, regional analgesia can be used in camels by infiltration of 2% lidocaine in a reverse-seven pattern along the caudal edge of the last rib and the distal tips of the lumbar transverse processes. Epidural anesthesia can also be attempted in camels with the animals fastened in the sitting position. Injection is made with a 5-cm needle at the sacrococcygeal or first coccygeal space, with the needle slanted forward about 45° from vertical. Administration of 12 to 16 mL of 2% lidocaine produces analgesia of the anus, udder, vagina, scrotum, and hind limbs. Administration of 50 mL of 2% lidocaine in adult camels anesthetizes the hindquarters and abdominal somatic tissues up to the level of the umbilicus.

A mixture of guaifenesin (110 mg/kg) and thiopental (4.4 mg/kg) has been administered IV to induce anesthesia in camels. For short-term (1 h or less) maintenance of general anesthesia, 5% guaifenesin in 5% dextrose plus thiopental (2 mg/mL) is administered to effect. As with other large domesticated ruminants, once intubated, inhalant anesthetics such as halothane, isoflurane, or sevoflurane can be used to maintain longer periods of anesthesia.⁷⁴

Giraffes

Some investigators feel that xylazine alone is unsuitable for restraint of giraffes.⁷⁵ When combined with etorphine, however, results are more satisfactory. The sedative-anesthetic effects of this drug combination can be antagonized with the coadministration of diprenorphine (2 to 4 mg total dose IV) and an α_2 -antagonist such as yohimbine (0.1 to 0.15 mg/kg IV) or tolazoline (1.0 mg/kg IV). Administration of etorphine alone has been used for surgical analgesia and restraint of adult reticulated giraffes (*Giraffa camelopardalis reticulata*)⁷⁶ but is usually administered IM (total dose of 2.5 mg) along with xylazine (0.3 mg/kg IM) or acepromazine (total dose, 30 mg IM). This combination produces recumbency and, when supplemented with an additional 1 mg of etorphine, produces surgical analgesia. Carfentanil has been combined with xylazine and ketamine has been combined with medetomidine to immobilize free-ranging giraffes safely.^{77,78}

Perissodactyls

Wild and Feral Equids

Etorphine (0.017 mg/kg IM) alone or in combination with acepromazine (0.04 mg/kg IM) has been used to restrain captive

wild asses for electroejaculation procedures.^{45,79} Carfentanil, administered in similar doses of 0.015 to 0.033 mg/kg IM, has been used to immobilize zebras (*Equus burchelli*) and Mongolian wild (Przewalski's) horses.^{80–82} Immobilization usually occurs within 10 min after carfentanil injection. Xylazine (0.6 mg/kg IM) is often used as a synergist to decrease both the dose requirement of carfentanil (0.02 mg/kg IM) or etorphine and narcotic-induced muscle rigidity.⁸³ Following carfentanil injection, mild tachycardia, hypertonia, and hyperthermia have been observed in some wild horses. Severe physiological disturbances have been observed in domestic horses after the coadministration of xylazine (1 mg/kg IM) and carfentanil (0.015 mg/kg IM).⁸⁰ These changes were characterized by a hypermetabolic state including tachycardia, vigorous muscle activity, tachypnea, and increased rectal temperature. One horse was euthanized because of the onset of severe pulmonary edema that was unresponsive to treatment.⁸⁰ The authors speculated that these untoward responses may have been the result of insufficient dosage. Medetomidine (0.06 to 0.08 mg/kg IM) combined with ketamine (1.5 to 2.0 mg/kg IM) has also been used to immobilize wild horses effectively (Table 31.1). This combination produces good muscle relaxation, and recovery is rapid and complete after IV or SC administration of atipamezole. Generally speaking, once sedated, wild Equidae may be given injectable and inhalant general anesthetics in the same manner and dosages as domesticated horses.

Rhinoceros

In the 1960s, white rhinoceros (*Dicerus simus simus*) were typically immobilized with a mixture of morphine and chlorpromazine administered IM.⁸⁴ The doses used were approximately 1.5 g of morphine, 175 mg of scopolamine, and 725 mg of chlorpromazine. Complete immobilization required 30 to 45 min in a 1600-kg animal. A variation of this mixture was made by substituting diethylthiambutene for morphine. For a 1400-kg animal, the dose of diethylthiambutene was approximately 3.0 g. These mixtures were also used successfully to immobilize black rhinoceros. Other combinations used to immobilize black rhinoceros included (a) etorphine and acepromazine, (b) etorphine, acepromazine, and azaperone, or (c) etorphine and azaperone (Table 31.5).⁸⁵ In the late 1970s, carfentanil alone was used to immobilize rhinos. The total IM dose ranges from 1.0 to 1.5 mg in juveniles to 2.5 to 3.0 mg in adults. These doses achieve deep sedation. The effects of carfentanil can be readily antagonized with diprenorphine.⁸⁶ Recommended carfentanil dosages and adjunctive drugs for immobilizing rhinoceros and a variety of other wild African species are listed in Table 31.6. Recent reports of anesthesia in rhinoceros species have emphasized the sensitivity of these animals to potent opioids and the safety concerns accompanying their use.⁸⁷ To reduce the etorphine dose requirement, a combination of etorphine with detomidine and ketamine has been successfully used to immobilize an adult one-horned rhinoceros repeatedly for semen collection.⁸⁸ In captive white rhinos conditioned to repeated handling, the administration of a combination of butorphanol (total dose, 70 mg) and azaperone (total dose, 100 mg) alone can produce heavy sedation to light anesthesia (animals became recumbent) for laparoscopy.⁸⁹

^aAnalgesic or additive total dose = analgesic rate × body weight.

^bAnalgesic antagonist total dose = analgesic total dose × multiplication factor.

^cCarfentanil was not recommended for zebras. Etorphine is recommended as the principal immobilizing agent.

^dNumbers in parentheses denote noncasting dosage levels for giraffes.

The dosages listed are for free-ranging wild animals. Wild animals adapted to captive conditions usually require lower dosages.

When a short induction period is required, the carfentanil dosage rate can be drastically increased.

Carfentanil can be used without an additive. In cases of excitable species and warthogs, a mixture (cocktail) with a sedative is recommended. Xylazine is preferred.

Although diprenorphine is not listed as an antagonist, it can be used with equal success in dosages slightly less than those cited for cyprenorphine.

Nalorphine hydrobromide can also be used as an antagonist.

From DeVos.⁸⁶

Elephants

Several sedatives and anesthetics have been used to immobilize and anesthetize elephants. As early as the 1950s, meperidine hydrochloride was reportedly administered IV at the dose of 2.2 mg/kg to help in the manipulation of an elephant's painful fracture.⁹⁰ In the 1960s, there was a report of Indian elephants being anesthetized with pentobarbital IV administered through the middle auricular vein.⁹¹ Beginning in the 1970s, elephants were more commonly immobilized with etorphine administration. The IM dose of etorphine for the African elephant varies from a total dose of 4 to 8 mg, or approximately 1.5 mg/1000 kg of body weight. Hyaluronidase can be combined with etorphine to enhance drug uptake from the IM injection site.⁹² A commercial mixture of etorphine-acepromazine (Immobilon LA: 2.45

mg/mL of etorphine and 10 mg/mL of acepromazine) has been used to sedate and control adult Asian elephants. A 2004 report has further confirmed the usefulness and safety of this combination in adult Asian elephants by providing 30 to 60 min of recumbency and neuroleptanesthesia for placement of radio collars on free-ranging animals.⁹³ The average IM dose of Immobilon LA administered was 3.3 mL, with a range of 6 to 11 mg of etorphine and 25 to 45 mg of acepromazine in ten adult wild elephants.⁹³ The dose recommendation was based on an unusual measurement: 1 mL/4 ft of shoulder height. Immobilon LA appears to induce more predictable narcotization than does etorphine alone.⁹⁴ Nevertheless, etorphine administration (total IM doses ranging from 4 to 6 mg) in African elephants (*Loxodonta africana*) ranging in weight from 2700 to 6000 kg usually produces either ster-

nal or lateral recumbency.⁹⁵ The latter is preferred because sternal recumbency reduces ventilation by placing great pressure on the diaphragm. A simple method of providing intermittent positive-pressure ventilation following etorphine immobilization of elephants in the field has been described.⁹⁶ This technique of constructing a portable ventilator with the use of two high-flow demand valves and a Y piece of a large animal anesthesia circuit dramatically increased arterial oxygen partial pressure (PaO₂) from 40 to 366 mm Hg in one elephant.⁹⁶ It should be appreciated that large elephants may become immobilized in the standing position when the lower dose (total dose, 4 mg) of etorphine is used. If this occurs, elephants may be administered acepromazine to improve sedation and immobilization. Again, although etorphine alone can immobilize adult African elephants satisfactorily, the addition of acepromazine (total dose, 25 to 50 mg) will usually enhance and prolong the tranquil state.

Adult Asian and African elephants can be sedated for air or other modes of transport in the field with the administration of either xylazine (total dose, 100 to 175 mg) or azaperone (total dose, 120 mg).⁹⁷ Elephants usually remain standing in cages and are somnolent. Injections of xylazine can be repeated at the same dose rate at approximately 3-h intervals to maintain standing sedation during air transport.⁹⁸ Medetomidine has also been assessed as a sedative in Indian elephants at a dose of 3 to 5 µg/kg IM. Sedation was evident on average in 6 min and lasted 1 h 6 min with the 3-µg/kg dose and 2 h 14 min with the 5-µg/kg dose. The head drooped, and the tail and trunk became flaccid. Bradycardia was common, and hypothermia developed in some animals.⁹⁹

A report on repeated inhalation anesthesia of an African elephant was published by Dunlop et al. in 1994.¹⁰⁰ Food was withheld for 1 day and water for 12 h prior to induction. Chemical restraint and sternal recumbency were induced with 0.0017 mg/kg of etorphine administered IM. Atropine (0.04 mg/kg IM) was administered prior to an additional 0.0006 mg/kg etorphine administered IV. Following the second dose of etorphine, the elephant was placed in lateral recumbency. A stomach tube was placed into the larynx by digital palpation, as is done in adult cattle. A 40-mm-ID cuffed endotracheal tube was passed into the trachea by using the stomach tube as a guide, the cuff was inflated, and the endotracheal tube was connected to two large animal breathing circuits joined in parallel at the Y piece. Initially, each machine was set to deliver 5% isoflurane in 15 L/min of oxygen. After 45 min, the two vaporizers were reset to deliver 2% to 3% isoflurane in 5 L of oxygen/min. Anesthesia was maintained for 2 h 35 min, at which time end-tidal isoflurane concentration ranged from 1.05 to 1.15 vol%. At the completion of surgery, isoflurane administration was discontinued. Diprenorphine was administered IV 25 to 40 min later, and the elephant stood unaided within 3 to 4 min.¹⁰⁰

In another report by Gross et al.,¹⁰¹ an Asian elephant was anesthetized for cesarean section for removal of a dead fetus. Excitement was observed in this elephant shortly after the IV injection of atropine. Azaperone (0.035 mg/kg IM) premedication had been followed 1 h 30 min later by a 0.05 mg/kg IV dose of atropine. Within 1 min of atropine injection, the elephant began swaying, kicking, and moving in an agitated manner around the

stall. Normally responsive to commands, the elephant refused to obey verbal direction. When this behavior had not abated after 30 min, an additional dose of azaperone (0.018 mg/kg IM) was administered. Within 15 min, the elephant became calm and responsive to commands, and anesthesia was then induced with etorphine (0.002 mg/kg IV). Following intubation, anesthesia was maintained with two large animal anesthetic machines arranged in parallel delivering 100% oxygen and was supplemented with additional doses of etorphine when necessary. The authors speculated that the excitement observed following atropine administration was caused primarily by atropine rather than by a drug interaction with azaperone. Atropine has often been used in elephants, and suggested dosages vary from 0.11 mg/kg IM to 0.01 mg/kg IV. As with domestic animals, differences in sensitivity to the effects of atropine on the central nervous system may exist in elephants, especially when preexisting pathology or abnormal physiological conditions are present.¹⁰¹ Information on the use of carfentanil for immobilization of free-ranging elephants and other species is listed in Table 31.6. Information on the use of etorphine in captive elephants and other species is listed in Table 31.7.

Hippopotamus

Relatively little information is available on restraint and anesthesia of hippopotamus. These large artiodactyls live in and around rivers and shallow lakes and have raised eyes and nostrils that enable them to float partially submerged while viewing and breathing. Their nostrils have valves, and a hippopotamus can remain completely submerged for up to 4 min. Large males may weigh up to 2800 kg. Etorphine can be administered IM at a total dose of 2 to 6 mg alone to produce sedation and anesthesia. Adult captive hippopotamus have been administered etorphine (1 to 5 mg/kg) in combination with xylazine (70 to 80 µg/kg IM) or acepromazine (20 µg/kg IM) to produce chemical restraint. Immobilization can be reversed with the administration of either diprenorphine (3 µg/kg IM) or naltrexone (150 to 180 µg/kg IM). Reversal reportedly occurs more rapidly with naltrexone administration (4 vs. 21 min).¹⁰² Animals will often seek the safety of their water pools once injected and should be kept away from water when immobilization procedures are attempted in a zoo or wildlife-park facility. Phencyclidine (0.6 to 1.1 mg/kg IM) has also been combined with xylazine or acepromazine to immobilize free-ranging animals in large African parks. Many animals have been injected while in the water or near it. It is reported that animals that remain in water will float to the surface once sedated. These animals can be safely roped and hauled to the shore. Animals have remained immobilized for approximately 40 min after injection with these drug mixtures.³⁰

Primates

Primates present many unique problems regarding their capture and restraint. When kept in a zoo or other management facility, it is beneficial to perform routine procedures on primates with as little stress to the animal as possible. Consequently, many primates are being conditioned to cooperate with handlers voluntarily for routine blood draws, tranquilization, and administra-

Table 31.7. Intramuscular (IM) etorphine (M991) restraint of large, feral animals kept in captivity

Family Groups	Suggested IM Drugs and Dosage	Comments on Other Drugs	Other Comments
Kangaroos and wallabies	Etorphine 0.1 mg per 20 lb body wt	Phenothiazine-derivative tranquilizers are not effective for restraint. Succinylcholine is effective but hazardous.	No longer recommended.
	Etorphine 1 mg per 200 lb		
Elephants	Etorphine 1 mg per 2000 lb body wt given intramuscularly		If this dosage is ineffective, further attempts for restraint should not be made for 1 day; then the dosage can be increased by half the original dosage.
Zebraws and other wild equines	Etorphine 1 mg per 200 lb body wt. Can be mixed with acepromazine 2 mg per 100 lb body wt	Phenothiazine tranquilizers are ineffective as sole restraint agents.	Care must be exercised not to cause severe exertion and excitement in these animals. A tie-up syndrome has been seen in sedentary individuals that were exerted.
Camels and llamas	Etorphine 2 mg per 500 lb body wt		Emprosthotonic reflexes have occurred.
Tapir	Etorphine 1 mg per 100 lb body wt		
Elk and large deer	Etorphine 1 mg per 100 lb body wt		This drug is not very effective in small deer.
Giraffes	Etorphine 3 mg per 400 lb body wt		Etorphine has variable effect on giraffes. A relatively high dose is suggested because of the effectiveness of the antagonist, cyprenorphine.
American bison	Etorphine 1 mg per 200 lb body wt		Great care must be taken with herds because of their tendency to charge a single downed animal and human handlers.

From Sedgwick and Acosta.¹³⁷

tion of IV medications and anesthetics.¹⁰³ Outside of the laboratory situation, traditional capture and restraint techniques typically have to be employed as a prelude to anesthetizing nonhuman primates.

Oral benzodiazepines can be used to facilitate handling but may produce unpredictable levels of sedation in many individuals.¹⁰⁴ Oral sedation of chimpanzees can be successfully accomplished with Telazol (15 mg/kg) mixed with orange juice or other liquids.¹⁰⁵ An alternative sedative technique relies on the use of potent oral and/or transmucosal opioids for sedation. Chimpanzees have also been successfully sedated with droperidol (1.25 to 2.5 mg orally) followed by the transmucosal administration of carfentanil (2.0 µg/kg). Within 40 min of carfentanil exposure, chimps will usually become sedate enough to allow IM hand injection of an anesthetic regimen like naltrexone-tiletamine-zolazepam.¹⁰⁶ A lollipop formulation of fentanyl (intended dose, 10 to 15 µg/kg) has also been used to sedate captive orangutans (*Pongo pygmaeus*) and gorillas (*Gorilla gorilla*)

successfully but was found to be unreliable in chimpanzees (*Pan troglodytes*).¹⁰⁷

Medetomidine-ketamine combinations can be used to restrain a wide variety of primate species. This combination induces a rapid induction, stable immobilization, excellent relaxation, and calm recoveries.^{108–111} α_2 -Agonist-dissociative combinations have the advantage of being easily antagonized with atipamezole. Telazol can also be used alone or in combination with an α_2 -agonist to immobilize primates.

Captive primates are increasingly being trained to present their arms for IV injections so that anesthetic induction agents such as propofol are can be used for induction and maintenance.¹⁰⁴ Inhalant anesthetics are often used for maintenance of longer periods of anesthesia. Most primate species are easily intubated by using a laryngoscope and proper positioning. It is important to note that primates have a very short trachea relative to many other mammals and care should be taken not to intubate a mainstem bronchus.

Ursids

Several anesthetic techniques have been used for capturing, immobilizing, and anesthetizing bears. In the 1960s, investigators reported on the use of α -chloralose mixed with honey to capture black bears (*Ursus americanus*) in the field. The effective dose for wild bears is 2 g per 3 to 8 kg of feed. Recovery usually occurs between 8 and 10 h from the time of ingestion.¹¹² More recently, a number of favorable reports have been published on the use of carfentanil mixed in small volumes of honey (5 to 20 mL) administered incrementally to captured bears.^{113–115} This appears to be a promising technique for immobilizing a number of bear species. The dose range for ingested carfentanil ranges from 7 to 17 μ g/kg. The mean dose requirement is 8 to 10 μ g/kg. Muscle rigidity and oxygen desaturation were evident in some bears, and, in one study, diazepam was administered to alleviate muscle rigidity.¹¹³ Anesthesia in bears was effectively reversed with naltrexone administration at a ratio of 100 mg/mg of carfentanil ingested. A rapid return to mobility resulted within 10 min of naltrexone administration.

Ketamine and xylazine combined in a ratio of approximately 2:1 on a per-milligram basis produces good anesthesia in captive and wild black bears (*Ursus americanus*). The optimum dose range is 4.5 to 9.0 mg/kg of ketamine and 2.0 to 4.5 mg/kg of xylazine when injected IM. Smaller bears appear to be induced more quickly. Supplemental injections have been used to maintain tractability for as long as 31 h.¹¹⁶ Free-ranging polar bears (*Ursus maritimus*) can be immobilized with a concentrated solution of ketamine (200 mg/mL) plus xylazine (200 mg/mL). Cubs apparently require approximately 3 mg of each drug per kilogram of body weight, whereas adults require 7 mg/kg.¹¹⁷ Relatively low doses of medetomidine (0.03 to 0.06 mg/kg IM) and ketamine (2.5 to 4.0 mg/kg IM) have also been used to immobilize brown and polar bears (Table 31.1). More recently, free-ranging bears have been immobilized with a combination of either xylazine or medetomidine with Telazol. These studies indicate that either xylazine (2 mg/kg IM) plus Telazol (3 mg/kg IM) or medetomidine (50 μ g/kg IM) plus Telazol (2 mg/kg IM) provide rapid, smooth, reliable immobilization with adequate analgesia that is reversible with atipamezole.^{118–121}

As early as the 1960s, bears were being successfully anesthetized with thiopental, thiamylal, or pentobarbital sodium administered IV in the cephalic or saphenous vein. A squeeze cage facilitates the procedure. If this is not available, the caged animal is offered a favorite food; when it reaches for the food, the paw is grasped by an assistant wearing gloves. A rope is tied around the limb to act as a tourniquet and to distend the vein. With this technique, 715 mg of pentobarbital provided surgical anesthesia for a 35-kg Malayan sun bear for 2 h.¹²² Reportedly, an average IV dose of 13.5 mg/kg of pentobarbital enables safe handling and minor surgery of American and Himalayan black bears.¹²³ Following induction with an IV thiobarbiturate, anesthesia is maintained with either isoflurane or sevoflurane administered via a muzzle mask or endotracheal tube–delivery method. Inhalants are the preferred drugs for maintaining anesthesia for long procedures because they provide good reliable muscle relaxation and more rapid emergence.¹¹⁵ As with most

large carnivorous animals, endotracheal intubation can be easily accomplished.

Marsupials

Care should be used when catching and restraining kangaroos, because the claws on their hind limbs are well developed and sharp. Occasionally, a kangaroo will bite or claw with its forepaws. For field capture of macropods in the 1970s and 1980s, ketamine (3.0 mg/kg) was often combined with etorphine (0.005 mg/kg) and administered IM for immobilization.¹²⁴ Immobilization usually occurred within 3 to 4 min after injection. Ketamine has also been combined with xylazine (8 mg/kg IM of each) to induce satisfactory anesthesia.¹²⁵ Alternatively, Althesin has been administered at the rate of 15 mg of total steroid per kilogram IM for anesthesia and good muscle relaxation.

Generally, phenothiazine tranquilizers have a slow onset of action in marsupials, and effects may last for 2 to 3 days. For this reason, benzodiazepine tranquilizers such as midazolam (0.2 mg/kg IM) have been considered a better and safer class of drugs for tranquilization of marsupials.¹²⁴ Because macropods are prone to trauma-related injuries and capture myopathy, a smooth and rapid induction is paramount. The two ideal combinations that are currently used are medetomidine-ketamine and tiletamine-zolazepam to achieve a rapid, smooth induction. Medetomidine-ketamine holds the advantage of rapid reversal with atipamezole, as well. Doses of medetomidine range from 40 to 70 μ g/kg IM mixed with 4 to 7 mg/kg of ketamine IM for most kangaroo species.² As is typical, the recommended dose of atipamezole is fivefold the medetomidine dose administered. The Telazol dose varies from 2 to 8 mg/kg for a wide range of macropod species. Once anesthetized with either combination, ketamine (1 to 2 mg/kg) can be administered IV to prolong anesthesia. Propofol can also be administered IV to effect (6 to 8 mg/kg) to achieve additional anesthesia. Larger kangaroos can be somewhat difficult to intubate.²

Red and gray kangaroos have been anesthetized by IV administration of thiopental in the recurrent tarsal vein. Small kangaroos (tammar wallabies and quokkas) are often anesthetized with thiopental (28 mg/kg IV), intubated, and maintained with an inhalant in oxygen.¹²⁶ The rat kangaroo (*Potorous tridactylus* Kerr), or potoroo, is a small species that can be picked up by the tail. It will bite, kick, and scratch if not handled carefully. A large plastic tube can be devised (6-inch diameter by 13 inches long) with a slot in the end gate to enable access to the tail for venipuncture. The vein, located at the lateral aspect of the base of the tail, can be distended with a tourniquet. It has been appreciated for several decades that rat kangaroos may have a lower tolerance to thiopental and pentobarbital anesthesia than many other kangaroo species.¹²⁷ Several drugs and older anesthetic protocols successfully used for inducing anesthesia in marsupials are listed in Table 31.8.

Possoms and gliders belong to several marsupial families. Of these marsupials, the most common species in captivity is the sugar glider. These small marsupials are best anesthetized with isoflurane in a chamber or mask. Alternatively, both ketamine (20 mg/kg IM) alone or Telazol (5 to 6 mg/kg IM) alone can be

Table 31.8. Sedation and anesthesia of marsupials

Agent	Dose and Route	Species and Comments
Azaperone, 40 mg/mL	2–4 mg/kg by IM injection	Tranquilization in large macropods
Diazepam, 5 mg/mL	2–4 mg/kg IM or IV	All marsupials; tranquilization or anticonvulsant
Diazepam	Oral (in feed) 2 mg/kg	Tranquilization in all marsupials
Acepromazine	0.1 mg/kg IM	Indications of some delayed effect (lasts some days); needs quiet and dark for some hours to have maximum effect
Ketamine HCl	20 mg/kg IM	Monotremes for light surgical anesthesia
	25 mg/kg IM	Anesthesia (light) in dasyurids, macropods, wombat, koala
	30–50 mg/kg IM	Phalangers for light anesthesia; variable; give 30 mg/kg first and then, if insufficient, give additional 20 mg/kg
Thiopental	20 mg/kg as 2.5% or 5% solution (exactly as small animals) by IV injection	All marsupials (tail veins usually easy to use)
Alphaxolone, 9 mg/mL	0.25–0.5 mL/kg IV to effect	Macropods and phalangers; short duration, can top up; recover fast
Alphadolone, 3 mg/mL		
Halothane	Inhalation to effect	Bell jar for tiny dasyurids; anesthetic machine and mask or tube in larger species
Etorphine and combinations	0.5 mL of “large animal Immobilon” per large kangaroo by IM projectile	Only for capture; restricted availability; can cause excitement and self-injury
Ketamine-xylazine	5 mg/kg ketamine; 2 mg/kg xylazine in same projectile	Capture of macropods

IM, intramuscular; IV, intravenous.
Adapted from Reddacliff.¹³⁸

used. Ketamine (20 to 25 mg/kg IM) and fentanyl-droperidol (0.75 to 1.0 mL/kg IM) have both been used to immobilize opossums satisfactorily for handling.¹²⁸ Over the years, both inhalants and pentobarbital sodium have been commonly used to anesthetize this marsupial. Pentobarbital at a dose of 36 mg/kg, produces satisfactory anesthesia when administered IV. IP injection, which is less reliable and provides a narrower margin of safety, is no longer recommended. α -Chloralose has also been safely used in opossums to produce long periods of anesthesia. Induction is achieved with thiopental administered IV, followed by α -chloralose administered at a dose of approximately 12 mg IV every 2 h.

Inhalants can be administered via a closed system or via a mask once an opossum is adequately sedated.¹²⁹ For prolonged procedures, thiopental can be given for induction of anesthesia and intubation, followed by administration of isoflurane or sevoflurane. For smaller possum species, as for sugar gliders, chamber induction with a fast-acting inhalant anesthetic (isoflurane or sevoflurane) is the preferred technique, but depression of the central nervous system may be difficult to assess when possums are stressed (enter into a physiological sleep) and become nonresponsive to external stimuli. For larger possum species, as well as koalas, Telazol can be given in a dose range of 4 to 10 mg/kg IM or 1 to 3 mg/kg IV.¹³⁰ In free-ranging mountain possums, Telazol was dosed IM as high as 20 to 30 mg/kg for rapid immobilization.¹³¹ In another report, surgical anesthesia was achieved

in possums with 5 mg/kg IM of xylazine combined with ketamine at 20 to 30 mg/kg IM.¹³² Koalas have also been immobilized safely and rapidly with alphaxalone-alphadolone (Althesin) at doses of 3 to 6 mg/kg IM or 1 to 2 mg/kg IV.^{2,133}

Insectivora

Hedgehogs

Hedgehogs and other insectivores, such as tenrecs, shrews, and moles, are easily anesthetized with isoflurane or sevoflurane in oxygen in an induction chamber or box. Anesthesia can be maintained with the inhalant delivered via a face mask or endotracheal tube at a concentration ranging from 0.5% to 1.5% for isoflurane and 2.5% to 3.5% for sevoflurane. Hedgehogs can be intubated relatively easily. The most commonly used injectable anesthetic is ketamine (5 to 20 mg/kg IM), alone or in combination with diazepam (0.5 to 2.0 mg/kg IM), xylazine (0.5 to 1.0 mg/kg IM), or medetomidine (100 μ g/kg IM) (Table 31.1). Telazol can also be effective at a dose of 1 to 5 mg/kg IM. Hypothermia is a real threat because of the hedgehog's small body size. Fluids can be given IV or SC in the loose tissue beneath the spines. SC fat may account for up to 50% of the hedgehog's body weight and can cause delayed absorption of fluids and anesthetics when injected in this tissue. IM injections require a needle length sufficient to extend through fatty subcutaneous tissues. Either buprenorphine (0.01 mg/kg) or butorphanol (0.2 to 0.4 mg/kg IM or SC) can be administered to provide analgesic therapy following surgery.¹³⁴

Introduction

Chemical immobilization of free-ranging wildlife can be challenging. The nature of the procedure dictates that veterinarians must ignore many of the principals that underlie good anesthetic practice in other settings. It is generally not possible to access the

patients for a preanesthetic physical examination or laboratory work. Physical status of the patients cannot be accurately assessed, and generally animals are assumed to be healthy. Even if physical status and anesthetic risk could be determined, generally only a few effective protocols are available. Induction of anesthesia in wildlife can be extremely stressful, and stress-related conditions or injuries can result. Free-ranging wildlife are subject to environmental hazards and are often at risk for hypothermia or hyperthermia. Appropriate supportive care, such as controlled ventilation, intravenous fluid therapy, or inotropic support, is often not possible in field situations. Veterinarians may be required to work on species for which there is very little information about their physiology or pharmacological response to drugs. Extrapolation between similar species may be required, but can result in unexpected complications. Issues of human safety also must be considered. Given the challenges that are encountered during wildlife capture, it is not surprising that morbidity and mortality of animals can be high and injury to people engaged in the capturing procedure common.

Wildlife anesthesia should be a cooperative effort between biologists and veterinarians. A team approach is invaluable and draws on the strengths of different backgrounds and training. Veterinarians can play an important role in protocol development, monitoring, supportive care, and stress reduction. Additionally, because procedures performed on wildlife are becoming more invasive, provision of appropriate analgesia is an important emerging role of veterinary care.

This chapter focuses on the major principals of wildlife capture and handling. It includes some drug recommendations for commonly encountered wildlife, but it is beyond the scope of a single chapter to provide complete dose recommendations for terrestrial mammals. The *Handbook of Wildlife Chemical Immobilization* is a very complete synopsis of currently recommended dosages in most terrestrial mammals.¹ The handbook is a valuable reference for anyone involved in wildlife capture. The authors have retained parts of the original chapter from the third edition of *Lumb and Jones' Veterinary Anesthesia*, written by Leon Nielsen, in this revised edition, and we acknowledge his contribution.

Field Anesthesia

General Considerations

Wildlife capture is often required for research purposes. Capture events should be carefully planned because, with careful fore-

thought, complications can be anticipated and treatments better prepared. Capture sites may be preplanned and chosen based on their suitability. The capture can be planned at an appropriate time of the year when environmental hazards are minimized. For example, ungulates may be captured in late winter or spring to decrease the risk of hyperthermia and enable tracking in snow or visualization of animals in deciduous forest. Often individual animals are not targeted, and the capture team can choose any animal in a relatively safe capture environment. It is generally possible to adhere to strict pursuit times. If it is not absolutely necessary to capture the target animal, pursuit can be terminated to decrease the risk of stress-related disease, such as exertional myopathy. Current literature and experts in the field can be consulted prior to the capture event to ensure the most suitable technique is used. It may be possible to close areas to the public where wildlife are captured. Finally, appropriate equipment for monitoring and supportive care should be obtained and taken into the field.

Wildlife capture, in management situations, takes place in a much less controlled environment, which may be more hazardous. It is becoming increasingly common to have to deal with wildlife in urban environments that contain many hazards. Public safety and crowd control can be issues. Management-related capture may be required at any time of the day or night and any time of the year. Generally, a chase cannot be terminated, and injury or myopathy may result. In most situations, attempts at capture must continue until the animal is under control or destroyed. These situations arise quickly and usually must be resolved quickly. Often the personnel involved in capture are wildlife managers such as wardens or conservation officers. A limited choice of drugs may be available. In these situations, it is important to use drug combinations with a rapid onset and a high margin of safety. Wildlife managers often need to deal with a variety of species, and ideally a drug combination should be used that is effective in a wide range of species.

Terrain

Choosing an ideal location for wildlife capture may not always be possible. Ideally, the capture site should be open enough to enable good visualization of the animal during the induction period. Particular attention should be paid to bodies of water, because some species may enter the water after drug administration and be at risk of drowning. Obvious risks are associated with mountainous terrain (Fig. 32.1). Forest can be a particular hazard because animals may be very difficult to track beneath a forest canopy. Telemetry darts may be useful in these situations. Some species, such as black bears and mountain lions, may climb trees to escape capture. Equipment should be available to cushion their fall or to facilitate removing the animal from the tree. In an urban environment, particular attention must be paid to traffic. It is often advisable to enlist the help of law enforcement officers for crowd and traffic control.

Weather

Weather conditions may dictate whether wildlife capture is possible. Helicopter work is generally not possible in high winds or foggy conditions. Snow and rain can lead to hypothermia, particu-

Fig. 32.1. Mountainous terrain carries the risk of sudden weather changes, avalanches, loss of the animal under the forest canopy, and falls from cliffs or steep slopes.

ularly if wind is also present to enhance convective heat loss. Smaller mammals may be particularly prone to hypothermia. Several of the drug regimens used for wildlife capture can impede thermoregulation and lead to hypothermia or hyperthermia.^{2,3} Hyperthermia is a serious complication that can be difficult to treat in field situations. When possible, captures should be planned for the cooler hours of the day. In remote locations, sudden changes in weather may also be a hazard to personnel. It is important to keep track of current and changing conditions during planned events. Capture for management purposes may occur at any time. Provision should be made to prevent heat loss and actively cool animals, if required.

Equipment

Logistics and space limitations generally dictate what type of equipment can be carried in a field situation. It is often difficult to carry all but the most necessary pieces. Fortunately, there are compact ambulatory monitors suitable for field use. Hypoxemia is a common complication of wildlife anesthesia, particularly with ruminants.⁴⁻¹⁰ Oxygen is fundamental supportive care during anesthesia. Aluminum E and D cylinders, combined with a sturdy regulator and flowmeter, are ideal for field use (Fig. 32.2). Often, nasal insufflation of oxygen is adequate to treat hypoxemia. In some situations, equipment for ventilatory support is also recommended. It is difficult to carry a wide range of emergency drugs or an adequate volume of crystalloid fluids to treat shock. A basic emergency kit containing epinephrine, atropine, lidocaine, and reversal agents should always be carried. Equipment for airway support should also be included in an emergency kit. Ruminants are predisposed to ruminal tympany. It is wise to carry a suitably sized tube or hose to facilitate rumen desufflation. Equipment should also be carried to treat lacerations and other incidental injuries. Equipment should be carefully chosen to withstand use in a field situation and to be as lightweight and compact as possible.

Fig. 32.2. Portable oxygen cylinders and sturdy regulators will greatly facilitate oxygen delivery in field situations.

Capture Technique

An animal may be captured initially by physical or chemical means. The choice of capture technique depends on the species, the terrain, the facilities, and the experience of the capture crew. Many species of ungulates can be effectively captured and handled by experienced teams with physical techniques such as net guns.^{11–13} Physical restraint can be very stressful for wild animals, and methods need to be developed to reduce stress. Sedatives or anesthetics can be used to decrease the stress of handling once animals have been netted.¹³ Net gunning can cause high rates of mortality if it is performed by inexperienced personnel. The risk to capture personnel can also be high. Jessup et al.¹⁴ reported that, over a 12-year period in New Zealand, there were 127 helicopter crashes and 25 human fatalities during net-gun capture of red deer. These figures stress the need for experienced pilots and capture personnel. The terrain may dictate the choice of capture technique (Fig. 32.3). Grizzly bears can be effectively darted from a helicopter in open Alpine areas. This technique is less effective in forested parts of their range. In forested areas, it is often safer to capture the animal first with a snare or culvert trap, followed by remote delivery of anesthetics. The use of physical restraint will confine an animal's movements during the induction of anesthesia. Physical restraint can induce greater stress than chemical restraint.¹⁵ Generally, physical restraint should be of brief duration to avoid stress-related complications.

Target and Nontarget Species

Prior to embarking on a capture session, it is important to become as familiar as possible with the target species. This can include a search of current literature and texts. Ideally, experts in the field should be consulted to determine the most suitable technique and supportive care for the target species. In research-related captures, it may not be a particular individual that requires capture (i.e., a certain gender or age class may be the target). This gives researchers some leeway to choose animals in

Fig. 32.3. A skilled pilot is required for effective aerial capture. Everyone working around helicopters should receive appropriate training.

an ideal capture situation. Nontarget animals may include capture of the right species, but the wrong gender or age class. If traps are used, nontarget species may be caught. Researchers need to anticipate which nontarget species may be trapped and be familiar with the best current techniques for anesthesia of these species. Wildlife managers need to be familiar with techniques for all the species that they may encounter in their work. In management situations, a technique that facilitates anesthesia in a variety of species is often preferable.

Other Hazards

A number of hazards can be encountered during anesthesia of free-ranging wildlife. It is important to perform a risk assessment prior to embarking on a project. Potential risks should be identified and steps taken to reduce risk. The target species can pose a risk. There are the obvious risks of serious injury from large carnivores. Ungulates can also act aggressively, and injury may also occur from flailing limbs or heads in lightly anesthetized animals. Smaller carnivores can inflict serious injuries if they are not handled properly. It is important to know how a species will act in a stressful situation. It is also important to leave an exit for the animal and an exit for the capture personnel. Many species carry zoonotic disease, so capture personnel should be aware of potential zoonotic disease and handle the animal in an appropriate manner.

A firearm backup is important with more dangerous species (Fig. 32.4). The primary person performing the backup should be trained and experienced in the use of firearms, and an appropriate firearm should be used. If firearms are commonly used, all members of the capture team should receive firearm safety training. Similar training is advisable for people using dart rifles or dart pistols. Since helicopters can be hazardous, appropriate training and protective equipment, such as helmets, will help to minimize the risk of injury.

The environment itself can be hazardous. Capture may occur

Fig. 32.4. A firearm backup is vital when potentially dangerous animals are approached. In this picture, one fish-and-wildlife officer is focused on the target bear. The other officer is scanning the vicinity for other bears.

in remote locations. In these situations, capture personnel must be prepared to look after themselves if they cannot return to a base area. A method of communication with rescue services may need to be established. In some environments, weather can change rapidly and will often dictate whether capture can take place. There are hazards specific to the terrain and region; for instance, capture personnel should receive avalanche training before working in mountainous regions with an avalanche risk. It is important to anticipate risks in any environment.

Pharmaceuticals used for wildlife anesthesia can present a serious human health hazard because of their high potency and concentrated formulations. Potent narcotics, such as carfentanil, etorphine, and thiafentanil, can induce serious toxicity in people.¹⁶ These drugs must be handled with extreme caution. Protective clothing, such as disposable gloves or face shields, should be used to prevent skin or mucous membrane contact. A pharmacological antagonist should be available to treat human exposure. Potent narcotics receive a great deal of attention, but any concentrated sedative or anesthetic must be treated with respect. Medetomidine can be formulated at a concentration of 10 mg/mL (Zalopine; Orion Pharma Animal Health, Turku, Finland) for use in wildlife. Dexmedetomidine, which is used at a dose of 1 to 2 µg/kg in people,¹⁷ is approximately twice as potent as medetomidine, because levomedetomidine has no clinical effects.¹⁸ This dose would be equivalent to 2 to 4 µg of medetomidine per 1 kg of body weight or a total of 150 to 300 µg in a 75-kg person. The high end of this dose range is equivalent to 0.03 mL of Zalopine. Obviously, there is the risk of toxicity from exposure to a very low volume of Zalopine. Telazol (tiletamine-zolazepam) is another immobilizing mixture that can be delivered in a concentrated form and therefore must also be handled with caution. Everyone working on a capture team should be trained in first aid, and equipment should be available to provide respiratory and airway support in the hands of trained personnel.

Fig. 32.5. Postmortem image of a hematoma caused by a high-velocity injection of Telazol into the forelimb of a polar bear. The drug was delivered via an explosive discharge mechanism.

Prior to any capture, it is advisable to meet with local medical personnel and discuss an evacuation and treatment plan in the face of drug exposure. A meeting of this nature will familiarize physicians and emergency medical services personnel with the drugs that are being used and the potential treatments. In the event of an emergency, this can save valuable time and someone's life.

Remote Drug-Delivery Equipment

Wildlife capture often requires remote drug delivery, often over relatively long distances. Generally, it is difficult to deliver drugs accurately at distances greater than 40 m. There have been major advances in the equipment available for remote drug delivery. It is important to realize that these systems have the potential to produce serious injury or death if they are used inappropriately. The major sources of injury arise from dart-impact trauma, high-velocity injection of dart contents, and inaccurate dart placement (Fig. 32.5). Dart-impact trauma results from dispersion of energy on dart impact. Impact kinetic energy is represented by the following equation: $KE = 1/2M \times V^2$, where M = mass of the dart and V = velocity.¹ High velocity is the major factor that will cause trauma. A good general rule is to use the lowest velocity that will provide an accurate trajectory at a given distance. Practice with a darting system at a variety of distances is vital to minimize velocity. The other major factor is the mass of the dart. Darts with a lower mass will have less impact energy at a given velocity. This should be a consideration in the choice of a darting system, particularly when dealing with smaller animals that are more prone to trauma.

Inaccurate dart placement can cause injury. This most frequently occurs if darts penetrate the abdomen, thorax, or vital structures of the head and neck. The major factors that can lead to inaccurate dart placement include a lack of practice with the

Fig. 32.6. In most species, darts should be placed in the large muscle mass of the hind limb. This facilitates drug absorption and decreases the risk of trauma to vital structures.

darting system, an attempt to place a dart over an excessive range, and inherent inaccuracy of the darting system.

The final source of injury is related to high-velocity injection of dart contents. Systems that expel drug via an explosive charge can disrupt tissue and produce trauma. These systems should only be used on large, well-muscled animals (Fig. 32.6). Injection volume should be minimized to decrease the degree of tissue trauma. When possible, the use of darts that deliver their contents via compressed air should be considered to minimize trauma. The choice of system depends on the range required, the dart size, and individual characteristics of the target animal. The next section is a general discussion of remote delivery equipment. A more complete review can be found elsewhere.¹⁹ A further review and manufacturer information can be found in the *Handbook of Wildlife Chemical Immobilization*.¹

Pole Syringe

This is a simple device that can be used to extend reach for injection. In its simplest form, the pole is an extension of the syringe plunger, with the barrel of the syringe covering the end of the pole. It is typically used on confined animals (e.g., animals confined in traps or cages) or can be used to top up anesthesia in recumbent, but lightly anesthetized, animals. It is generally used on approach to the animal before initial contact is made (Fig. 32.7).

Pole syringes vary in length, but generally do not exceed 3 or 4 m. These can be simple homemade devices that consist of a disposable syringe attached to the tip of a wooden or plastic pole, or they may be commercial products. Commercial pole syringes come in a variety of designs. It is generally advantageous to select a pole syringe that can be disassembled into segments for transport and storage. Another factor to consider is ease of cleaning. Some devices use a disposable syringe that facilitates the use of proper aseptic technique. It is preferable to select a device that has a variety of syringe heads to facilitate accurate delivery of a variety of volumes.

Fig. 32.7. The pole syringe is useful for drug delivery in caged or trapped animals. It can be used cautiously, as in this image, to facilitate additional drug administration in lightly anesthetized, but recumbent, animals.

Fig. 32.8. Blowguns are useful for distances of up to 10 m. They are quiet and produce minimal trauma to animals. They are most useful in caged, snared, or treed animals.

Blowgun

This is the most basic of all remote drug-delivery systems. By blowing into a 1- to 2-m pipe, a trained operator can accurately propel a lightweight (3 to 5 mL) drug dart up to 10 or 15 m. The blowgun is useful as a short-range, limited-volume, drug-delivery system. It is commonly used in zoo work, wildlife rescue, and urban animal-control work (Fig. 32.8). The blowgun is nearly silent, uncomplicated to use and maintain, and well suited for immobilization of smaller animals. Because of their light weight, limited mass, and low velocity, blowgun darts cause minimal impact damage and tissue trauma. The discharge mechanism in most blowgun darts is compressed air or butane gas (Fig. 32.9). Practice with the blowgun is required before range and accuracy can be attained. Leaky darts can be hazardous to the op-

Fig. 32.9. **A:** Dart with explosive discharge mechanism. **B:** Dart with air-activated drug-discharge mechanism. **C:** Dart with coil spring-activated drug-discharge mechanism.

erator, and pressurized darts should be carefully inspected before loading. Several excellent systems are commercially available, but they can also be manufactured inexpensively from disposable syringes and plastic or conduit pipes.

Power Projection Systems

A variety of systems are commercially available to propel darts up to 50 m. Rifles are available that propel the dart via a .22-caliber powder charge, carbon dioxide (CO₂) gas, or compressed air. Pistols generally use CO₂ or compressed air.

Powder-Charged Projectors

These systems use the gas expansion from a fired .22-caliber charge to propel the drug dart. There are two basic types of this projector. The first uses different .22-caliber charges to compensate for various distances. The Palmer rifle (Palmer Chemical and Equipment, Douglasville, GA) is a good example of this technology. It is very important that the correct charge be used for the dart size and distance, and that the manufacturer's recommendations are followed. The use of long-range charges at short distances can produce serious trauma. Dart velocity may also be regulated by pushing the dart farther down the barrel of the projector. The farther the dart is moved toward the muzzle, the lower will be its velocity. A rod with markings for different settings and distances is useful for consistency in positioning the dart in the barrel. This method can be useful when darting at short distances.

The second type of powder projector vents the gas from a single blank .22-caliber charge through a ported velocity control. By adjusting the velocity control, the range of the dart can be regulated in accordance with dart size and distance. This system affords greater versatility and faster operation in cases where the distance to the animal may change frequently or suddenly. It requires practice at a variety of settings to become an effective

marksperson, and the velocity control must be kept clean to maintain consistency and accuracy. Paxarms (Timaru, New Zealand) and Pneu-Dart (Williamsport, PA) manufacture systems that use this technology.

Compressed Gas-Powered Projectors

These systems typically use compressed air or CO₂ to propel darts 5 to 50 m. They are manufactured in the form of pistols, rifles, and pistol grips that can be attached to a blowgun, and are available from a variety of companies worldwide. CO₂-powered projectors use gas from a CO₂ cartridge to propel the drug dart. Only fresh CO₂ cartridges should be used. Projectors should be stored according to the manufacturer's recommendations because some units must be stored cocked to preserve the O-rings.

Compressed air-powered projectors use compressed air from a tank or pump to propel the dart. A control valve and/or gauge on the projector, pump, or tank provide a means of regulating the air pressure for dart size and distance. Air-propulsion systems are often used in connection with blowgun components and to propel lightweight drug darts short to medium distances.

Darts

Darts must deliver their contents into a muscle group on impact. There are three major systems in common use to facilitate drug injection. Choice of these systems will depend on the situation and the size of the animal. Darts that use an explosive discharge mechanism can produce considerable muscle trauma and should be reserved for large, well-muscled animals.

Explosive Discharge Mechanisms

These darts have an aluminum or plastic body into which a small explosive cap is placed between the plunger and the tail. Upon impact, a firing pin inside the cap is forced forward, against the resistance of a spring, detonating the charge. The expanding gas pushes the plunger forward, and the drug is expelled through the needle. The speed of injection, 0.001 s, may cause tissue damage.¹⁹ The explosive caps are very sensitive to moisture and must be kept dry. When placed in the dart, the cap must have its open end against the tail. If it is turned around, detonation and expulsion of the drug will occur at the moment the projector is fired (Fig. 32.9).

If reusable darts are used, the fit of the dart should be tested by inserting the dart in the muzzle. If it slides in and out with ease, the dart is not deformed and can be loaded. If the dart jams in the muzzle, the dart barrel is deformed and should not be reloaded. With repeated use, the dart barrel may expand where the aluminum is weakened by the threads cut into it. This is caused by the high pressure created in the dart when gases from the explosive charge push the plunger forward at great speed. All of the darts with explosive discharge mechanisms inject through the tip of the needle. The needle should be barbed so that it stays in the animal during injection. If there is no barb or if the barb is removed, the force of the frontal expulsion of the drug is often sufficiently powerful to drive the dart out of the animal with only partial injection.

Air-Activated Mechanisms

These darts consist of an aluminum or plastic body into which air is introduced through a one-way valve in the tail piece and compressed behind the plunger. At impact, a silicone seal is displaced, exposing a port in the side of the needle. The plunger is pushed forward by air pressure, and the drug is expelled through the port (Fig. 32.9). Depending on the type and usage, plastic darts can be used repeatedly, but will eventually begin to leak or lose air pressure. In extreme cold, the drug may freeze inside the dart; therefore, darts should be kept warm in a secure container placed in an inside pocket or in a heated vehicle or helicopter until used.

Spring-Activated Discharge Mechanisms

These darts consist of an aluminum or plastic body that contains a coil spring behind the plunger. After the drug is loaded into the front of the dart, a rubber seal is placed over the needle tip. The tail piece with the coil spring is then screwed into the dart, compressing the spring behind the plunger. Upon impact, the needle tip penetrates the rubber seal, and the coil spring pushes the plunger forward, expelling the drug (Fig. 32.9).

Pharmacology

Ideal Drug Combination

Wildlife immobilization has progressed a great deal in recent years. A variety of drugs are available to facilitate capture and handling, and new techniques continue to develop. If an ideal drug combination could be developed, it would need to possess most of the properties listed here:

Rapid Onset of Activity

A rapid effect is one of the most important attributes required in a capture drug. The induction period is a hazardous time. Handlers and bystanders may be at risk of injury if induction is prolonged. Rapid onset will limit the risks of trauma, hyperthermia, and possibly capture myopathy. Ideally, the animal should be immobilized within 1 to 5 min after injection. Practically, most current combinations can take longer than 5 min to induce anesthesia.

High Margin of Safety

Drugs used for wildlife capture must have a high margin of safety. It is difficult to transport supportive equipment into the field; therefore, capture drugs should produce minimal cardiopulmonary depression. Wild animals are not weighed prior to capture, and it is not uncommon to overestimate weight. Capture drugs must have a high therapeutic index to decrease the risk of mortality from overdose.

Handler Safety

Precautions must always be taken to avoid exposure to potent drugs. Ideally, drugs should be relatively safe to handle, with minimum risks of intoxication if the handler contacts the drug. The ability to antagonize the effects of the drug is also desirable in field situations.

Small Volume of Delivery

Capture drugs should be potent and concentrated enough to facilitate delivery at low volumes (ideally, <3 mL). This decreases the risk of injection trauma from high-velocity injection and facilitates accurate dart flight.

Narcosis

The animal should lose consciousness and be unaware of its surroundings.

Ability to Antagonize Immobilization

Free-ranging wildlife often live in an environment full of potential hazards, so they must be cared for until they are fully awake. A pharmacological antagonist should be available because the ability to antagonize immobilization will speed recovery and is also of value in emergency situations. Because it can be difficult to provide supportive care, complications such as hyperthermia can become life threatening, and antagonism of immobilization may be the only viable option in managing unexpected complications.

Versatility

Wildlife managers often deal with a variety of species. Thus, an ideal drug combination could be used, with predictable effects, in a wide range of species. This limits the variety of drugs required to be kept on hand and leads to familiarity with the effects of the combination most commonly used.

Drug Stability

Wildlife capture may need to be performed in a wide range of ambient temperatures. Ideally, drugs should remain stable, in solution, over a wide range of ambient temperatures.

Analgesia

In recent years, it has become more common to perform potentially painful procedures during wildlife handling. These procedures can include ear tagging, tooth removal, biopsies, and even surgery for abdominal or subcutaneous implant placement. These situations dictate that appropriate intraoperative and postoperative analgesia must be provided.

Paralytic Agents

These have been used in wildlife capture for thousands of years. Remote delivery of curare was used by South American hunters to procure game. Early work by wildlife researchers used nondepolarizing muscle relaxants, such as tubocurarine and gallamine. Succinylcholine, a depolarizing muscle relaxant, has also been used for wildlife capture. Nicotine alkaloids stimulate autonomic ganglia to produce paralysis.

All neuromuscular junction–blocking agents produce immobilization via paralysis of skeletal muscle. The dosage must be adequate to provide a locomotor block, while sparing diaphragmatic function. Obviously, this technique has a very narrow margin of safety. Animals immobilized with paralytic agents are conscious and under considerable stress. The use of paralytics, as the sole agent for wildlife capture, is considered inhumane and is no longer

acceptable. Fortunately, a variety of safer and more humane techniques are available to facilitate wildlife capture and handling.

Opioids

A variety of opioids have been used for wildlife capture. Opioids can be used in a wide range of species, but are particularly effective in ungulates. The opioids produce analgesia and sedation, but lack muscle-relaxant properties. They have been used alone or, more often, with the addition of a neuroleptic agent, the inclusion of which potentiates the opioid, produces a smoother induction by counteracting the excitatory state associated with opioid induction, and decreases muscle rigidity. Opioids are predictable in action, act relatively fast, and can be reversed with the administration of a suitable antagonist. If not reversed, the duration of immobilization is lengthy, often several hours, during which the animal is at risk from opioid-induced respiratory depression and environmental hazards. Underdosing of opioids can result in a prolonged induction time, characterized by central nervous system (CNS) excitation, which can cause hyperthermia, exhaustion, lost animals, and/or death of the animal. The side effects of opioid-induced immobilization include

1. Excitation after administration, resulting in aimless running, pacing, or walking, which may lead to hyperthermia or capture myopathy²⁰
2. Regurgitation of ruminal content or vomiting, with the risk of regurgitation increased when carfentanil is combined with xylazine²¹
3. Severe respiratory depression and hypoxemia^{4,8}
4. Muscle rigidity²⁰
5. Renarcotization^{20,22,23}

Many of these drugs are extremely potent and must be handled carefully to avoid accidental human exposure.^{16,24,25}

Carfentanil

This has been used for wildlife captures since the early 1980s. The commercial preparation, produced by ZooPharm (Fort Collins, CO), is available at a concentration of 3 mg/mL. Carfentanil is approximately 8000 times as potent as morphine, making the commercial preparation very effective at low volumes of administration. Carfentanil is particularly useful in ungulates, but has also been used in large carnivores.^{1,26–28} Advantages of carfentanil include a rapid onset of activity, reliability, potency, and reliable reversal if an appropriate antagonist is used. The use of carfentanil alone can cause muscle rigidity; therefore, it is often combined with a sedative agent with muscle-relaxant properties, such as xylazine.²⁰ There are disadvantages of using this combination in moose, because the addition of xylazine to carfentanil may produce an increased incidence of aspiration pneumonia.²¹

Carfentanil has a relatively long action. Carfentanil-induced immobilization should be antagonized with an appropriate antagonist. If the duration of the antagonist is shorter than that of carfentanil, renarcotization can result. Naltrexone should be used for reversal of carfentanil, because renarcotization has been reported following antagonism with naloxone, diprenorphine, and nalmefene.^{22,23} Other adverse effects of carfentanil-based combi-

nations include respiratory depression, hypoxemia, hypertension, CNS excitation, and hyperthermia.^{4,8,29}

Etorphine

Etorphine hydrochloride has been used successfully in many species, but has been particularly effective in ungulates, rhinoceroses, and elephants. Etorphine, which is approximately 2½ times less potent than carfentanil, can be used alone or in combination with a suitable neuroleptic synergist. Induction course, induction time, and immobilization duration are dose dependent. Underdosing can cause excitation, with associated problems. At optimum doses, the first effects may be observed 3 to 8 min after intramuscular injection. The full effect may be reached in 20 to 30 min. Recovery is slow (up to 7 or 8 h) if no antagonist is given. When an antagonist is administered, animals will recover in 1 to 3 min after intravenous injection and in 5 to 10 min following intramuscular injection. The most serious side effect is respiratory depression. For that reason, an animal should not be kept immobilized longer than necessary, and drug effect should be reversed as soon as possible. Other side effects are often dose or species dependent and may include excitement, muscle tremors, convulsions, regurgitation, bloat, bradycardia, tachycardia, hypertension, hyperthermia, and renarcotization.

Thiafentanil (A-3080)

This is a potent narcotic that has some potential advantages over carfentanil. Thiafentanil is approximately 6000 times as potent as morphine (vs. 8000 for carfentanil)³⁰ and has a higher therapeutic index than carfentanil in some species (48 vs. 16 in domestic ferrets).³⁰ The major advantages of thiafentanil are a more rapid onset and a briefer action than carfentanil, which should result in a lower incidence of renarcotization.³⁰ Thiafentanil is not yet commercially available, but its use has been described in a variety of species.^{5,30–33} It has been used alone or in combination with α_2 -adrenergic agonists.^{31–33} Side effects are similar to those of other narcotics and include respiratory depression and hypoxemia.³¹ Reports have detailed the use of thiafentanil combined with medetomidine and ketamine.^{5,32} This is a promising combination that appears to be efficacious and have fewer side effects than does high-dose narcotic anesthesia.^{5,32}

Opioid Antagonists

A major advantage of opioid-based anesthesia is the ability to antagonize the opioid and rapidly reverse immobilization. To be effective, the antagonist should outlast the agonist drug and ideally be highly selective for the desired receptor type(s). Three drugs are commonly used for this purpose: naltrexone, naloxone, and diprenorphine. Naltrexone is probably the most versatile drug, with the lowest risk of renarcotization.

Naltrexone

This is commercially available in a 50-mg/mL concentration. It is a pure opioid antagonist that will produce rapid antagonism of μ opioid receptor agonists. The major advantage of naltrexone is that it will produce reliable antagonism of longer-acting opioids, such as carfentanil. A study comparing carfentanil reversal with

nalmefene, diprenorphine, and naltrexone demonstrated renarcotization with diprenorphine and nalmefene.²² Naltrexone has been recommended at a dose of 100:1 (naltrexone-carfentanil). The drug is active following intramuscular and intravenous administration. A more rapid antagonism will occur if the drug is administered intravenously.

Naloxone

Naloxone hydrochloride is a pure narcotic antagonist (i.e., it has no known agonistic properties). It may be used to reverse the effects of all the aforementioned opioids, and reversal occurs within 1 to 3 min of intravenous injection. Naloxone has a short half-life; therefore, animals may revert to a state of immobilization within a few hours and require repeated treatment with naloxone. Renarcotization has been noted in field studies that used naloxone as an antagonist for carfentanil.²³ A low dose of naloxone (2 µg/µg carfentanil intravenously) has been shown to improve oxygenation while maintaining immobilization in elk.⁴

Diprenorphine

Diprenorphine hydrochloride (M50-50; Lemmon, Sellersville, PA) is the antagonist used to reverse the effects of etorphine. While relative to etorphine as an antagonist, it does have agonistic properties of its own. Reversal is rapid following intravenous injection, with animals becoming ambulatory in 1 to 3 min. If the antagonist is injected intramuscularly, reversal takes longer (up to 15 to 20 min). Side effects are rare, although overdosing may cause continued immobilization because of its partial agonist activity. Following accidental human exposure to etorphine, diprenorphine hydrochloride should not be used as an antagonist because of its agonist effects. Naloxone or naltrexone are the preferred human antagonists.

Cyclohexamines

These produce a state of dissociative anesthesia. Phencyclidine hydrochloride was the first drug in this class used for wildlife capture. The cyclohexamines, used alone, produce muscle rigidity or twitching. Other side effects are hyperthermia, excessive salivation, catecholamine release, and convulsions. The cyclohexamines act fast, have a relatively wide margin of safety, and depress respiration and circulation only moderately at optimum doses. Laryngeal reflexes are somewhat preserved with these agents.

Cyclohexamines may be used alone in some species, but the effects of the addition of a benzodiazepine or α_2 -adrenergic agonist will be additive or synergistic with the cyclohexamine, produce a smoother induction and recovery, and alleviate the muscle rigidity common to dissociative anesthesia.² The cyclohexamines have been used in a wide variety of species, but are particularly known for their effectiveness in carnivores, bears, primates, and birds. There are no known antagonists for this class of drugs. The drugs in this category include ketamine and the tiletamine-zolazepam combination (Telazol; Fort Dodge Laboratories, Fort Dodge, IA).

Ketamine

Ketamine hydrochloride is a dissociative anesthetic commercially available in 10-, 50-, and 100-mg/mL aqueous solutions.

Since these concentrations may be too low for efficient delivery to larger species, it may be lyophilized and reconstituted at 200 mg/mL. Ketamine should never be used as the sole immobilizing agent. A tranquilizer-sedative should be used in almost all cases to reduce or prevent its hypertonic effects. Ketamine has been used successfully in many species, and doses vary widely from one species to another. Induction time and immobilization duration are dose and species dependent. At optimum doses, the first effects are observed in 2 to 5 min following intramuscular injection, with the full effects reached in 5 to 10 min. Immobilization usually lasts from 45 min to 2 h. Side effects of ketamine immobilization may include convulsions, catatonia, apnea, excessive salivation, and hyperthermia as a consequence of catatonia. Many of these side effects can be negated by adding a benzodiazepine or α_2 -adrenergic agonist. Medetomidine-ketamine has some advantages over xylazine-ketamine because a lower dose of ketamine is usually required.³⁴ This will result in smaller injection volumes and the ability to antagonize the medetomidine with fewer adverse side effects from the remaining ketamine. Ketamine-based combinations are unreliable in bears. Sudden recoveries have been encountered with xylazine-ketamine and medetomidine-ketamine in brown and polar bears.^{34,35}

Tiletamine-Zolazepam

A commercial preparation of tiletamine, a dissociative anesthetic, and zolazepam, a benzodiazepine drug, is available as a freeze-dried powder (Telazol). It is effective in a variety of species and, at optimum doses, first effects may be noticeable within 1 or 2 min of intramuscular injection, with full effects reached within 15 to 30 min. The induction is usually smooth, with good muscle relaxation and somatic analgesia. The duration varies with species, but may persist for several hours. Because tiletamine and zolazepam are metabolized at different rates, the quality of emergence and duration of recovery may be affected. Recovery occurs in 3 to 8 h in most cases, but may be prolonged in some species.

Tiletamine-zolazepam combinations may cause hypertension and increase heart rate and cardiac output. Other effects are salivation, occasional muscle rigidity, and hyperthermia (particularly if the mixture is combined with an α_2 -adrenergic agonist).³⁵⁻³⁸ Telazol has been used alone in a variety of species.³⁹ It is very effective in carnivores, and recovery tends to be smooth, but can be prolonged. The use of Telazol alone in ungulates can result in rough recoveries. Reconstitution of Telazol with an α_2 -adrenergic agonist will decrease the volume injected, enhance analgesia, and decrease recovery times following antagonism of the α_2 -adrenergic agonist.³⁵⁻³⁸ These combinations will produce a better quality of immobilization and recovery, particularly in ungulates.^{7,40,41} Generally, the addition of an α_2 -adrenergic agonist will greatly decrease Telazol requirements. In polar bears, the Telazol requirement was reduced by up to 75%.^{35,36}

α_2 -Adrenergic Agonists

These are CNS depressants with sedative, muscle relaxant, and analgesic properties. Used alone, α_2 -adrenergic agonists produce unreliable immobilization. They are best used in combina-

tion with opioids or dissociative anesthetics. When used in high dosages, α_2 -adrenergic agonists may critically depress respiration and circulation. Commonly encountered side effects include hypoxemia in ungulates and hypertension with or without bradycardia.^{6-9,34,36,37,42} These agents can also contribute to ruminal tympany and regurgitation in ungulates.^{7,21} In very excited animals, they do not produce a satisfactory level of immobilization. They also disrupt thermoregulatory mechanisms, leading to hyperthermia or hypothermia.^{2,36,37} Recovery, without reversal, from high doses is usually prolonged and difficult. In field situations, it is generally recommended that the effects of α_2 -adrenergic agonists be antagonized at the completion of the procedure.

Xylazine

This is commonly available in 20- and 100-mg/mL aqueous solutions. It is also available as a powder and as 300-mg/mL solution specifically for wildlife capture. The 20-mg/mL solution is too dilute to be useful for remote injection.

When administered alone, xylazine does not produce reliably immobilized free-ranging wildlife. Its effectiveness appears to be decreased in excited or stressed animals. It may appear to induce a recumbent sleeplike or anesthetic-like state; however, stimulation may cause rapid arousal with defense responses intact. In calm animals, the initial effect may be seen within 4 to 5 min of intramuscular injection, with full effect reached within 15 to 20 min. Adverse effects can include hypoxemia, bradycardia, hypotension, ruminal tympany, and decreased thermoregulatory ability.

Xylazine has been used effectively as a synergist with opioids and cyclohexamines. The inclusion of xylazine has decreased dose requirements of the primary immobilizing drugs, produced a faster and smoother induction, and countered some of the undesirable side effects of these drugs. The response to high doses of xylazine may conceal a recovery from the primary immobilizing drug and place workers at risk if the animal is suddenly aroused by noises, touch, or other stimulation.

The effects of xylazine may be reversed with the administration of an α_2 -adrenergic antagonist. In general, 1 mg of atipamezole is required to antagonize 10 mg of xylazine. If xylazine is used in combination with a cyclohexamine, its effects should not be reversed before the animal has metabolized a significant fraction of the latter drug, in order to avoid the side effects of the cyclohexamine.

Xylazine is typically used intramuscularly for wildlife immobilization. Intranasal administration of xylazine can be beneficial to decrease stress and struggling following net-gun capture.¹³ This route has a rapid onset of activity and is simple to administer in physically restrained animals.¹³

Detomidine

Detomidine hydrochloride is available in a 10-mg/mL solution. The effects of detomidine have been well studied in horses, but information on its use for immobilization of captive and free-ranging wild animals is somewhat limited. It has been combined with etorphine in rhinoceros and has proven to be effective in ze-

bras when combined with carfentanil and ketamine.^{43,44} The action of detomidine is much like that of xylazine. Its effects may be reversed by an appropriate α_2 -adrenergic antagonist. In general, 1 to 3 mg of atipamezole should be used to antagonize 1 mg of detomidine.

Medetomidine

Medetomidine hydrochloride is a potent α_2 -adrenergic agonist that has proven to be a very useful drug for wildlife capture. The 1-mg/mL formulation is suitable for use in small mammals, but is too dilute for use in larger species. Medetomidine is also available in 10 mg/mL (Zalopine; Orion Pharma Animal Health) and 20 mg/mL (ZooPharm) concentrations. The latter concentrations are adequate for capture of most large land mammals. Medetomidine will produce sedation, analgesia, and muscle relaxation. The drug should not be used alone because, as with xylazine, immobilization is unreliable. Medetomidine can be combined with a low dose of ketamine or Telazol. A relatively low dose of the dissociative drug is required with medetomidine, and antagonism of medetomidine with atipamezole (at three to five times the medetomidine dose) will hasten recovery.³⁴ Side effects of medetomidine include hypertension, bradycardia, and hypoxemia.^{7,8,34,36,42,44} Hypoxemia may be particularly pronounced in ruminants.⁷ Medetomidine can also impair thermoregulatory ability, resulting in hyperthermia.^{35,36}

Romifidine

A fourth α_2 -adrenergic agonist, romifidine, at 10 mg/mL (Sedivet; Boehringer Ingelheim Vetmedica, St. Joseph, MO) has been developed for use in domestic animals. Its action is similar to the other α_2 -adrenergic agonists. There is minimal data on the use of romifidine in free-ranging mammals.

α_2 -Adrenergic Antagonists

The utility of α_2 -agonist-induced sedation is greatly increased by the availability of antagonists. Several competitive antagonists are used in wildlife work. Atipamezole is the most selective of the three antagonists currently used and can be used in all species. There are species dependent differences in response to yohimbine and tolazoline.² Yohimbine, for example, is not particularly effective in wild bovids, and either tolazoline or atipamezole is preferred in these species. Antagonists should generally be administered intramuscularly unless the situation is emergent. CNS excitement, tachycardia, and hypertension may be seen with intravenous administration.^{34,45} Animals may arouse rapidly from immobilization following intravenous administration of atipamezole.^{7,35,42} With potentially dangerous species, this may not allow adequate time to retreat to a safe distance.

Atipamezole

This is the most specific and potent α_2 -adrenergic antagonist currently available. It is typically used to antagonize medetomidine at three to five times the medetomidine dose administered.³⁴ It is equally effective in the antagonism of xylazine (1 mg of atipamezole per 10 mg of xylazine) and detomidine (1 to 3 mg of atipamezole per 1 mg of detomidine).

Yohimbine

Yohimbine hydrochloride is an effective α_2 -adrenergic antagonist for reversal of xylazine in a variety of species. Some species may respond reliably, whereas others may show no or only partial recovery. Yohimbine may cause tachycardia, hypertension, and CNS excitement. At clinical doses, it does not produce effective antagonism of medetomidine.

Tolazoline

This has proven to be an effective α_2 -adrenergic antagonist in some wild and domestic species. High dosages of tolazoline may produce systemic hypotension, and tachycardia has been observed in sheep.² Tolazoline is effective in bison and other bovids where yohimbine lacks efficacy.

Drug Combinations

It is uncommon to use single agents for wildlife capture. Typically, agents are combined either for their synergistic effects or to counter adverse side effects. The combination of an opioid with an α_2 -adrenergic agonist has already been discussed. Xylazine-ketamine has been used for many years and has the advantage of versatility (i.e., it is effective in many ungulate and carnivore species). The major disadvantages of xylazine-ketamine are the large volume required and the residual effects of ketamine if xylazine is antagonized soon after administration. Medetomidine-ketamine shares the versatility of xylazine-ketamine, with the advantages of decreased volume and lower ketamine requirement. Antagonism of medetomidine will likely cause fewer side effects from residual ketamine, because the overall amount of dissociative anesthetic administered is lower.³⁴

Medetomidine-ketamine is useful in a wide range of species.³⁴ It should be used cautiously, or its use avoided, in bears, because sudden recoveries have been reported in brown bears and polar bears.^{34,35} Xylazine-Telazol and medetomidine-Telazol can be delivered in small volumes and are useful in a wide range of wildlife species. Antagonism of the α_2 -adrenergic agonist will hasten recovery. Time to sternal recumbency and standing is generally more rapid after antagonism of medetomidine compared with xylazine.^{6,35-38} This is probably the result of a lower Telazol dose required in the medetomidine-Telazol combination, when compared with xylazine-Telazol.^{6,37}

Neuroleptic Drugs

Neuroleptic agents such as acepromazine and droperidol have been used as adjunctive agents in wildlife capture for many years. Typically, they have been used in combination with potent opioids such as etorphine. A more recent application of these agents is the use of long-acting tranquilizers to facilitate translocation of wild animals. Long-acting neuroleptics have been developed to treat human psychosis. Depending on the formulation, these drugs may have effects for days to weeks. These drugs will produce an overall reduction in stress of handling, which should decrease the incidence of trauma and myopathy and facilitate adaptation to a novel environment. Typically, these agents are phenothiazines, butyrophenones, or benzodiazepines.⁴⁶ A short-

acting agent, such as haloperidol, may be combined with a long-acting agent, such as perphenazine enanthate, to produce rapid onset of action and prolonged activity.⁴⁶

Perphenazine Enanthate

Perphenazine is a phenothiazine derivative that is formulated in a sesame oil vehicle. The onset of perphenazine is 12 to 16 h, and its effects can last up to 10 days. The use of this drug has been reported in a variety of species, including red deer and Przewalski's horses.^{47,48} Flight distance is decreased in red deer, and animals maintain better body condition than controls.⁴⁷ In Przewalski's horses, the drug has been used to effectively decrease dominance aggression during the establishment of a bachelor herd.⁴⁸

Zuclopenthixol Acetate

This is a thioxanthine derivative that has been used in a variety of species and will have effects lasting 3 to 4 days.^{47,49-51} Treated animals have a decreased flight distance and are easier to manipulate. Animals spend more time eating and drinking compared with controls and have been observed to spend less time pacing. A dose of 1 mg/kg has been used in most studies. Occasionally, extrapyramidal signs have been noted at this dose.⁵¹ These signs usually resolve without treatment.⁵¹

The Capture Event

Precapture Planning

Before undertaking any wildlife capture, an appropriate plan of action must be devised for the capture procedure. The species should be researched to determine the most effective and current technique for capture. A decision needs to be made as to the use of physical or chemical restraint. Logistical considerations are important. In remote areas, communication and evacuation plans must be established. Equipment must be carefully selected for use in the field. Drug needs must be anticipated, and it is generally wise to budget for at least 50% more drug than is actually needed for the target animals. This will help to offset any drug wasted from lost darts or poor dart placement.

In the immediate recapture period, the target animal is located and weight is estimated. The terrain, weather, and situation must be evaluated to determine whether capture will be attempted. Most commonly, the drug dart is loaded after the target animal has been located and observed; however, there may be times when it is more practical to load the darts beforehand. Drug doses may be calculated for specific sizes or age groups, and the darts are preloaded and marked accordingly. However, metal darts should not be kept loaded for longer than a 12-h period because of the possibility that corrosive action of the drugs may impair the injection mechanism and damage the dart. Preloaded darts with air-activated discharge mechanisms should not be pressurized because they have a tendency to leak, or lose pressure, if armed for an extended period. Choose darts that are lightweight and have barbed needles of an appropriate length for the target animal.

Generally, the animal will need to be approached to within a

distance of 30 to 40 m for accurate drug delivery. There are many methods to facilitate approaching to within this distance. Animals may be stalked, approached in a vehicle or helicopter, or trapped or snared prior to approach. Trapping has the advantage of limiting movement during the capture event, but it may prove to be more stressful than helicopter capture.¹⁴ Pursuit of animals should generally be limited to no more than 2 to 5 min. The incidence of capture myopathy, hyperthermia, and trauma will increase with prolonged chase times. In management situations, pursuit may often be required until the animal is captured. It is beyond the scope of this chapter to consider species-specific considerations. It is advisable to include experienced personnel on the capture team and to consult with experienced wildlife managers, biologists, and veterinarians to determine anticipated complications, animal behavior when stressed, and the current approaches to dealing with the target species.

Induction

Many factors may influence induction time. These include the drug dose received, the animal's physical condition, its age and gender, and its sensitivity to the immobilizing drug. Dart placement is probably the most important determinant of induction time. To facilitate quick absorption of the drug, the muscle masses of the neck, shoulder, or hindquarter must be injected (Fig. 32.6). Animals that are excited or stressed can have induction times that are considerably longer than in calm animals.

Some animals will put on considerable fat deposits prior to denning and fasting and must be dealt with in a different manner during these times. Brown bears, for example, can generally be darted in the hindquarter when they emerge from spring dens. In the fall, these animals have considerable fat deposits overlying the rump and must be darted in the shoulder or neck. As soon as the dart is placed, the time should be recorded, and the animal must be carefully observed to ensure that it is not lost during the induction period.

Induction is a dangerous time during which animals may be lost or injured. If a helicopter was used in pursuit, it will need to back off to a safe distance where an animal can be observed, but not stressed. The helicopter may need to steer an animal away from potential hazards such as cliffs or water. Time to sternal recumbency and head down should be recorded.

Initial approach to an animal can be dangerous. The animal should be observed from a safe distance to determine that there is no purposeful movement. When α_2 -adrenergic agonist-based protocols are used (e.g., medetomidine-ketamine or xylazine-tiletamine-zolazepam), the animal's head or limbs should not move prior to approach. If tiletamine-zolazepam alone or narcotics are used, there may be some involuntary movement in adequately immobilized animals. Once it has been determined that the animal is safe to approach, it should be cautiously approached accompanied by a firearm backup, if necessary. It is important to leave safe exits for the capture team and the animal. To gauge the animal's response, auditory stimulation such as clapping or shouting should be employed as the animal is approached. If there is no response to auditory stimulation, the response to tactile stimulation should be gauged. It is advisable to

Fig. 32.10. Initial contact should be made from a safe distance. In this picture, a pole syringe is being used to initiate contact with a grizzly bear.

use a stick or pole syringe to extend reach when stimulating the animal (Fig. 32.10). When it is safe, the palpebral reflex and airway can be checked. A set of vital signs, including rectal temperature, respiratory rate, and heart rate, should be monitored. The animal's eyes can be lubricated with an ophthalmic solution or gel, and a blindfold can be placed to decrease visual stimulation. At this point, hobbles may be considered to limit movement in the event of sudden recovery in ungulates.

Monitoring and Supportive Care

Following capture, the animal should be positioned to avoid pressure points and ensure optimum ventilation. Carnivores may be positioned in lateral or sternal recumbency, but ruminants should be positioned in sternal recumbency whenever possible. The head and neck should be extended to maintain a patent airway. A stretcher system may be employed to facilitate movement of the animal and to keep it elevated above the ground. Vital signs should be monitored every 5 to 10 min. Ideally, continuous monitoring as with a pulse oximeter should be used. Painful procedures such as tooth extraction or biopsies should be performed soon after induction when the animal is in the deepest plane of anesthesia. If animals are manipulated to determine body mass, it is best to do this during a deep plane of anesthesia because the stimulus can result in arousal.⁵²

Hypoxemia is not uncommon during wildlife anesthesia.^{4-10,29,31,36,42} Hypoxemia, in the face of hyperthermia, is a particularly serious situation, because hyperthermia increases tissue oxygen demand. This can increase the risk of exertional myopathy or cause acute mortality. Hypoxemia can often be prevented or treated in the field with the administration of supplemental oxygen. The animal should be monitored for hypoxemia, ideally with a pulse oximeter. A multisite sensor applied to the tongue generally provides a good signal. Normal hemoglobin saturation should be 95% to 98%, and below 85% is considered hypoxemic. If a pulse oximeter is not available, the mucous membranes

Fig. 32.11. A nasal catheter is being used to deliver supplemental inspired oxygen to an anesthetized musk ox. The oxygen flow is adjusted to try to achieve a desired percentage of hemoglobin saturation of 95% or more.

should be monitored for cyanosis. Severely hypoxemic animals are often tachycardic. Tachycardia, followed by severe bradycardia (heart rate, <30 beats/min) is often a warning sign that hypoxemia is very severe and the heart may soon fail.

The use of supplemental inspired oxygen should be considered in hypoxemic animals. Portable equipment is available to facilitate oxygen delivery. An ambulance-type regulator (Easy Reg; Precision Medical, Northampton, PA) and an aluminum D cylinder is lightweight, portable and sturdy. It can provide a 10-L/min flow for up to 30 min. An E cylinder will provide this flow for 1 h or more. A nasal catheter can be used in most animals. The catheter should be threaded as far as the medial canthus of the eye. The flow rate should be adjusted to maintain a saturation of greater than 95% (Fig. 32.11).

Heart rate and pulse quality should be monitored every 5 min. The auricular artery is easily palpated in many ungulate species. If the auricular artery cannot be palpated, a femoral pulse can be used. Equipment is available to measure direct or indirect blood pressure and electrocardiographic status in the field (Fig. 32.12).

In ruminants, maintenance in sternal recumbency will help to prevent ruminal tympany. If ruminal tympany is a problem, the animal may be rocked gently to stimulate eructation. A rumen tube can be used, but may predispose the animals to regurgitation and aspiration. Generally, if ruminal tympany is severe, it is advisable to finish the procedure quickly and antagonize the anesthetic agents. If α_2 -adrenergic agonists have been used, the administration of tolazoline, yohimbine, or atipamezole will stimulate ruminal activity and facilitate the correction of tympany.

Rectal temperature should be monitored every 5 to 10 min. Ungulates are particularly prone to hyperthermia, especially after a long chase. Rectal temperatures higher than 40°C are cause for concern, and attempts should be made to cool the animal. Cold water sprayed on the animal or snow packed into the inguinal and axillary regions may help. Rectal temperature higher than 41°C is an emergency and should be treated aggressively. It is difficult

Fig. 32.12. Portable monitors are available to perform in-depth physiological monitoring during wildlife capture. In this image, a monitor is used to measure direct arterial pressure and electrocardiographic status in a polar bear.

to cool large animals actively, and often the best option with severe hyperthermia is to antagonize the immobilizing agents and allow the animal to recover. Hyperthermic animals should receive supplemental inspired oxygen to offset any hypoxemia and reduce the likelihood of anaerobic tissue metabolism.

Anesthesia depth should be closely monitored. Some drug combinations have proven to be unreliable in bears. Xylazine-ketamine and medetomidine-ketamine are unreliable, and sudden recoveries may be encountered.^{34,35} The use of these combinations is best avoided in most situations. Factors that increase the risk of sudden arousal include loud noise, and distress vocalization of offspring is particularly dangerous. Other factors include movement of a bear (i.e., changing the body position or location of the anesthetized animal) or painful stimuli such as tooth extraction. Techniques for monitoring anesthesia depth will depend on the agent used. Tiletamine-zolazepam will produce reliable anesthesia with predictable signs of recovery. As anesthesia lightens, spontaneous blinking will occur. Carnivores often develop chewing and paw movements. They will start to lift their head and may attempt to raise themselves with their forelimbs. Animals with significant head movement generally require a top-up dose of tiletamine-zolazepam or ketamine unless they are to be left to recover. Top-up or small additional doses of tiletamine-zolazepam can significantly prolong recovery and should be used only if longer than 30 min of additional downtime is required. Ketamine is a better choice if 5 to 20 min of additional time is needed.

With xylazine-ketamine or medetomidine-ketamine, head lifting or limb movement signals that the animal is extremely lightly anesthetized and should not be approached or manipulated. Increased intensity of the palpebral reflex or nystagmus are generally good indicators that the animal is lightly anesthetized. When procedures on the animal have been completed, the area should be cleared of equipment, and personnel should retreat to a safe area and observe the recovery.

Fig. 32.13. Since modern antagonists can work very rapidly, it is always important to have an avenue of escape with potentially dangerous animals.

Recovery

Considerations for recovery vary, depending on the choice of drug and the situation. In most situations, a reversible technique is desirable. If a reversible technique is not used, the animal should be observed until it can ambulate. Prior to reversal, equipment should be removed from the capture site, and personnel should retreat to a safe distance. The animal should be placed in a comfortable position and its airway cleared. A final set of vital signs are obtained and monitoring equipment removed. Typically, one person remains with the animal and a backup person, if required. Antagonists are administered intramuscularly unless there is an immediate need for rapid recovery. The animal's recovery should be observed from a safe distance (Fig. 32.13).

Human Safety

Many hazards to human safety are inherent in wildlife immobilization. Potent narcotics have received considerable attention because of the risk of intoxication from very small volumes. However, any agent used for wildlife capture should be treated with caution and respect. The most important piece of safety equipment is the latex glove. Gloves should be worn whenever drugs are handled; indeed, it is good practice to wear gloves throughout the capture procedure.

Wildlife anesthesia should never be performed by a single person. At least two people should be present whenever potent drugs are handled, and everyone working on the capture team should be trained in cardiopulmonary resuscitation and first aid. Loading and charging of darts is a time of high risk for exposure to drugs, during which the use of face shields may be considered to prevent contamination of mucous membranes. Darts should be charged under a protective cover to decrease the risk of accidental drug exposure. Antagonists, such as naloxone, should be immediately available if they are indicated for treating human exposure.

Dart-delivery equipment should be handled with care and only

by trained individuals. Darts have the potential to induce significant tissue injury and death. Firearm safety rules apply to darting equipment, and individuals handling this equipment should be appropriately trained.

Helicopters present a significant hazard. Wildlife capture requires a very skilled pilot to decrease risk of injury to the target animal and the capture personnel.⁵³ Anyone working around a helicopter must receive training in helicopter safety.

The target animal can present a risk to personnel. This risk is obvious with large carnivores, but ungulates can also present a significant risk that can be greatly increased if they are cornered or protecting young. Many deer species undergo a period of rut during the breeding season, during which stags are often more aggressive. The best way to avoid injury is to work with people who are familiar with animal behavior and to leave an escape route for the animal and personnel. As previously mentioned, a firearm backup should be available when working with dangerous animals.

During capture, the focus tends to be on the captured animal. It is always important to be aware of the surroundings because other animals may approach the capture team. This is particularly important with social carnivores, such as lions. It is also important with bears, particularly if members of a family group are captured. In these situations, an armed lookout should be posted to protect the capture team.

Complications Related to Wildlife Capture

Physical Trauma

During immobilization and capture, physical injuries such as contusions, lacerations, abrasions, punctures, and fractures may be inflicted on an animal accidentally or by mishandling. Minor injuries can be treated successfully in the field, but fractures and other serious conditions are difficult to treat effectively and often require that the animal be euthanized.

Minor lacerations may be cleaned, treated with a topical antibiotic ointment, and protected with an insect repellent. An appropriate antibiotic may be given intramuscularly to help prevent infection. Closure may be considered for large lacerations, which should be cleaned and debrided as much as possible. These lacerations are often contaminated, and, if they are closed, appropriate drainage and administration of long-acting antibiotics must be considered.

Physical trauma may be prevented by taking notice of any hazard in the environment that may cause injury to the animal during capture and by careful handling. Traps, snares, nets, or other forms of manual capture or restraint that are used should be appropriate for the species and set by trained individuals.

Hyperthermia

This is commonly encountered during wildlife capture. The most immediate sign is a critical rise in body temperature to above 41°C. Other symptoms include rapid shallow breathing, panting, and weak, rapid, or irregular heart rate. Ultimately, animals can convulse and die. Causative factors of hyperthermia in-

Fig. 32.14. Ungulates are particularly prone to hypoxemia during immobilization. Treatment of hyperthermia is difficult in the field; therefore, antagonism of immobilization is often the best option.

clude high ambient temperatures, excessive muscular exertion from prolonged pursuit, and interference with normal thermoregulatory mechanisms by α_2 -adrenergic agonists. Treatment in the field may include moving the animal into shade or spraying it with cold water. Packing ice or snow around the animal and/or cold-water enemas may also be indicated. The use of supplemental inspired oxygen should be considered to optimize arterial oxygen content. Treatment is often not effective, and generally the best option in field situations is to complete procedures rapidly and administer antagonists (Fig. 32.14).

The risk of hyperthermia may be reduced by avoiding immobilization or capture on very warm days or by limiting activities to the coolest part of the day. It is best to avoid prolonged pursuit, keep stress to a minimum, and use the least severe method of physical restraint. Protecting animals from high ambient temperatures and direct exposure to the sun can also reduce hyperthermia.

Hypothermia

This is a concern when animals are immobilized when ambient temperatures are low. It occurs most commonly in young animals, animals with small body masses, and animals in poor body condition. Hypothermia is characterized by decrease in body temperature to below 35°C. If untreated, hypothermia may result in prolonged recovery, acidosis, and arrhythmias. Causative factors of hypothermia include low ambient temperature, evaporative cooling, wetness, precipitation, and drugs, such as α_2 -adrenergic agonists, that impair thermoregulation. Supportive procedures consist of an immediate attempt to increase body temperature by drying a wet animal, covering the animal, and providing external heat sources such as hot-water bottles (Fig. 32.15).

Bloat

Bloat during wildlife capture is commonly caused by ruminal atony associated with the administration of α_2 -adrenergic agonists and other drugs that alter gastrointestinal motility. The re-

Fig. 32.15. Young animals, such as this brown bear cub, should be insulated from the ground and covered to reduce heat loss.

sult is the inability to relieve gases from the rumen or stomach through normal eructation. The impact of bloat can be reduced by placing the immobilized animal in sternal recumbency with the neck extended and the head forward, permitting saliva and any regurgitated material to drain. Smaller animals can be moved from side to side over the brisket, and their front quarters can be elevated. If positioning does not relieve the bloat, inserting a lubricated and properly sized tube via the esophagus into the rumen will relieve pressure. The last resort to relieve abdominal pressure is emergency trocharization of the rumen. Generally, bloat will resolve following the administration of an α_2 -adrenergic antagonist or recovery from drug effects. In the face of severe bloat, procedures should be completed rapidly or discontinued, and drug effects rapidly reversed.

Exertional Myopathy

Most free-ranging animals exert themselves infrequently only to escape danger. They are not conditioned for running at full effort over long distances. Chasing wild animals with a helicopter or motor vehicle imposes a tremendous amount of stress. The effects of sympathetic exhaustion from sustained stress, combined with intense muscular exertion, are the causative factors of various life-threatening syndromes known as *exertional myopathy*.⁵⁴⁻⁵⁶

Intense sustained muscular exertion associated with capture pursuit or resisting physical restraint leads to the production and buildup of lactate in muscle cells and metabolic acidosis. Severe lactate accumulation may cause metabolic dysfunction or death of skeletal muscle cells, resulting in the release of intracellular potassium ions (K^+), calcium ions (Ca^{2+}), and myoglobin. High concentrations of myoglobin in the plasma and ultrafiltrate within the renal tubules can cause acute renal failure. Hyperkalemia and acidosis cause arrhythmias and circulatory failure.

Exertional myopathy is difficult to treat, so prevention is of utmost importance. Capture myopathy may be prevented by reducing and minimizing capture stress, fear, and exertion. Chase time should be limited to 2 min and capture efforts not resumed for at

least 1 day once capture has failed. Visual and auditory stimulation, handling, and restraint of the captured animal are kept to a minimum. One should provide a stress-free postcapture environment. Captured wild animals should not be handled or stressed for at least 6 weeks following capture. Four common clinical syndromes of exertional myopathy have been identified: acute death syndrome, delayed peracute death syndrome, ataxic-myoglobinuric syndrome, and muscle-rupture syndrome.

Acute Death Syndrome

With the *acute death syndrome* form of exertional myopathy, the animal appears depressed and weak and remains recumbent after reversal. Breathing is rapid and shallow, heart rate is rapid and weak, and hypotension persists, progressing to shock signs and/or death within 3 to 4 h. Causative factors include exhaustion, lactic acidemia, hypoglycemia, and hyperthermia. Supportive procedures consist of fluid therapy to increase blood volume and pressure, restore electrolyte balance, correct acidosis, and increase renal perfusion and diuresis.

Delayed Peracute Death Syndrome

In this syndrome, the animal appears to be in reasonably good condition after the initial capture episode. However, when stressed again (usually 1 day after the initial capture episode), it dies of ventricular fibrillation and cardiac arrest. The pathogenesis of this syndrome is believed to be muscle destruction and potassium release, sensitizing the heart to catecholamines and arrhythmias.

Ataxic-Myoglobinuric Syndrome

This condition is characterized by ataxia, brownish urine, and possibly death within hours or days after capture. Increased levels of serum glutamic-oxaloacetic transaminase (SGOT), creatine phosphokinase (CPK), lactate dehydrogenase (LDH), and blood urea nitrogen (BUN) are associated with lesions in skeletal muscles and kidneys. Death may occur acutely or within 4 to 5 days from kidney failure following myoglobin-mediated tubular destruction. Some animals may survive this syndrome, provided appropriate supportive therapy is instituted.

Muscle-Rupture Syndrome

The first signs of this syndrome can be observed within 1 to 2 days after capture. The animal seems unable to support weight on its hind legs. Hocks are hyperflexed, and CPK, LDH, and SGOT levels are increased, but the BUN level is normal (Fig. 32.16). The animal will usually die within 3 or 4 weeks. On necropsy, there are extensive, light-colored areas in the large muscles used for escape (fight-or-flight response).

Respiratory Depression and Hypoxemia

Hypoxemia is common during wildlife anesthesia and immobilization.^{4–10,29,31,36,42} Major causative factors include respiratory depression from immobilizing agents (particularly potent narcotics), ventilation-perfusion mismatching, airway obstruction, and other factors. Immediately after initial contact with a down animal, steps must be taken to ensure a patent airway (Fig.

Fig. 32.16. An elk with muscle rupture syndrome and hyperflexion of the hocks.

32.17). Severe hypoxia can cause hypotension, arrhythmias, and death. Hypoxemia in the face of hyperthermia can rapidly result in tissue hypoxia.

The best treatment for hypoventilation is endotracheal intubation and controlled ventilation with supplemental inspired oxygen. This can be difficult in field situations, particularly with very large animals. Partial reversal of narcotics has been used successfully to treat respiratory depression.⁴

Ventilation-perfusion mismatching will generally respond to supplemental inspired oxygen.^{6,9} Hypoxemia caused by hypoventilation will also respond to supplemental inspired oxygen, although arterial CO₂ partial pressure will remain elevated and respiratory acidemia untreated.²⁹ In the field, the simplest way to treat hypoxemia is to administer supplemental inspired oxygen via a nasal cannula.⁶ The animal should be monitored with a pulse oximeter and oxygen flow adjusted to maintain a saturation of peripheral oxygen (SpO₂) greater than 90%. Other causes of hypoxemia include aspiration and pneumothorax (secondary to dart penetration of the thoracic cavity). Pneumothorax might be treatable with thoracocentesis, so equipment should be carried to perform thoracocentesis in the field.

Capture-Associated Mortality

Chemical immobilization of free-ranging mammals is a form of veterinary anesthesia conducted under the most extreme circumstances. The anesthetic risk in wild animals undoubtedly is highly influenced by the capture protocol that is applied. Typically, most deaths are observed in the early phase of a large capture project before the methods have been refined, drug doses have been adjusted, and the immobilization team has gained experience. Moreover, an increased risk of mortality may be seen when captures are carried out for specific purposes like health evaluation of animals under environmental or pathogenic stress. Mortalities caused by capture and anesthesia of free-ranging mammals can be grouped into three different categories. The first is direct effects

Fig. 32.17. Airway management and supportive care in a grizzly bear. The head and neck have been extended to achieve a clear airway. The bear has been placed on a flat surface and insulated from the ground. After eye lubrication, a blindfold is placed to decrease visual stimuli.

of the immobilizing drug itself (e.g., respiratory depression, shock, hyperthermia, and asphyxia caused by tympany or vomiting). The second group, indirect effects (e.g., drowning, pneumothorax due to misplacement of darts, and trauma from dart impact), might be a direct consequence of the drug used (e.g., etorphine often induces hyperthermia, which may cause the animal to seek water actively for cooling, with drowning as a possible sequela). Finally, the third category is secondary effects caused by the capture process (e.g., trauma from traps, long-term effects from chasing or stress, separation of family groups, and various problems with radio collars or implantable transmitters). Secondary effects have nothing to do with the anesthetic risk per se and should be treated as a separate entity.

In his review of stress and capture myopathy in artiodactylids, Spraker⁵⁵ stated that a mortality rate greater than 2% during trapping is unacceptable. This should be the rule of thumb when a large number (>100) of free-ranging animals are being anesthetized or captured (e.g., a mortality rate greater than 2% during

chemical immobilization requires that the anesthetic protocol be reevaluated). By using immobilizing drugs and doses with proven safety, proper remote drug-delivery systems, and established capture methods and techniques, an experienced capture team should be able to minimize the risk of mortality.

Considerations for Commonly Anesthetized Free-Ranging Wildlife

This section deals with general recommendations and considerations for representative species. The species have been chosen because they are commonly encountered or extensively studied. Readers are referred to the *Handbook of Wildlife Chemical Immobilization* for complete dosing information and a reference list by species.¹ Dosages required for immobilization of free-ranging animals are generally higher than those required in captive individuals.⁵⁷ This factor must be kept in mind when dosages are planned for wildlife capture, or a relative underdose may occur. Injection site and method of drug delivery can also affect dose requirements. A comparison of hand injection versus dart delivery demonstrated that 50% more drug was required when animals were darted.⁵⁸ Method of capture, season, and potentially the gender of an animal can also alter drug dose requirements.

American and Northern European Species *White-Tailed Deer* (*Odocoileus virginianus*) and *Mule Deer* (*Odocoileus hemionus*)

These species are commonly encountered in management situations. Mature white-tailed deer can weigh 60 to 150 kg, and mature mule deer usually weigh 75 to 135 kg.¹ They are not particularly difficult to anesthetize if they are kept reasonably calm during immobilization. Excited or stressed deer tend to be less affected by the sedative actions of α_2 -adrenergic agonists and often require higher dosages. Common complications include trauma, hyperthermia, and capture myopathy. Ruminal tympany is not commonly encountered during anesthesia of these species. Hypoxemia is not uncommon with narcotic-based or α_2 -adrenergic agonist-based protocols, and supplemental inspired oxygen should be considered.⁸

A variety of techniques have been used to induce immobilization. White-tailed deer can be anesthetized with 2.2 mg/kg of xylazine combined with 4.4 mg/kg of Telazol.^{40,59} This combination is equally effective on mule deer, and immobilization can be partially antagonized with 0.1 to 0.2 mg/kg of yohimbine. A dosage of 0.1 mg/kg of medetomidine combined with 2.5 mg/kg of ketamine will produce a good quality of immobilization in mule deer and white-tailed deer.⁸ Atipamezole administered at three to five times the medetomidine dose will effectively antagonize immobilization.

North American Elk (*Red Deer*, *Cervus elaphus*)

Elk or red deer may be captured via physical or chemical means. If physical capture (net gunning) is used, sedation can be quickly induced with intranasal xylazine.¹³ Mature elk weigh approximately 230 to 318 kg, and red deer weigh 60 to 180 kg.¹ Chemical immobilization can be induced with narcotics or

α_2 -adrenergic agonists combined with dissociatives. Complications are similar to those expected with other deer species. Elk should be monitored for ruminal tympany and hyperthermia. Hypoxemia is common in anesthetized elk, especially during immobilization with xylazine-carfentanil or xylazine-Telazol.^{4,6} Hypoxemia can be effectively treated by partial antagonism of drugs or by administration of supplemental oxygen.

Elk can be immobilized with 10 $\mu\text{g}/\text{kg}$ of carfentanil combined with 0.1 mg/kg of xylazine.^{1,4} Immobilization can be antagonized with naltrexone. Alternatively, a mixture of 0.4 mg/kg of xylazine and 3 mg/kg of Telazol is also effective.^{41,60} Immobilization with this combination can be partially antagonized with 0.125 mg/kg of yohimbine.

Red deer are smaller than elk, but the considerations for immobilization are similar. The drugs of choice for red deer capture are 0.11 mg/kg of medetomidine with 2.2 mg/kg of ketamine.⁶¹ In this combination, medetomidine should be antagonized with 0.5 mg/kg of atipamezole. An alternative drug combination is 2.5 mg/kg of xylazine with 2.5 mg/kg of Telazol.¹ However, because of the long elimination time of Telazol, recoveries can be prolonged.

Moose (Alces alces)

Moose are the largest member of the deer family, with adult males averaging 500 kg.¹ They are found in the northern latitudes of Europe, Russia, and North America. Moose in the far northern latitudes of these regions may reach a much larger body mass (up to 800 kg). Their large size necessitates the use of potent drug combinations to maintain a low drug volume. The use of carfentanil-xylazine has been recommended as in other deer species.⁶² The addition of xylazine to carfentanil decreases the incidence of muscle rigidity, but also increases the risk of regurgitation and aspiration pneumonia.²¹ For this reason, if carfentanil is used in moose, it should be administered as the sole agent at a dose of 10 $\mu\text{g}/\text{kg}$. In addition to the risk of regurgitation, moose are at risk for hyperthermia and capture myopathy.

In Europe, moose have been effectively immobilized with 60 $\mu\text{g}/\text{kg}$ of medetomidine combined with 1.5 mg/kg of ketamine.^{34,63} Immobilization can be antagonized with 0.3 mg/kg of atipamezole. Currently, the drug of choice for free-ranging moose is etorphine alone at a dose of 7.5 mg per adult and half this dose in calves.⁶⁴ Xylazine (1.5 mg/kg)-Telazol (3 mg/kg) has been used in management situations. Immobilization with this combination can be partially antagonized with yohimbine or tolazoline.

Fallow Deer (Dama dama)

A variety of techniques have been used to anesthetize fallow deer, often with unreliable effects. Adult fallow deer weigh approximately 40 to 100 kg.¹ Currently, the recommended drug combination for fallow deer is 0.1 mg/kg of medetomidine with 1.0 mg/kg of Telazol.⁶⁵

American Bison (Bison bison) and European Bison (Bison bonasus)

Bison range in size from 350 to 1000 kg, with the largest subspecies being the wood bison (*Bison bison atabascae*) found in

northern Canada.¹ The large size of these animals dictates that potent, concentrated drugs be used to facilitate delivery of the smallest drug volume possible. Bison are prone to bloat and regurgitation. Fasting can decrease the risk of these complications, but obviously this is not possible in free-ranging animals. Hypoxemia is another major complication,⁷ but can generally be managed with supplemental oxygen. A dosage of 5 $\mu\text{g}/\text{kg}$ of carfentanil combined with 0.07 mg/kg of xylazine can be used to immobilize North American and European bison.^{23,66} Naltrexone should be used to antagonize carfentanil in bison, because renarcotization has been encountered with naloxone.^{23,66} Alternatively, 0.06 mg/kg of medetomidine combined with 1.2 mg/kg of Telazol, or 3 mg/kg of Telazol combined with 1.5 mg/kg of xylazine can be used to anesthetize bison.⁷ Xylazine-Telazol is best reserved for small, calm animals because the volume can become too large. Ketamine (2.5 mg/kg) combined with 0.08 mg/kg of medetomidine has been used effectively in European bison.³⁴

Caribou (Reindeer, Rangifer tarandus)

Caribou can be very difficult to immobilize and often have higher drug dose requirements compared with related species.⁶⁷ Their speed and agility make them a difficult target for remote drug delivery. *Rangifer* species range in size from 80 to 300 kg, with woodland caribou being the largest subspecies.¹ The drug combination of choice for reindeer and caribou is 0.1 mg/kg of medetomidine with 2.5 mg/kg of ketamine.³⁴ These doses are not effective in free-ranging woodland caribou. In these animals, 0.2 to 0.25 mg of medetomidine with ketamine is recommended.⁶⁸

Pronghorn Antelope (Antilocapra americana)

Pronghorn antelope can be extremely difficult to immobilize. They often have very high drug dose requirements, and immobilization is often unreliable with α_2 -adrenergic agonist or dissociative-based protocols. Hyperthermia is a common complication.

Pronghorn antelope usually weigh 40 to 50 kg.¹ The current combination of choice is 0.05 mg/kg of carfentanil combined with 1.0 mg/kg of xylazine.⁶⁹ Although not yet available, thiafentanil alone and thiafentanil-xylazine have proven to be superior to other drug combinations for pronghorn antelope capture.³³

Baird's Tapir (Tapir bairdii)

This is one of three New World tapir species. Adult animals, which weigh 200 to 300 kg,¹ have been effectively anesthetized with a total dose of 2 mg of etorphine in combination with 8 mg of acepromazine.⁷⁰ This combination often results in hypoxemia and, since the animals are often captured at night, an increased human safety risk is associated with the use of potent narcotics.⁷⁰ An alternative technique is to use 0.2 mg/kg of butorphanol combined with 0.4 mg/kg of xylazine. This technique is effective in calm animals and will induce approximately 30 min of recumbency.⁷¹ Immobilization can be prolonged with 1 mg/kg of ketamine given intravenously. The mixture can be antagonized with 0.2 mg/kg of naltrexone plus 0.125 mg/kg of yohimbine.

Brown Bear (Ursus arctos)

Brown bears range across parts of North America, Europe, and Asia. Adult bears generally weigh between 100 and 325 kg.¹ Most brown bears are captured in spring or early summer. Body weights are 80 to 100 kg for adult females and 140 to 240 kg for adult males. In the autumn, body weights increase by up to 40% as animals prepare for hibernation.

A variety of techniques can be used to immobilize brown bears. Telazol is routinely used for management of brown bears in North America. Reversible combinations are desirable in certain situations, particularly in free-ranging sows with cubs. Telazol (or Zoletil), 7 to 9 mg/kg, will produce reliable immobilization, but can also result in prolonged recoveries.⁷² Injection volume requirements are high, necessitating the use of large darts that can produce excessive tissue trauma. Xylazine (2 mg/kg) combined with Telazol (3 mg/kg) is effective. This combination is partially reversible with yohimbine or atipamezole, but some residual sedation will probably remain. Animals immobilized with this mixture will benefit from supplemental inspired oxygen, since hypoxemia is common.³⁸ Medetomidine (M) combined with Telazol (TZ) will produce reliable immobilization. This combination has been used effectively on European brown bears. These are the standard doses used for fieldwork (spring and early summer) on Scandinavian brown bears: yearlings (15 to 45 kg), 1.25 mg M + 62.5 mg TZ; small bears (2 to 3 years, 45 to 70 kg), 2.5 mg M + 125 mg TZ; adult females and small males (70 to 120 kg), 5 mg M + 250 mg TZ; adult males (120 to 200 kg), 10 mg M + 500 mg TZ; and large males (>200 kg), 15 mg M + 750 mg TZ. The M-TZ ratio is kept constant so that doses can be split or combined. For reversal, atipamezole at 5.0 mg per 1.0 mg of medetomidine is given intramuscularly.⁷³

Polar Bear (Ursus maritimus)

Polar bears can have substantial body-fat deposits throughout the year. The shoulder and neck are the best sites for drug delivery. Male polar bears can be large and heavy. Body weights greater than 500 kg are not uncommon. To keep drug volume and dart size to a minimum, concentrated drug combinations are required. Once anesthesia is induced, the bears should be positioned carefully to avoid compartment syndrome caused by excessive pressure on the limbs. Polar bears enter a hypometabolic state during the summer. At that time of the year, the bears are fasting and body temperature is decreased (34° to 35°C), so immobilizing drug requirements may also be decreased. In areas where large numbers of polar bears congregate, reversible anesthetic protocols should be considered. This decreases the risk of predation from other bears. Reversible protocols should also be considered for mother bears with cubs. One drug choice is 8 to 10 mg/kg of Telazol,⁷⁴ which produces reliable immobilization, but can also lead to prolonged recoveries. Volume requirements are high, which can produce excessive tissue trauma and necessitate the use of large darts. Xylazine (2 mg/kg)-Telazol (3 mg/kg) will also induce effective immobilization.³⁷ This mixture, which can be delivered at approximately half the volume of Telazol alone, is potentially reversible with yohimbine or atipamezole. However, reversal of this mixture is not reliable, probably be-

cause of residual Telazol sedation. Animals immobilized with this mixture will benefit from supplemental inspired oxygen. Medetomidine (75 µg/kg)-Telazol (2.2 mg/kg) is very effective in polar bears. This combination produces reliable immobilization with a rapid onset,^{35,36} can be delivered in a small volume, and is readily reversible with atipamezole (administered at four times the medetomidine dose).

Black Bear (Ursus americanus)

Black bear females weigh 92 to 140 kg, and males weigh approximately 115 to 270 kg.¹ Generally, these bears have a more placid nature than brown bears, and Telazol dose requirements are lower. The bear may be snared or captured in a culvert trap prior to drug administration. Physical capture of the bear will facilitate drug administration and limit mobility on anesthesia induction. One drug choice is 4 to 6 mg/kg of Telazol, which produces reliable immobilization and can be delivered at a relatively low volume in most bears.⁷⁵ Xylazine-Telazol is also effective in black bears at the same dose described for brown and polar bears (2 mg/kg of xylazine with 3 mg/kg of Telazol).⁷⁶ This dose could possibly be lowered, but further work is needed to determine the optimal dose for this species. Medetomidine (52 µg/kg)-Telazol (1.7 mg/kg) is also effective.⁴² This combination produces a rapid onset of immobilization and can be delivered in a small volume. It is readily reversible with atipamezole administered at four times the medetomidine dose.

Lynx (Felis lynx and Lynx canadensis)

European and North American lynx can be treated in a similar manner. Female European lynx weigh 16 to 18 kg, and males weigh 21 to 23 kg. North American lynx weigh 5.1 to 17.2 kg.¹ Lynx are often captured by physical means prior to immobilization. Medetomidine (0.2 mg/kg)-ketamine (5 mg/kg) is considered the drug combination of choice in European lynx.^{34,77} This dose can be reduced by 50% in captive lynx.⁷⁷ Telazol is an alternative mixture that can be administered to lynx at 5 mg/kg.⁷⁸

Mountain Lion (Felis concolor)

Mountain lions are commonly anesthetized for translocation by wildlife managers. It is common to tree mountain lions prior to dart placement. Hounds can be effectively trained to pursue and tree them. The current drug combination of choice for mountain lion capture is 2 mg/kg of ketamine combined with 75 µg/kg of medetomidine.⁷⁹ This mixture is readily reversible with atipamezole. Telazol has been used alone at a dose of 8 mg/kg; however, recoveries can be prolonged.³⁹ Xylazine-Telazol has been effectively used by wildlife managers. Initial results suggest that a dose of 2 mg/kg of xylazine combined with 3 mg/kg of Telazol will anesthetize mountain lions effectively.

Jaguar (Panthera onca)

The jaguar is the largest New World felid, weighing 64 to 114 kg. Jaguars may be baited or captured by physical means prior to immobilization. Telazol has been described for immobilization of jaguars at a recommended dose of 4 to 8 mg/kg.^{39,80} This dose can be supplemented with 1 to 2 mg/kg of ketamine, as needed.

The use of medetomidine (70 µg/kg)-ketamine (2.5 mg/kg) has also been described in captive animals.³⁴

Wolverine (Gulo gulo)

Wolverines are found in the northern latitudes of Europe, Russia, and North America. Males are typically 50% heavier than females, and normal body weight ranges are 9 to 11 kg in adult females and 14 to 16 kg in adult males. Wolverines can be immobilized from a helicopter or in the den. Standard doses for capture are 3 mg of medetomidine combined with 75 mg of ketamine for adult females and 4 mg of medetomidine and 100 mg of ketamine for adult males. Inductions are rapid, and there are no major clinical side effects. Effective reversals are achieved with 5 mg of atipamezole per 1 mg of medetomidine. Alternatively, 175 mg of Telazol can be used to immobilize adult wolverines.⁸¹

Gray Wolf (Canis lupus)

Gray wolves are widely distributed throughout the northern hemisphere. Males typically weigh 25% more than females. Average body weights in Scandinavian gray wolves are 40 kg for adult females and 50 kg for adult males. Occasionally, adult males will be much heavier (especially in North America). Gray wolves are immobilized from a helicopter or after being captured in a snare or a leg-hold trap. The drug of choice is Telazol. A standard dose of 500 mg can be used for all animals weighing more than 25 kg. Anesthesia inductions are rapid, but recoveries are prolonged and may take 4 to 6 h. Medetomidine-ketamine should be used with care for immobilization of wolves from a helicopter because some animals tend to develop severe hyperthermia (41° to 42°C) with this combination.⁸²

Wild Boar (Sus scroffa)

Eurasian wild pigs or wild boars are indigenous to Europe, Asia, and North Africa, and have been introduced into North America, Australia, and New Zealand. Wild boars are captured in traps and immobilized from a short distance with a tranquilizing pistol or blowgun. For brief procedures, 0.1 mg/kg of medetomidine with 0.2 mg/kg of butorphanol and 5 mg/kg of ketamine have been recommended.⁸³ Effective reversal is achieved by using 5 mg of atipamezole per 1 mg of medetomidine. Combinations of medetomidine-butorphanol-Telazol can also be used to anesthetize wild boars, but recoveries are more prolonged.⁸⁴

African and Asian Species

Tiger (Panthera tigris)

Eight different subspecies of tiger have been recognized, although some may only represent morphological variations. Small populations of tigers are found in India, Southeast Asia, and southeast Russia. Tigers usually weigh 100 to 160 kg (adult females) or 180 to 260 kg (adult males).⁸⁵ Commonly, 70 µg/kg of medetomidine combined with 3 mg/kg of ketamine is used.¹ Effective reversal is achieved with 5 mg of atipamezole per 1 mg of medetomidine. An alternative drug combination is 0.8 mg/kg of xylazine combined with 11 mg/kg of ketamine.^{86,87} Xylazine can be antagonized with 0.125 mg/kg of yohimbine, but because of the high dose of ketamine, reversals are not as effective as with

medetomidine-ketamine. Telazol has caused several adverse reactions in tigers and should be used with caution and only when other drugs are unavailable.^{1,88}

Lion (Panthera leo)

Five subspecies of lion are recognized. Lions are found on the African continent from South Sahara to South Africa. A remnant population exists in India. Body weights range from 120 to 180 kg in adult females to 150 to 240 kg in adult males.⁸⁵ There are two excellent drug combinations for immobilization and anesthesia of lions. For brief procedures, 70 µg/kg of medetomidine combined with 2.5 mg/kg of ketamine can be used.¹ Inductions are rapid, and analgesia and muscle relaxation are good. Due to the low dose of ketamine, animals may demonstrate sudden unexpected recoveries and should be closely monitored.⁸⁹ Immobilization can be prolonged by administration of additional ketamine at 1.5 mg/kg.¹ Telazol alone at a dose of 4 to 5 mg/kg can be used, but recoveries usually take several hours.^{1,90} Low-dose Telazol (0.8 mg/kg) in combination with medetomidine (50 µg/kg) has also been successfully used for capture of lions.⁹¹ Inductions are smooth, immobilization complete, muscle relaxation good, analgesia adequate for minor procedures, and the anesthetic actions last approximately 1½ h. Atipamezole can be used to reverse the effects of medetomidine, and it is recommended that 5 mg of atipamezole per 1 mg of medetomidine be administered to ensure that sedation does not recur.¹

Leopard (Panthera pardus)

Seven subspecies are currently recognized. Leopards are found in Africa south of the Sahara and in South Asia. Scattered populations are in North Africa, Arabia, and the Far East. Leopards weigh 30 to 70 kg. Males are typically 50% heavier than females.⁸⁵ Medetomidine (70 µg/kg)-ketamine (3 mg/kg) is usually sufficient and the combination most commonly used.¹ However, higher doses (0.1 and 5 mg/kg, respectively) of these two drugs may be needed to achieve complete anesthesia in cage-trapped leopards. Atipamezole, at 5 mg per 1 mg of medetomidine, can be used for reversal of immobilization.¹ Telazol alone at 5 to 8 mg/kg, or xylazine at 1 mg/kg in combination with ketamine at 8 to 11 mg/kg, can also be used to immobilize leopards.¹

Cheetah (Acinonyx jubatus)

Two subspecies of cheetah are recognized: the African cheetah and the Asian cheetah (nearly extinct). Cheetahs weigh 39 to 65 kg. Males are typically 15% heavier than females.⁸⁵ Recommended drugs for immobilization are medetomidine at 70 µg/kg combined with ketamine at 3 mg/kg.¹ If necessary, additional ketamine (2 mg/kg) can be given. For reversal, 5 mg of atipamezole per 1 mg of medetomidine can be administered. Another combination for reversible anesthesia is 50 µg/kg of medetomidine and 1.5 mg/kg of Telazol. These doses have been used on free-ranging African leopards and were modified from a study on zoo animals.⁹² Atipamezole at 5 mg per 1 mg of medetomidine is effective for anesthesia reversal in captive leopards, but sedation, lasting up to 4 h, can persist in some captive animals. This raises concerns about the use of this combination in free-ranging ani-

mals that must be released shortly after the anesthetic event.⁹² Alternative combinations include 3 mg/kg of Telazol alone or 0.5 mg/kg of xylazine with 6 to 8 mg/kg of ketamine.

Plains Zebra (Equus burchelli)

Zebras are indigenous only to Africa. The plains or common zebra is distributed widely in eastern and southern Africa, with more than half a million animals in the Serengeti–Masai Mara ecosystem of Tanzania and Kenya. Three subspecies are recognized. Plains zebras weigh 200 to 340 kg.⁸⁵ Two other zebra species, mountain zebras (*Equus zebra*) and Grevy's zebras (*Equus grevyi*), are endangered and are restricted to small populations on the continent. Most recommended drug combinations for immobilization of zebras involve the use of etorphine.^{1,93,94} In free-ranging plains zebra etorphine (4 to 7 mg for males and 3 to 4 mg for females) combined with either azaperone (40 to 60 mg), xylazine (40 to 60 mg), acepromazine (30 mg), or detomidine (5 to 10 mg) will induce recumbency. Immobilization is often not complete, and blindfolding is recommended. Complete muscle relaxation is difficult to obtain, and paddling, shivering, and sweating are often seen. Respiratory depression is a common side effect in zebras during chemical immobilization. Hyperthermia is another major complication, particularly if induction is prolonged. Hemoglobin saturation and rectal temperature should be closely monitored. Supplemental oxygen, equipment for intubation and ventilation, and water for cooling should be available, as well as emergency drugs (e.g., respiratory stimulants and benzodiazepines in case of convulsions). Upon induction, zebras can be positioned either in sternal or lateral recumbency. Recently, a comparison of three combinations was carried out.⁹⁵

1. 6 mg of etorphine with 80 mg of azaperone for males, and 4 mg of etorphine with 80 mg of azaperone for females
2. 5 mg of etorphine with 5 mg of medetomidine for males and females
3. 3 mg of etorphine with 150 mg of ketamine and 10 mg of detomidine for males and females

All combinations induced complete immobilization with lateral recumbency; however, hypoxemia ($\text{SpO}_2 < 85\%$) occurred in most animals. Rapid reversal was achieved with standard doses of antagonist drugs (e.g., diprenorphine and atipamezole).¹ Preliminary results indicate that etorphine-ketamine-detomidine is superior to the other two combinations. Zebra skin is thin, and lightweight darts with low impact energy should be used to avoid penetration wounds. Dart wounds often bleed profusely, and prophylactic antibiotic treatment is recommended.

African Buffalo (Syncerus caffer)

The African buffalo is indigenous to Africa south of the Sahara. Two subspecies are recognized, Cape buffalo and forest buffalo, with intermediate forms. Large males weigh up to 800 kg and females up to 750 kg.⁸⁵ Recommended drugs are 8 to 10 mg of etorphine combined with 150 to 200 mg of azaperone for adult bulls and 6 to 8 mg of etorphine combined with 150 mg of azaperone for adult cows.⁹⁴ Diprenorphine at 2.4 mg per 1 mg of etorphine is used for reversal.⁹⁴ Etorphine (at the same doses for

males and females) can also be combined with xylazine (70 to 80 mg for bulls and 40 to 60 mg for cows). A standard dose of yohimbine is used for reversal of xylazine effects.¹

African Elephant (Loxodonta africana)

African elephants are found south of the Sahara. Two subspecies are recognized: savannah elephant and forest elephant (some authorities classify them as different species). Savannah elephants may reach 4000 to 6500 kg, and forest elephants are significantly smaller.⁸⁵ Females are usually two-thirds of male weight within a given geographical area. Etorphine at 8 to 12 mg is the drug of choice for adult African elephants.⁹⁴ Azaperone at 70 to 100 mg can be added in the dart, but may prolong recovery, and animals may struggle to rise following reversal. The recommended dose is 14 to 20 mg of etorphine for bulls and 10 to 15 mg for cows. Hyaluronidase at 1000 to 3000 IU has been added in the dart to hasten induction. Preferred darting sites are the rump or shoulders; areas near the ears and trunk should be avoided. Elephants are large and difficult to handle. To avoid respiratory compromise, they should not be allowed to remain in sternal recumbency following induction.^{1,94} Breathing through the trunk must be unimpaired, and dart wounds should be flushed with an antimicrobial solution to prevent abscessation. Diprenorphine at 3 to 4 mg per 1 mg of etorphine given intravenously is commonly used to reverse etorphine immobilization.

Giraffe (Giraffa camelopardalis)

Giraffes are found in Africa south of the Sahara. Nine subspecies are recognized. Males and females may reach a height of 4.9 to 5.2 and 4.3 to 4.6 m, respectively, and weigh up to 1800 and 1180 kg, respectively.⁸⁵ The current capture philosophy for giraffes is to administer a high dose of immobilizing drug to facilitate induction in the shortest possible time and then quickly antagonize the drugs after physical restraint has been achieved.^{1,94} Immobilization of giraffes should not be attempted without prior consultation with an experienced handler. Blood pressure must be maintained in a normal range to supply blood to the brain. The head should be held at all times, from initial recumbency to the point where it is starting to recover.^{1,94} Etorphine-azaperone is the recommended drug combination for giraffe anesthesia.⁹⁴ Doses are 10 to 12 mg of etorphine and 40 to 60 mg of azaperone for adult bulls and 8 to 10 mg of etorphine and 40 mg of azaperone for adult cows. Hyaluronidase (2000 IU) has been added in the dart to hasten induction. Reversal is achieved by administration of diprenorphine at 2.4 mg per 1 mg of etorphine. Preliminary trials indicate that thiafentanil (15 to 18 mg for bulls and 10 to 14 mg for cows) may be superior to etorphine in giraffes, with induction times as quick as 3 min. A medetomidine-ketamine regimen with doses based on shoulder height, followed by atipamezole, has been used for reversible immobilization of free-ranging giraffes.⁹⁶ However, the results of trials in the Kruger National Park have been inconclusive regarding the efficacy of this combination, which is currently under continued evaluation.⁹⁴

White Rhinoceros (Ceratotherium simium)

The white rhinoceros is endangered and is found in scattered populations in South and Northeast Africa. Males weigh 2200 kg

and females 1600 kg.⁹⁴ The recommended drug combination is etorphine combined with detomidine, xylazine, or azaperone. Dose recommendations vary between researchers and areas. Etorphine at 3 to 4 mg and detomidine at 10 to 20 mg for adults seem to be superior to other combinations.^{1,94} Hyaluronidase at 2000 IU should be added to the drug mixture to shorten induction. White rhinoceroses are prone to significant respiratory depression following etorphine administration, so close monitoring is necessary. The standard protocol in Africa is to administer 10 to 15 mg of nalorphine intravenously immediately to all immobilized animals. Respiration can also be improved by intravenous administration of 300 to 400 mg of doxapram. Reversal is achieved by 75 to 150 mg of naltrexone, with one-third of the dose given intramuscularly and two-thirds intravenously.^{1,94} Detomidine and xylazine can be reversed by standard doses of yohimbine or atipamezole.

Black Rhinoceros (Diceros bicornis)

The black rhinoceros is also critically endangered and is found in tiny, isolated populations in Africa from the Cape to Kenya. Males weigh 850 to 1000 kg, and females average 880 kg.⁹⁴ The recommended drug combination for immobilization is etorphine (2 to 4 mg) combined with either azaperone (50 to 150 mg), detomidine (10 to 15 mg), or xylazine (60 to 100 mg).⁹⁴ Black rhinoceros are less sensitive to the effects of etorphine than are white rhinoceroses, and the highest safe dose should be used to produce shorter induction times, especially in rough terrain.⁹⁴ Hyaluronidase, at 2000 IU, should be added in the dart to hasten induction. Although hypoxia does not appear to be a problem in the majority of black rhinoceros, they should be monitored for signs of respiratory depression.^{1,94} Sternal recumbency is preferred, but the animals can be kept in lateral recumbency, if necessary. Body position should be changed every 30 min to avoid ischemia of dependent tissues. Naltrexone at 75 to 150 mg or diprenorphine at 2.4 mg per 1 mg of etorphine can be used for reversal. Reversal may rapidly arouse potentially aggressive animals. When used, detomidine and xylazine can be reversed by standard doses of either yohimbine or atipamezole.

African Wild Dog (Lycaon pictus)

The African wild or hunting dog is an endangered species found in fragmented populations in Southern and East Africa. Males and females are of similar size and weigh 20 to 32 kg.⁸⁵ Recommended drugs are medetomidine at 100 µg/kg and ketamine at 5 mg/kg, followed by atipamezole at 5 mg per 1 mg of medetomidine for reversal.⁹⁴ Fentanyl-xylazine has also been recommended in African wild dogs.⁹⁰ Severe hypoxia may develop, so the dogs should be closely monitored. For reversal, naltrexone is superior to naloxone. Xylazine effects can be antagonized with either atipamezole or yohimbine.⁹⁴

Spotted Hyena (Crocuta crocuta)

There are four species in the hyena family: spotted hyena, striped hyena, brown hyena, and aardwolf. The best known of the hyenas is the spotted hyena, which is distributed in Sub-Saharan Africa except the Congo rain forest and the far south. Males

weigh 45 to 60 kg and females 55 to 82 kg. Telazol at 5 mg/kg has been recommended for immobilization.^{1,92} However, recent experiences show that 8 to 12 mg/kg of ketamine combined with 0.5 to 1.0 mg/kg of xylazine or 100 µg/kg of medetomidine combined with 5 mg/kg of ketamine is superior to Telazol alone. These combinations produce a smoother anesthesia with less salivation and excitement (Dr. Markus Hofmeyr, personal communication). Atipamezole can be used to antagonize medetomidine effects, whereas yohimbine or atipamezole are equally effective for xylazine reversal.

Chapter 33

Aquatic Mammals

David B. Brunson

General Considerations

Cetaceans

Toothed and Balen Whales

Pinnipedia

Odobenidae (Walruses)

Otariidae (Sea Lions and Fur Seals)

Phocids (True Seals)

Sirenia (Manatees)

Carnivora

Polar Bears

Sea Otters

General Considerations

Marine mammals, which are air-breathing animals that have evolved for a primarily aquatic environment, include seals, sea lions, walruses, whales, cetaceans, polar bears, sea otters, and manatees. These animals have highly adapted physiology that presents unique anesthetic challenges.

Drug delivery is difficult for several reasons. Animals that live in a cold aquatic environment have heavy fur coats, thick blubber, or fat layers for insulation. Remote drug delivery requires special considerations for the site, depth, and method of drug injection. Intravenous (IV) access is usually very limited even on immobilized or anesthetized animals.

The pulmonary systems are highly developed to facilitate rapid oxygen and carbon dioxide exchange, as well as breath holding. Marine mammals frequently have short upper airways with extensive cartilaginous support down to the small bronchioles. They also take large breaths (tidal volumes), which aids in rapid gas exchange.

Seals breathe episodically in sleep. Higher centers in the brain modulate the central rhythm generator both positively and negatively for breathing. During episodic breathing, these modulating influences alternate in a fashion that produces periods of apnea alternating with periods of relatively high-frequency ventilation.¹ If seals are awoken during high-frequency ventilation, their breathing immediately slows.

Marine mammals have a highly developed dive reflex. This is a complicated physiological adaptation that is characterized by breath holding (apnea), decreased heart rate, and shunting of blood to critical aerobic organs. During a dive, peripheral tissues either reduce metabolic functions or function by hypoxic or anaerobic pathways. The implication for anesthesia is that absorption may be unpredictable or slower if central nervous system (CNS) depressants are administered intramuscularly during

breath holding or during activation of the dive reflex. Once breathing is initiated, blood flows to the periphery. Daring or drug administration should be timed to occur during active ventilation and avoided during apnea.

Much is still unknown regarding specific marine mammal species and their physiological adaptations. Most immobilization and anesthetic information is obtained through observations during field capture or during medical management of captive animals. Thus, much of what we know is anecdotal and observational rather than from blinded, well-controlled studies of the drugs and animal physiology. As a result, when an anesthetic technique works well, it is adopted and used repeatedly. On the other hand, when even a single immobilization or anesthetic management is associated with either ineffective or adverse effects, the drugs are frequently abandoned. This chapter attempts to provide guidance to readers on what has been used successfully and cautions where information is still limited. For each species and situation, chemical capture, restraint, and anesthetic procedures should be carefully researched, planned, and executed. Networking with individuals experienced with the species and working conditions will increase the chances of a successful outcome. Generally, marine mammals should not be darted with an anesthetic while remaining in their aquatic environment, because they can dive out of sight and drown.

Cetaceans

Porpoises and whales breathe through a modified nasal orifice, called the *blowhole*, located on the dorsum of the head just anterior to the cranial vault. It appears on the surface as a single, transversely crescentic opening with a forward-facing concavity. It is closed by a muscular nasal plug and opens through the action of forehead muscles. Normally under water it remains closed. In porpoises, ventral to the blowhole are vestibular and tubular air sacs connected to the paired nares, which begin a few centimeters down the respiratory passage. A septum divides the nares for 10 to 12 cm, after which the respiratory passage becomes single again just above the glottis. The larynx forms an arytenoepiglottal tube giving a direct opening from the internal nares to the lungs, thus enabling the animal to breathe only through the blowhole (Fig. 33.1). Approximately 10 cm from the base of the larynx, the trachea branches into a separate right bronchus which, at about 15 cm, bifurcates into two main bronchi. It is important, when a porpoise is intubated, that the endotracheal tube not extend into the bronchus. To ensure proper

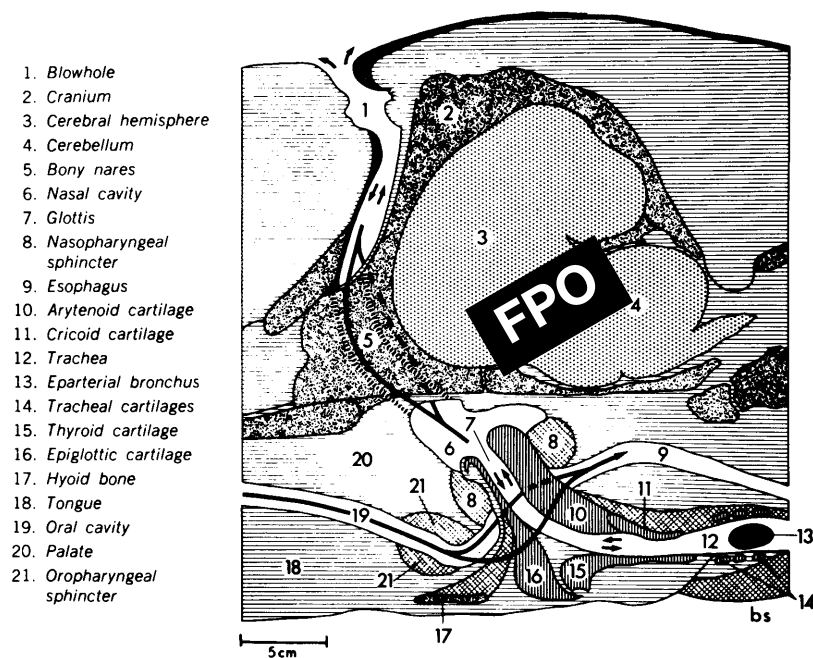

Fig. 33.1. Sagittal view of the head and neck of the bottlenose dolphin. From Nagel et al.³⁶

placement, the tube should be measured and marked prior to placement.

Porpoises can take one full respiration in 0.3 s. With a tidal volume of 5 to 10 L, the flow rates through the air passages range from 30 to 70 L/s during expiration and inspiration. Porpoises breathe two or three times each minute. Each breath is deep (approximately 80% tidal air). After inspiration, the animal holds an apneustic plateau for 20 to 30 s, followed by rapid exhalation and inspiration.

Preanesthetic treatment with anticholinergics is recommended. Bradycardia, which is frequently observed during anesthesia, may be produced by strong parasympathetic stimulation or the effects of sedatives or analgesics. An IV or intramuscular (IM) dosage of 0.02 mg/kg is recommended.

Sedation and analgesia have been studied in porpoises to identify drugs that produce minimal respiratory depression. Sedation with diazepam has produced variable results. As in many mammalian species, benzodiazepines appear to have mild sedative effects, with minimal respiratory or cardiovascular depression. The primary use of these drugs should be for their antianxiety and the synergistic effects with other CNS depressants, such as opioids. Diazepam or midazolam at 0.05 to 0.1 mg/kg IV has been used safely in cetaceans.²

The relatively short-acting opioid meperidine hydrogen chloride (HCl) provides moderate restraint in cetaceans, without obvious deleterious effects. Three dosages of meperidine HCl have been studied in several species of cetaceans and pinnipeds (Table 33.1). The IM dosages evaluated were 0.11, 0.23, or 0.45 mg/kg administered by hand syringe.³ Restraint was achieved rapidly, with maximum effect occurring 20 min after IM injection and lasting for 2 to 3 h. Analgesia appeared to last as long as 4 h and was sometimes accompanied by restoration of appetite in animals suffering physical discomfort. The higher doses increased

sedation and analgesia without noticeably depressing respiration. Based on the results of this study, the recommended initial dose of meperidine is 0.2 mg/kg IM when sedating cetaceans. If deemed necessary, higher dosages can be used safely, however.

Porpoises can be intubated while awake but intubation is more easily accomplished after sedation or induction of unconsciousness. Porpoises have relatively large airways. A 24- to 30-mm equine endotracheal tube with an inflatable cuff can be used. The mouth is held open with towels by assistants. The hand is inserted into the pharynx and grasps and pulls the larynx anteroventrally from the normal intranarial position. The endotracheal tube is then guided into the trachea by inserting two fingers into the glottis and passing the tube along the palm of the hand. A method of introducing the endotracheal tube through the blowhole has been described for use in smaller cetaceans, like *Delphinus delphis* and *Stenella styx*.⁴ For induction without thiopental, 3.5% isoflurane or halothane is administered for 5 to 15 min via a mask or endotracheal tube, after which 1.0% to 1.25% is used to maintain surgical anesthesia. If thiopental is used to induce anesthesia before intubation, 1.5% to 2.0% isoflurane or halothane is sufficient for maintenance. Sevoflurane should be an excellent inhalant anesthetic for cetaceans. Because of its lower blood-gas solubility, it equilibrates faster than isoflurane, thus hastening induction and recovery. The lower potency of sevoflurane requires higher vaporizer settings for induction and maintenance. Expected settings would be 4.5% to 5.0% for mask induction and 2.25% to 2.75% for maintenance.

Induction can be achieved by the IV administration of thiopental at 10 mg/kg or propofol at 4 to 6 mg/kg via one of the tail-fluke veins. These dosage recommendations are for unsedated animals. Lower dosages should be used if an animal is already sedated or debilitated. Injection of thiopental alone (10 mg/kg IV) produces 10 to 15 min of light anesthesia followed by 45 min

Table 33.1. Meperidine dosage used in dolphins and whales.

Species	Total number of restraints	Meperidine		
		0.11 mg/kg	0.23 mg/kg	0.45 mg/kg
Bottlenose dolphin	74	2	62	10
Pilot whale	4		2	2
Killer whale	4		2	2
White-sided dolphin	3		3	
False killer whale	10		9	1
Common dolphin	1		1	

of respiratory depression, during which the animal may require artificial ventilation. A dose of 15 to 25 mg/kg IV produces surgical anesthesia for 10 to 25 min, with respiratory depression lasting 1 to 2½ h. Sensitivity to barbiturates has been further demonstrated following high doses of intraperitoneal pentobarbital (10 to 30 mg/kg), which has reportedly caused respiratory failure and death.⁵ Consequently, this technique is no longer recommended. Likewise, because plasma cholinesterase levels may be extremely low or absent in bottlenose dolphins (*Tursiops truncatus*), the use of succinylcholine to induce muscular paralysis is not recommended.

The heart rate during general anesthesia is typically 100 to 120 beats per minute (beats/min). During delivery of 100% oxygen, arterial pH averages 7.35, partial pressure of oxygen (PaO₂) is maintained at 100 to 200 mm Hg, and partial pressure of carbon dioxide (PaCO₂) is 35 to 50 mm Hg. In conscious cetaceans breathing ambient air, arterial PaO₂ reportedly ranges from 65 to 98 mm Hg, and PaCO₂ ranges from 40 to 60 mm Hg.

Cessation of tail-fluke movements indicates surgical anesthesia and occurs after loss of strong corneal and eyelid reflexes. The swimming reflex is considered the best criterion for assessing the depth of anesthesia. Reflexes typically observed when assessing depth of anesthesia in porpoises include (1) the palpebral reflex, (2) corneal reflex, (3) swallowing in response to tactile stimulation of the pharynx, (4) retraction of the tongue, (5) reflex movements of the body when the anus is distended, (6) tail movements, (7) movements of the pectoral flippers in response to surface stimulation, (8) movement of the blowhole after stimulation of the nares or vestibular sacs, and (9) vaginal or penile movements when the area is manipulated.

During the recovery period, the endotracheal tube is kept in position until the blowhole reflex returns. This usually requires 15 to 45 min after cessation of inhalant administration. Timing the removal of the endotracheal tube is critical. Extubation should occur only after the animal is capable of breathing on its own, as manifested by movements of the blowhole and thorax, and by struggling, coughing, and/or bucking. When the endotracheal tube is removed, the larynx must be placed in its normal intranasal position. If the animal does not exhale through the blowhole within 3 min or if the heart rate falls below 60 beats/min, the endotracheal tube must be reinserted and the animal ventilated for a few more minutes. In water, porpoises are near neutral in buoyancy. Out of

water, it is more difficult for them to breathe and maintain circulation. For this reason, animals should be returned to water as soon as possible following recovery from anesthesia.

Local anesthesia can be used to provide analgesia for minor painful procedures. Using structural landmarks, a method has been devised for anesthetizing the lower jaw of the bottlenose dolphin.⁶ With this procedure, its teeth can be extracted and age determined by counting dentine layers in sections of etched teeth. The toxic doses of various local anesthetics have not been determined in cetaceans, so one should use the smallest dose necessary to desensitize tissues or structures prior to surgery or invasive diagnostic procedure.

Toothed and Balen Whales

Chemical immobilization and anesthesia have been attempted in large cetaceans. Killer whales have been sedated with meperidine and midazolam for minor procedures coupled with local anesthesia. Sedation has been attempted in removing an embedded rope in a free-ranging North Atlantic right whale. The adult male was estimated to be 50 feet long and weigh 40,000 kg. Each attempt at sedation was separated by at least 2 weeks. The dosage was increased on each attempt, with the final attempt producing mild sedation. Based on killer whale experiences and initial ineffective attempts with lower dosages, the most effective dose of midazolam was determined to be 0.025 mg/kg IM. The meperidine dose was set at 0.17 mg/kg IM. Four doses were administered to the whale over 2 h 43 min for a total dose of 40 g of meperidine and 4 g of midazolam. Although the whale never stopped swimming, its respiratory frequency decreased and diving behavior ceased.⁷

Pinnipedia

Pinniped species are made up of the otarids (eared seals), phocids (true seals), and odobenids (walrus). The physical characteristics vary widely among these groups. Size is especially variable, and body weight should be estimated carefully based on species, age, and gender. As a group, these animals have highly efficient respiratory systems. The alveolar exchange in seals has been measured at approximately 46% as compared with terrestrial mammals, where the alveolar exchange is usually in the range of 12% to 16%. In species that can be physically restrained or se-

dated with benzodiazepine tranquilizers (diazepam or midazolam, 0.1 mg/kg IM), induction with gas anesthetics is recommended. Mask inductions with isoflurane or sevoflurane can be very fast, occurring in as little as three to four breaths because of high alveolar exchange and the low solubility of these anesthetic gases.

During anesthesia of pinnipeds, their temperature should be continuously monitored via esophageal or rectal probe. Hyperthermia or hypothermia can occur during physical restraint, sedation, anesthesia, and handling outside of the normal aquatic environment. It is important to be prepared to support body temperature by either warming or cooling the animal, as necessary. Assessment of ventilation requires the use of both carbon dioxide monitoring and pulse oximetry. A Doppler flow detector can also be an important tool in assessing peripheral perfusion.

Odobenidae (Walrus)

Walrus are very challenging to anesthetize. Adult males weight up to 3000 pounds (1360 kg). High mortality rates have been reported with the use of opioids and dissociative anesthetics but are most likely the result of severe respiratory and circulatory compromise when the animals are out of the water and under anesthesia. Respiratory arrest has been commonly reported during immobilization with potent opioids. Even with ventilatory support, these large animals may develop circulatory failure during anesthesia.

Captive walrus have been immobilized with a combination of midazolam (0.1 mg/kg) and meperidine (2.2 mg/kg). To prevent vagal induced bradycardia, the use of atropine (0.04 mg/kg) is also recommended. The recommended injection sites for IM injections are the hip and epaxial muscles. A long needle (3 to 4 inches) must be used to ensure effective IM drug absorption.

IV access is difficult, but vascular access can be obtained via the epidural venous sinus. Needle placement is identical to placement of epidural needles or catheters via the lumbosacral space. With the walrus in sternal recumbency, the wings of the ileums can be palpated. The needle should be perpendicular to the skin. For large walrus, a 6-inch-long spinal needle is required. Easy aspiration of blood with a syringe indicates proper depth and placement. Epidural IV access can be used for administration of fluid, emergency drugs, and anesthetics. Small boluses of propofol (40 to 60 mg) can be used to relax muscles and facilitate endotracheal intubation. During inhalant anesthesia, emergency drugs can be administered via the endotracheal tube when IV access is not available.

During the onset of immobilization and anesthesia, heart rate is usually between 80 and 100 beats/min. As anesthesia deepens, heart rate slows to around 60 beats/min. Apnea is common during anesthesia and immobilization. Ventilatory support is essential when working with walrus.

Intubation is easiest with the walrus in sternal recumbency with head extended. Despite their large size, walrus have small oral cavities. Digital palpation of the larynx and direct placement of the endotracheal tube is possible once the animal is relaxed and the mouth pulled open by an assistant.

Isoflurane can be used to maintain general anesthesia in walrus. Oxygen flow rates and vaporizer settings are similar to those recommended for equine anesthesia. The oxygen flow rate should be at least 4 L/min to ensure adequate delivery of anesthetic and oxygen.

When used alone, meperidine has been administered by IM injection at dosages ranging from 0.23 to 0.45 mg/kg. In this dose range, sedation/restraint is usually moderate, without apparent detrimental effects.³

Otariidae (Sea Lions and Fur Seals)

Attempts to sedate seals and sea lions have met with variable success. As is the case for most wildlife, sedatives alone should not be relied on for immobilization. Additionally, species response may vary with the use of phenothiazine and benzodiazepine tranquilizers.⁸ Nevertheless, the use of tranquilizers is beneficial in the overall management of Otariidae because tranquilizers decrease the overall anesthetic dose requirement and adverse side effects when combined with dissociatives or opioids.

Ringed seals and sea lions have been immobilized with ketamine alone (4.5 to 11.0 mg/kg IM).⁹ However, because of the concern for excessive salivation, animals with respiratory problems should not be given high doses of ketamine alone. Atropine (total dose, 0.3 to 0.6 mg) can be given concurrently to prevent excessive salivation. Phocid seals have been successfully anesthetized with a combination of ketamine (1.5 mg/kg) and diazepam (0.05 mg/kg) IM or IV.¹⁰ This protocol is preferred over ketamine (2 mg/kg) alone because the ketamine dose can be decreased and induction and recovery are generally smoother. Apparently, Weddell seals (*Leptonychotes weddelli*) can be safely immobilized with relatively low doses of ketamine (2 mg/kg IM) prior to induction with a gas anesthetic.¹¹

Southern elephant seals (*Mirounga leonina*) are generally so lethargic that they can be injected at close range with a pole syringe.¹² A 16- to 18-gauge needle up to 4 inches long is needed to penetrate the skin and underlying blubber. Although succinylcholine (2.5 mg/kg) has been used to immobilize seals rapidly,¹² it should not be used without concurrent analgesic or anesthetic drug administration and ventilatory support.

For IV injections, sea lions are best restrained in a squeeze cage to enable access to a protruding flipper. A vein on the ventral aspect of the flipper, approximately 3 cm anterior to its posterior edge, can be used for IV administration. Thiopental or thiamylal can be given at the rate of 2.2 to 4.4 mg/kg to produce anesthesia.¹³ Barbiturates should be given rapidly to minimize struggling and to produce relaxation. Alternatively, isoflurane or halothane can be administered by means of a face mask to induce anesthesia. Sea lions can hold their breath for as long as 5 min. When they do breathe, their air intake is enormous and rapid. For this reason, the respiratory pattern during anesthetic induction is not an accurate gauge of CNS depression. Once the animal is induced, the trachea is easily intubated for further inhalant administration. Concentrations of 0.75% to 1.5% are usually sufficient to maintain anesthesia.

Northern sea lions have been successfully anesthetized with Telazol (tiletamine-zolazepam). The recommended dose range is

1.8 to 2.5 mg/kg IM. The effective dose may vary from one animal to another. Tiletamine-zolazepam doses of more than 2.5 mg/kg IM can be fatal in sea lions. Hypothermia is commonly observed in animals that receive higher doses (2.5 mg/kg IM or larger).¹⁴

Several anesthetic regimens have been described for inducing anesthesia in California sea lions (*Zalophus californianus*).¹⁵ The first combination consists of atropine (0.02 mg/kg) given IM 10 min prior to medetomidine (0.14 mg/kg IM) and ketamine (2.5 mg/kg IM) administration. Sea lions of all ages and weights (13.5 to 145.0 kg) have been anesthetized with this mixture. Following IM injection, induction time ranges from 9 to 17 min, whereas anesthesia time ranges from 17 to 57 min.¹⁵ It should be noted that the standard 1.0-mg/mL concentration of medetomidine is too dilute and expensive for this technique and may limit its use. Reversal with atipamezole at a dosage of 0.2 mg/kg IM can hasten and reduce recovery time.¹⁵

In a similar study using 1.0 mg/kg IM of Telazol, the medetomidine dosage was reduced by half to 0.07 mg/kg IM. Induction time was reduced to approximately 5 min, while anesthesia/immobilization with this mixture averaged nearly 30 min. The disadvantages of this anesthetic regimen include prolonged ataxia, weakness, and some disorientation during recovery. Typically, this combination will provide a rapid induction with a reliable plane of anesthesia. Recovery can be hastened with atipamezole at a dosage of 0.2 mg/kg IM.¹⁶

Young California sea lion pups that are hand caught can be induced by mask technique alone using either isoflurane or sevoflurane. Induction and recovery times average under 10 min when using isoflurane alone to maintain anesthesia.¹⁷ Relaxation is evident within a few minutes of administration of isoflurane by mask.

Premedication with IM meperidine (0.23 to 0.45 mg/kg) apparently provides little restraint of sea lions, while causing profound respiratory depression. Consequently, low dosages are advised when using meperidine for analgesia or as part of the immobilization technique in this species of seals.³

Stellar sea lions have been darted using Telazol delivered via a carbon dioxide-powered blowpipe. The average dose administered was 2.3 mg/kg IM. Approximately one-third of the animals required additional CNS depression with isoflurane to achieve anesthesia. Following induction, all animals were intubated and maintained on isoflurane in oxygen. If apneustic breathing was observed after Telazol injection, doxapram was used to stimulate breathing and aid in induction of inhalant anesthesia.¹⁸ Young Steller sea lion pups and yearlings caught by trained scuba divers have become severely hypothermic (<90°F [$<32^{\circ}\text{C}$]) when anesthetized immediately after snaring, emphasizing the importance of monitoring temperature closely when working with this species.¹⁸

Both ketamine (2.1 mg/kg IM) and Telazol (1.1 mg/kg IM) have been used to immobilize fur seals. Individual animal response to these drugs appears to be highly variable, however. The dose requirement for satisfactory levels of anesthesia and immobilization appears to be less than for most other species of seals. Few side effects have been observed when using low doses of

these drugs, aside from mild tremors caused by ketamine, and respiratory depression or prolonged apnea caused by tiletamine-zolazepam. When working with fur seals, relatively low doses of ketamine or Telazol can be quite effective, especially for animals in good body condition.¹⁹

Phocids (True Seals)

Phocidae or true seals include northern hemisphere seals such as the harbor, gray, bearded, and hooded seals. The southern hemisphere seals include monk, crabeater, Weddell, leopard, Ross, and elephant seals. Many of these species have been studied in free-ranging environments and are commonly included in zoological parks and aquariums.

Southern elephant seals have been extensively studied, and multiple anesthetic techniques have been used successfully. Telazol has been administered to over 1000 southern elephant seals without acute fatality. Older and better-conditioned animals appear to have faster recoveries, and no gender differences have been noted. Apnea has been observed in some animals, but typically lasts less than 5 min.²⁰ A 1-mg/kg IM dose of Telazol is considered both safe and effective in this species.²¹ Telazol administration at a dose under 0.5 mg/kg IV will produce anesthesia in 30 s or less. Anesthesia achieved with IV Telazol, even at this low dose, will range from 15 to 20 min.²²

Ketamine alone can be administered to elephant seals at doses ranging from 2 to 8 mg/kg IM. At a dose of 8 to 9 mg/kg IM, immobilization should occur in 15 min. The dosage required depends greatly on which sedative is used in conjunction with ketamine. An IM dose of 0.4 to 0.5 mg/kg of xylazine has been combined with 5 to 6 mg/kg of ketamine for short periods of immobilization.²³ Alternatively, diazepam can be dosed at 0.3 mg/kg IM with 8 mg/kg IM of ketamine. Lower doses of xylazine (0.4 mg/kg) or diazepam (0.1 mg/kg) can also be given IV to supplement muscle relaxation during ketamine anesthesia. Medetomidine (0.013 mg/kg IM) has also been combined with ketamine (2 mg/kg IM) to enhance muscle relaxation during immobilization.²⁴

In a study on the use of antagonists and stimulants to reverse sedation in elephant seals, yohimbine (0.06 mg/kg IM) reversed xylazine sedation better than did doxapram, whereas 4-aminopyridine actually prolonged recovery.²⁵ Doxapram (0.5, 1, 2, and 4 mg/kg IV) caused a dose-dependent increase in the depth and rate of ventilation, which began within 1 min, peaked after 2 min, and lasted for up to 5 min. The 2-mg/kg dose appeared to be both safe and effective. Higher dosages (4 mg/kg) caused arousal and shaking in some seals. Administration of doxapram via the endotracheal tube was an unreliable route of drug delivery.²⁵

Butorphanol has been evaluated as an analgesic in young elephant seals at a dosage of 0.055 mg/kg IM.²⁶ The dosage was conservative and produced minimal observable effects. A complete evaluation of this opioid's analgesic efficacy in seals requires additional use and observation. Similarly, published reports of anesthetics in many phocids is sparse, making dosage recommendations based on efficacy and safety difficult. For example, when 30 Weddell seals were administered Telazol at IM doses ranging from 100 to 300 mg, only 16 were fully immobi-

lized, while 7 were moderately sedate and 7 were only lightly sedated. However, nearly 25% of the animals in the study died. The cause of mortality is unknown and likely not due solely to either the drugs or dosages used.²⁷

Several IM drugs or drug mixtures have been described for use in gray seals. These include ketamine (6 mg/kg) and diazepam (0.3 mg/kg), which produced adequate immobilization;²⁸ tiletamine-zolazepam (1 mg/kg); and carfentanil (0.01 mg/kg) with ketamine (5 mg/kg) and xylazine (1 mg/kg).²⁹ Each of these drug combinations was reportedly effective in immobilizing gray seals.

Sirenia (Manatees)

Many minor procedures can be performed with proper physical restraint. Local anesthetic infiltration should be used for procedures that are painful. Captive manatees are removed from the water by draining the pool or elevating the bottom of the holding tank. While out of the water, manatees should be sprayed with water to avoid skin drying and should be kept out of the sun to prevent skin burning. They should be held in sternal recumbency because the tail is potentially dangerous if placed in dorsal or lateral recumbency. The tail can be restrained by people and foam pads.

Sedation with midazolam generally works well. A dosage of 0.045 mg/kg IM is recommended. For light general anesthesia and restraint, the combination of midazolam (0.066 mg/kg IM) and meperidine (up to 1.0 mg/kg IM) is effective. Flumazenil and naloxone are effective antagonists for this combination.³⁰

Nasal-tracheal intubation is easily accomplished with the aid of a fiberoptic endoscope, which is placed in one nasal passage while the endotracheal tube is passed via the opposite nasal passage. Manual or mechanical ventilation is recommended to maintain the carbon dioxide level within normal limits during general anesthesia. Isoflurane or sevoflurane are appropriate anesthetics for maintenance with expected vaporizer settings of 1.5% to 2.5%.

Carnivora

Polar Bears

Since polar bears can have substantial fat deposits throughout the year, the shoulder and neck are the best sites for IM drug delivery. Male polar bears can be large and heavy. Body weights of greater than 500 kg are not uncommon. Because of their large size and drug requirements, potent drug combinations are required to keep drug volume and dart size to a minimum. Immobilized polar bears should be positioned to avoid excessive pressure on limb muscles because such pressure has caused muscle swelling and lameness. During the summer, polar bears enter a hypometabolic state that is characterized by fasting and decreased body temperature (93° to 95°F [34° to 35°C]). Immobilizing drug requirements may also be decreased during the summer. In areas where large numbers of polar bears congregate, reversible anesthetic protocols should be considered because they will decrease the risk of predation by other bears. Reversible protocols should also be considered for mother bears with cubs.

Polar bears immobilized with Telazol typically keep their heads out of the water better than bears immobilized with opioids. This is probably due to muscle extension with the use of dissociative anesthetic versus the relaxed curled body position associated with the use of carfentanil or etorphine.

Mature polar bears can be darted with 22-caliber blank powdered projectors and explosive-discharge darts. A needle up to 10 cm long is necessary to ensure the IM injection of drugs. Polar bears are notorious for pretending to be immobilized and have been known to awaken suddenly when approached. Always use caution when approaching this species.

Immobilization drug choices include dissociatives and opioids. Because Telazol is available in a lyophilized form, it can be reconstituted with an α_2 -agonist, keeping the total volume lower than with ketamine. Dosages of 8 to 10 mg/kg of Telazol will produce reliable immobilization, but can also result in prolonged recoveries.³¹ Used alone, the volume requirements are high, making the use of a large dart necessary. The greater mass of a large volume and the dart itself are more likely to produce excessive tissue trauma and animal injury when the projectile penetrates tissue. For this reason, an IM combination of xylazine (2 mg/kg) and Telazol (3 mg/kg) is preferred as it has approximately half the volume requirement of Telazol alone. Additionally, partial reversal can be accomplished by administration of either yohimbine or atipamezole. When rapid reversal of this mixture is not achieved, it is probably due to residual zolazepam sedation.

A similar anesthetic regimen consists of the IM injection of 75 μ g/kg of medetomidine mixed with 2.2 mg/kg of Telazol.³² This combination has a rapid onset of action and can be delivered IM in a small volume to free-ranging polar bears. To reduce volume, medetomidine (1 mg/mL) can be lyophilized and reconstituted to a concentration of 6 mg/mL. The IM dosage range reported for this mixture was 1.2 to 7.7 mg/kg. In all bears, the total volume injected was always less than 10 mL. The average dose of medetomidine injected was 0.07 mg/kg, whereas the average dose of Telazol injected was 2.3 mg/kg. This regimen resulted in an average anesthesia time of approximately 3 h. When medetomidine was reversed with atipamezole (0.24 mg/kg IM), recovery time was reduced to an average of 6 min.³² Medetomidine coadministration substantially reduced the volume requirement of Telazol while providing analgesia. If Telazol is used alone, dosage requirement increases from under 2.5 to 5 mg/kg IM. With the medetomidine-tiletamine-zolazepam mixture, bears become ataxic in 1 to 3 min, typically sit in 4 to 5 min, and become recumbent shortly thereafter. Maximal effects are usually seen in 20 min. The duration is dose dependent, with recumbency lasting approximately 2 h.³² Following immobilization, the suspension of polar bears in a cargo net can cause acute hypertension (up to a 50% increase in mean arterial pressure), hypoxemia, and evidence of stress. Cargo nets can restrict both ventilation and circulation. Bears should be transported on a rigid platform rather than lifted in a net.³³

Opioids can provide for some sedation and analgesia, as well as immobilization. Fentanyl, carfentanil, and etorphine have all been used to immobilize polar bears. The published mean IM

dosage for fentanyl in polar bears is 0.44 mg/kg. Unless concentrated forms of fentanyl become available, the volume needed is usually too large for the practical use of this drug in adult bears. Fentanyl reportedly provides better muscle relaxation than etorphine. Naloxone can be dosed at 25 mg per 10 mg of fentanyl or 25 mg per 0.5 mg of etorphine for rapid reversal (within 10 min).³⁴

Sea Otters

Numerous combinations have been assessed in sea otters, including Telazol, butorphanol-diazepam, oxymorphone-acepromazine-diazepam, azaperone-fentanyl-diazepam, and fentanyl-diazepam. Of these, the most effective combinations appear to be fentanyl (0.1 mg/kg) with either acepromazine or diazepam (0.22 mg/kg) IM.³⁵

Manual restraint and nets are often effective for capture and examination. Hand injection can be used in these situations. If manual restraint is feasible, mask induction with either isoflurane or sevoflurane works well. Altered thermoregulation may cause body temperature to increase during capture. Otters should be transported in well-ventilated cages that are iced to help keep animals cool during transport.

Experience in sedating sea otters after the 1989 Valdez oil spill resulted in the recommendation of combined fentanyl (0.05 to 0.1 mg/kg IM) and diazepam (0.1 mg/kg IM) as the preferred technique in this species. It should be noted that many other immobilizing mixtures were used only a few times, and the mortality rate for all anesthetized sea otters was extremely high because of oil exposure.³⁵

Other drug combinations used successfully to sedate, immobilize, or anesthetize sea otters include Telazol alone (2 mg/kg IM); ketamine (2.5 mg/kg IM) and medetomidine (0.25 mg/kg IM); ketamine (10 mg/kg IM) and midazolam (0.25 mg/kg IM); ketamine (1.5 mg/kg IM) and xylazine (1.5 mg/kg IM); and etorphine (0.03 to 0.05 mg/kg IM) with diazepam (0.06 mg/kg IM).

Introduction

The principles and practices of avian anesthesia depend on an understanding of avian anatomy, physiology, and pharmacology. This chapter focuses on the avian pulmonary and cardiovascular

systems because they are of the utmost importance in the anesthetic management of birds; where appropriate, however, other organ systems are discussed. Although drugs are discussed in general terms, and more specifically for ratites, this chapter is not a compendium of drugs and doses useful for anesthetic management of all species of birds. For such a compendium the reader is referred to the list of suggested readings at the end of this chapter.

Form and Function

Pulmonary System

The avian pulmonary system is very different from that of the mammalian system. A brief description of avian pulmonary anatomy and physiology will help to explain earlier misconceptions and current realities regarding the effects of anesthetics on birds, especially inhalant anesthetics. The avian respiratory system consists of two separate and distinct functional components: a component for ventilation (conducting airways, air sacs, thoracic skeleton, and muscles of respiration), and a component for gas exchange (parabronchial lung).

Ventilation Component

Larynx and Trachea

The avian larynx protrudes into the pharynx as a somewhat heart-shaped mound and consists of four laryngeal cartilages: the cricoid, procricoid, and the right and left arytenoid cartilages.¹ Unlike mammals, the thyroid and epiglottic cartilages are absent in birds.¹ In birds, the larynx functions as a barrier to foreign material entering the airway, opens the glottis during inspiration, assists in swallowing, and may modulate sound production.¹

In all avian species the tracheal cartilages form complete rings, but there are significant species-related variations in tracheal anatomy.¹ For example, the emu and ruddy duck have an inflatable saclike diverticulum (tracheal sac) that opens from the trachea.¹ In the emu the sac arises from the ventral surface of the trachea approximately three-quarters of the way down the neck, where there is a slitlike opening created by the incomplete tracheal rings ventrally (Fig. 34.1).¹ The caudal end of the sac may extend almost to the level of the sternum. This sac is present in both sexes and is responsible for the characteristic booming call of the emu.

In the ruddy duck the sac opens in a depression on the dorsal wall of the trachea immediately caudal to the larynx, thus lying between the trachea and esophagus.¹ In this bird the sac is found

Fig. 34.1. Tracheal slit of an emu (*Dromaius novaehollandiae*). From J. A. Smith, DVM, DACVA; with permission.

only in the male and may act as a sounding board for the bill-drumming display of the male.¹

The male of many anseriform species (waterfowl such as ducks and mergansers) has a unique anatomical feature of the trachea—the tracheal bulbous expansion—which is a bulblike structure in the trachea, and its exact function has not been determined.

A double trachea, found in some penguins and petrels, consists of a median septum dividing part of the trachea into right and left

channels.¹ In both groups of birds the septum extends cranially from the bronchial bifurcation, but the length of the septum is quite variable. For example, in the jackass penguin the septum extends to within a few centimeters of the larynx, whereas in the rockhopper penguin the septum is only 5 mm long.¹

Some species of birds have complex tracheal loops or coils that, depending on the species, may be located in the caudal neck, within the keel, or within the thorax and the keel (Fig. 34.2). Studies in cranes have demonstrated that tracheal coiling enables these birds to produce extremely loud calls by using very low driving pressures.²

The fact that birds generally have relatively long necks, not to mention tracheal loops and coils, has important implications for the functional morphology of the trachea, especially tracheal dead space. Studies indicate that the typical bird trachea is 2.7 times longer than that of comparably sized mammals, but because the bird trachea is 1.29 times wider, the tracheal resistance in birds and mammals is comparable.¹ Tracheal dead-space volume is increased in birds to about 4.5 times that of comparably sized mammals, but the relatively low respiratory frequency of birds, approximately one-third that of mammals, ensures that the effect of the larger tracheal dead-space volume is decreased.¹ As a result the minute tracheal ventilation rate is only about 1.5 to 1.9 times that of mammals.¹

Fig. 34.2. Different forms of tracheal loops: black swan (*Cygnus atratus*), whooper swan (*Cygnus cygnus*), white spoonbill (*Platalea leucorodia*), whooping crane (*Grus americana*), and helmeted curassow (*Crax Pauxi*). Adapted from McLelland.¹

Syrinx

The syrinx, the sound-producing organ in birds, is located at the junction of the trachea and mainstem bronchi. Its shape, size, and location are extremely variable among avian species. For a thorough review of this anatomical structure the reader is referred to the work by A. S. King.³ The location and structure of the syrinx explain why gas flowing through the trachea, especially during positive-pressure ventilation, can produce sound in an intubated bird.

Bronchi

The bronchial system of birds consists of three orders of branching: a primary bronchus (extrapulmonary and intrapulmonary), secondary bronchi, and tertiary bronchi (parabronchi), the latter of which, along with the periparabronchial mantle of tissue, forms the gas-exchange tissues of the lung.⁴

The primary bronchus enters the lung ventrally and obliquely at the junction of the cranial and middle thirds of the lung, and then passes dorsolaterally to the lung surface, where it turns caudally in a dorsally curved course until at the caudal lung margin it opens into the abdominal air sac.⁵ Under the low columnar, pseudostratified epithelium of the primary bronchi is a well-developed internal circular smooth muscle layer and longitudinally oriented smooth muscles that respond to a variety of stimuli and can change the internal diameter of the primary bronchus.⁶ Acetylcholine, pilocarpine, and histamine induce strong contraction of the bronchial smooth muscle, whereas atropine blocks their effects but has no effect when given alone.⁷

Secondary Bronchi

Any bronchus arising from a primary bronchus is a secondary bronchus, and in most birds the secondary bronchi are arranged into four groups: medioventral, mediodorsal, lateroventral, and laterodorsal secondary bronchi.⁴ The medioventral secondary bronchi arise from the primary intrapulmonary bronchus close to where it enters the lung, and these secondary bronchi occupy the ventral surface of the lung.⁸ The mediodorsal, lateroventral, and laterodorsal secondary bronchi arise from the caudal curved portion of the primary intrapulmonary bronchus. Between the medioventral group of secondary bronchi and the three remaining groups of secondary bronchi, depending on the species, is a section of primary bronchus devoid of secondary bronchi.⁴ For a short distance the secondary bronchi have the same histological structure as the primary bronchus, but subsequently develop simple squamous epithelium.^{9,10} There are single small circular bands of smooth muscle over which there is ciliated epithelium.⁶ Many of the medioventral and lateroventral secondary bronchi open into the cervical, clavicular, cranial thoracic, or abdominal air sacs.

Air Sacs

Birds have nine air sacs: two cervical, an unpaired clavicular, two cranial and two caudal thoracic, and two abdominal air sacs. The air sacs are thin-walled structures composed of simple squamous epithelium covering a thin layer of connective tissue, although close to the secondary bronchial openings into the air sacs are

groups of ciliated cuboidal and columnar cells.⁴ The air sacs are vessel poor and as such do not significantly contribute to gas exchange in birds.¹¹ To a varying extent, depending on the species, diverticula from the air sacs aerate the cervical vertebrae, some of the thoracic vertebrae, vertebral ribs, sternum, humerus, pelvis, and head and body of the femur.⁴

The air sacs functionally serve as bellows to the lungs by providing tidal air flow to the relatively rigid avian lung.¹² Based on their bronchial connections, air sacs are grouped into a cranial group consisting of the cervical, clavicular, and cranial thoracic air sacs, and a caudal group consisting of the caudal thoracic and abdominal air sacs.¹³ The volume is distributed approximately equally between the cranial and caudal groups of air sacs.¹⁴ During ventilation, all air sacs are effectively ventilated, with the possible exception of the cervical air sacs, and the ratio of ventilation to volume is similar for each air sac.¹⁴

Muscles of Respiration and the Thoracic Skeleton

In birds, unlike in mammals, both inspiration and expiration are active processes requiring muscular activity (Table 34.1). With contraction of the inspiratory muscles the internal volume of the thoracoabdominal cavity increases (Fig. 34.3), and since the air sacs are the only significant volume-compliant structures within the body cavity, volume changes occur mainly in the air sacs.¹⁴ Pressure within the air sacs becomes negative relative to ambient atmospheric pressure, and air flows from the atmosphere into the pulmonary system, specifically into the air sacs and across the gas-exchange surfaces of the lungs.

Gas-Exchange Component

Tertiary Bronchi

The basic unit for gas exchange is the tertiary bronchus or parabronchus and its mantle of surrounding tissue. The parabronchi, which connect the two main sets of secondary bronchi, are long, narrow tubes that display only a mild degree of anastomosing (Fig. 34.4).⁸ A network of smooth muscle surrounds the entrances to the parabronchi, and this smooth muscle, upon electric stimulation of the vagus nerve, can contract and cause narrowing of the openings to the parabronchi.¹⁵ The inner surfaces of the tubular parabronchi are pierced by numerous openings into chambers called atria that are separated from each other by interatrial septa (Fig. 34.5). The atrial openings also are surrounded by bundles of smooth muscle.⁴ Since the avian lung is richly innervated with vagal and sympathetic nerves, efferent and afferent pathways might exist for controlling pulmonary smooth muscle, and with it the flow of air through the parabronchial lung, in response to a variety of stimuli.¹³ Arising from the floor or abluminal surface of the atria are funnel-shaped ducts, the infundibula, that lead to air capillaries. The air capillaries measure 3 to 10 μm in diameter and form an anastomosing three-dimensional network intimately interlaced with a similarly structured network of blood capillaries.^{4,5} It is within this mantle of interlaced air and blood capillaries, this periparabronchial tissue, that gas exchange occurs.

The small radius of curvature of air capillaries is associated with very high surface tensions that work against their anatomical and gas-exchange integrity, but their functional integrity is

maintained by surfactant and by anatomical details that contribute to the rigidity of the avian lung. Surfactant is a lipoproteinaceous material produced by squamous respiratory cells, and it forms a trilaminar substance unique to birds.¹⁶ Not only does surfactant cover surfaces of the atria, infundibula, and air capillaries, but it is also found in outgrowths of squamous respiratory cells that form at the abluminal surface of the cells and extend through clefts between blood capillaries to reach other air capil-

laries. In addition to this network, squamous respiratory cells appear to project processes—retinacula—that bridge to the opposite side of air capillaries.¹⁶ All of this results in an intricate intercapillary anastomosing network that firmly anchors the air capillary system to the blood capillaries and forms the structural basis for the rigid avian lung that has a constant volume during all phases of ventilation.^{4,16,17}

There are two types of parabronchial tissue in the avian lung:

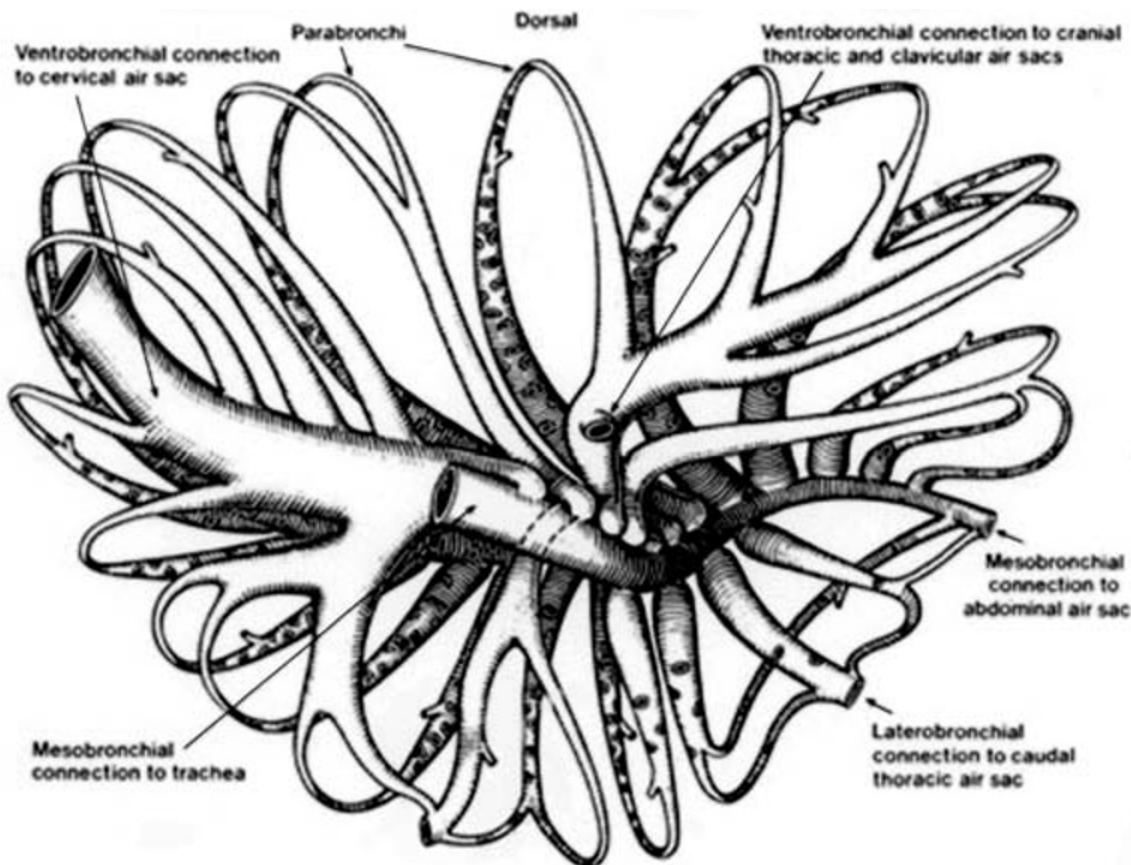

Fig. 34.4. Two views of secondary bronchi and parabronchi in the right lung of a goose. **A:** Medial view of the lung.

paleopulmonic and neopulmonic. The paleopulmonic parabronchial tissue consists of essentially parallel, minimally anastomosing parabronchi and is found in all birds (Fig. 34.6A). By comparison, neopulmonic parabronchial tissue is a meshwork of anastomosing parabronchi located in the caudolateral portion of the lung; its degree of development is species dependent (Fig. 34.6B and C).⁴ Penguins and emus have only paleopulmonic parabronchi. Pigeons, ducks, and cranes have both paleopulmonic and neopulmonic parabronchi, with the neopulmonic accounting for 10% to 12% of the total lung volume.¹³ In fowl-like birds and song birds the neopulmonic parabronchi are more developed and may account for 20% to 25% of the total lung volume.¹³ Although the paleopulmonic and neopulmonic parabronchi are histologically indistinguishable from each other, the direction of gas flow within the two types differs.

During inspiration and expiration the direction of gas flow in the paleopulmonic parabronchi is unidirectional, whereas in the neopulmonic parabronchi it is bidirectional (Fig. 34.7).^{13,14} The unidirectional flow of gas through the intrapulmonary primary bronchus, the secondary bronchi, and the paleopulmonic parabronchi is governed by processes of aerodynamic valving and not by mechanical valving mechanisms.^{18–25} Aerodynamic valving occurs as a consequence of the orientation of secondary bronchial and air sac orifices to the direction of gas flow, elastic pressure

differences between the cranial and caudal group of air sacs, and gas convective inertial forces.^{18,20,21,23,25,26} The potential advantage of unidirectional gas flow to birds is discussed later.

A cross-current model of gas exchange describes the relationship between gas and blood flows within the avian lung. In birds there is no equivalent of alveolar gas because parabronchial gas continuously changes in composition as it flows along the length of the parabronchus.²⁷ The degree to which capillary blood is oxygenated and carbon dioxide is eliminated depends on where along the length of the parabronchus the blood contacts the blood-gas interface. As a result the gas composition of arterial blood is formed by the mixing of streams of end-capillary blood of widely varying gas composition.²⁸ In addition, blood perfusing the inspiratory end of the parabronchus can equilibrate with gas entering the parabronchus that has a high partial pressure of oxygen. The overall result is that the partial pressure of carbon dioxide in end-parabronchial gas ($PECO_2$) can exceed the arterial carbon dioxide partial pressure ($PaCO_2$). In like manner, the partial pressure of oxygen in end-parabronchial gas (PEO_2) can be lower than the arterial oxygen partial pressure (PaO_2).^{29–31} This potential overlap of the ranges of blood and gas partial pressures for both carbon dioxide and oxygen, which cannot occur in the mammalian alveolar lung, demonstrates the high gas-exchange efficiency of the avian lung.^{29,30}

Fig. 34.4. (continued) **B:** Dorsal view of the lung. From Brackenbury,¹⁸⁵ with permission.

A number of factors limit gas-exchange efficiency in the avian lung, including mismatching of ventilation and perfusion, diffusion barriers, heterogeneity within the lung, and postpulmonary shunts.^{29,31} It is generally assumed that diffusion is the primary gas transport mechanism in air capillaries,³² but small amounts of iron oxide particles (mean diameter, 0.18 μm) have been found in air capillaries, indicating that there is some convective transport of aerosol to the atria and the initial portions of the infundibula.³³ The gas-exchange efficiency of the avian lung usually is not apparent under resting conditions (Table 34.2), but becomes readily apparent under conditions of exercise or stress, such as during flight at altitude or hypoxia.^{31,34–37}

Despite its relative efficiency, the avian lung does have some

limitations. By using casting methods and gas-washout techniques, the specific volume (respiratory gas volume per unit body mass) of the avian respiratory system is estimated at between 100 and 200 mL/kg (by comparison, the specific volume for dogs is 45 mL/kg).¹⁴ However, in birds the gas volume in the parabronchi and air capillaries is only 10% of the total specific volume, whereas that in the mammalian lung is 96% of the total specific volume. Because the ratio of residual gas volume to tidal volume is so much smaller in birds than in mammals, it has been suggested that cyclic changes in parabronchial gas flow, such as reversal of gas flow, could produce significant and intolerable cyclic changes in parabronchial gas exchange somewhat analogous to breath holding.¹² The unidirectional flow of gas within

Fig. 34.5. Three-dimensional drawings of a parabronchus and an atrium. **A:** Sagittal section of a parabronchus. On the left side are atria with infundibula departing from them and the three-dimensional air capillary meshwork arising from the infundibula. On the right side within the interparabronchial septa are the arterioles (dense stippling) from which the capillaries originate and run radially to the lumen. The infundibula lie between the capillaries, which are surrounded by a well-developed three-dimensional air capillary network. **B:** Atrium and infundibulum. At the left, two of the circular smooth muscle bundles surrounding the lumen of the parabronchus are shown in cross section. The atria are separated by this septa running horizontally and vertically. Originating from each atrium, a few infundibula pass perpendicularly into the parabronchial mantle. At the right, an infundibulum is shown in longitudinal section with air capillaries arising from it at all levels. The air capillaries cross-link and interlace, making up a three-dimensional meshwork around the blood capillaries. The very thin epithelium of the air capillaries and its surfactant film are shown as a single dark line. the avian lung solves this problem. In addition, it appears that the volume of parabronchial gas available for gas exchange may be larger than anatomical studies would indicate and may be due to factors such as cardiogenic mixing or pulsations of blood flow within the pulmonary capillaries.¹²

Control of Ventilation

Birds have many of the same physiological components for respiratory control as mammals, such as a central respiratory pattern generator, central chemoreceptors that are sensitive to partial pressure of carbon dioxide (PCO_2), and many similar peripheral chemoreceptors.³⁸ Birds have a unique group of peripheral receptors located in the lung, called intrapulmonary chemoreceptors (IPCs), that are vagal respiratory afferents inhibited by high lung PCO_2 and excited by low lung PCO_2 , and that provide phasic feedback for the control of breathing, specifically the rate and depth of breathing.^{38–41} They are not mechanoreceptors and are insensitive to hypoxia.^{42,43} This is not to imply, however, that IPCs are the sole receptors stimulated by inhaled gas containing even low partial pressures of carbon dioxide, as arterial and central chemoreceptors also are stimulated.⁴⁴

There may be species differences in carbon dioxide responsiveness depending on the ecological niche that a given species occupies. The carbon dioxide responsiveness of IPCs in chickens, ducks, emus, and pigeons is greater than the responsiveness

of IPCs of burrowing owls, a species of bird that lives underground, where the concentration of carbon dioxide is higher than that of aboveground-dwelling birds.^{45,46}

Cardiovascular System

The avian heart is a four-chambered muscular pump that separates venous blood from arterial blood. Birds have larger hearts, larger stroke volumes, lower heart rates, and higher cardiac output than do mammals of comparable body mass.⁴⁷ Birds also have higher blood pressures than do mammals.^{47,48} The atria and ventricles are innervated by sympathetic and parasympathetic nerves.⁴⁸ Norepinephrine and epinephrine are the principal sympathetic neurotransmitters, whereas acetylcholine is the principal parasympathetic neurotransmitter. Excitement and handling can increase the concentration of norepinephrine and epinephrine, especially the latter, in the heart and blood.⁴⁸ This has significant implications for the anesthetic management of birds because inhalant anesthetics, especially halothane, sensitize the myocardium to catecholamine-induced cardiac arrhythmias. Hypoxia, hypercapnia, and anesthetics, the last depending on the type and dose, all can depress cardiovascular function.

The conduction system of the avian heart consists of the sinoatrial node, the atrioventricular node (and its branches), and Purkinje fibers.⁴⁹ Two groups of animals can be identified by the depth and degree to which Purkinje fibers ramify within the ven-

tricular myocardium, and the pattern of ramification is classified as type 1 or 2.⁵⁰ The pattern of Purkinje fiber distribution within the ventricular myocardium is responsible for the QRS morphology of the electrocardiogram (ECG). In birds, Purkinje fibers completely penetrate the ventricular myocardium from endocardium to epicardium, and the pattern of ventricular activation is described as type 2b, a pattern that may facilitate synchronous beating at high heart rates.⁵¹ ECG characteristics have been described for a number of avian species, and the salient features of the avian ECG are summarized in Table 34.3.^{49,51–55}

Renal Portal System

The avian kidney receives venous blood from the legs through the renal portal circulation, as well as arterial blood through the arterial circulation.^{56,57} The flow of afferent venous blood, unlike in other nonmammalian vertebrates, is not obligatory, since blood can either perfuse the renal parenchyma or bypass it and enter the central circulation (Fig. 34.8). A unique valvelike structure, the shape of which ranges from a thin membrane to a thickened funnel with one or many openings depending on the species, is located within the external iliac vein at the point where the efferent renal vein joins the external iliac vein.⁵⁷ The valve contains smooth muscle innervated by cholinergic and adrenergic nerves. Epinephrine causes the valve to relax, whereas acetyl-

choline causes it to contract. When the valve contracts (closes), venous blood from the legs perfuses the kidney, but when the valve is relaxed (open), the venous blood is directed to the central circulation. The control of renal valve activity is complex, and its function is not fully understood.

Form and Function: Implications for Anesthetic Management

Air Sacs

The air sacs of birds are vessel poor and do not significantly participate in gas exchange. For this reason they do not play a major role in the uptake of inhalant anesthetics, nor, as has been suggested, do they accumulate or concentrate anesthetic gases.⁵⁸ Indeed, a study of anesthetized spontaneously breathing pigeons found that the concentration of isoflurane in the abdominal air sacs was always lower than the concentration measured at the end of the endotracheal tube.⁵⁹

Fluidic Valving and Mechanical Positive-Pressure Ventilation

During positive-pressure ventilation, it is possible that the direction of gas flow within the avian lung may be reversed, but such a reversal does not affect gas exchange, since the efficiency of the

Schematic representation of the right paleopulmonic lung and air sacs of a bird and the pathway of gas flow through the pulmonary system during inspiration and expiration (the neopulmonic lung has been removed for purposes of clarity). **A:** Inspiration. **B:** Expiration. Adapted from Fedde¹³ and Brown et al.,¹⁸⁶ with permission.

cross-current model does not depend on the direction of flow.¹⁴ Studies in which blood gases were collected from mechanically, bidirectionally ventilated birds did not show an adverse effect of mechanical ventilation on gas exchange.^{60,61}

Effects of Anesthesia and Body Position on Ventilation

As mentioned earlier, the avian lung is very efficient at gas exchange, but this efficiency is compromised by anesthesia. A number of causative factors are probably responsible. In mammalian species, it has been amply demonstrated that injectable and inhaled anesthetics, through their effects on the central nervous system and peripheral chemoreceptors, significantly depress ven-

tilatory responses to hypoxia and hypercapnia.^{62–64} Since birds have many of the same mechanisms for controlling ventilation as mammals, it seems reasonable to assume that anesthetics will similarly depress avian ventilatory control mechanisms. A number of studies have shown that inhalants depress the responsiveness of a number of peripheral control mechanisms that directly or indirectly affect ventilation.^{65–67}

Barbiturates depress ventilation in birds, but birds retain the ability to respond to inspired carbon dioxide.^{68,69} Furthermore, electromyograms from cocks lightly anesthetized with pentobarbital demonstrated that inspiratory and expiratory muscles of ventilation were equally depressed by the anesthetic.⁷⁰ Muscle relaxation is a feature of general anesthesia, and the degree

of relaxation depends on the anesthetic. Because inspiratory and expiratory muscle activity is essential for ventilation in birds, any depression of muscle activity will affect ventilatory efficiency.

The position of a bird during anesthesia can significantly affect ventilation. As early as 1896, it was recognized that ventilation was reduced in birds placed on their backs.⁷¹ A number of factors contribute to this phenomenon, not the least of which is the weight of the abdominal viscera compressing the abdominal air sacs and thus reducing their effective volume.

In summary, a number of factors regulating ventilation are affected by anesthetics. By understanding how anesthetics affect these control mechanisms, appropriate adjustments can be made in anesthetic management, thus minimizing or eliminating anesthetic-induced deleterious effects on pulmonary function in anesthetized birds.

Lung Gas Volume, Anesthesia, and the Dive Response

During anesthesia the lack of a significant functional residual volume within the lung limits the period of time that a bird can remain apneic. During induction of anesthesia in birds, especially waterfowl, apnea and bradycardia can occur and last for 3 to 5 min. Anesthetic gases are not required to elicit this response, as it can occur when a mask is placed snugly over a bird's beak and face. This response has been referred to as a *dive response*, but it is actually a stress response that appears to be mediated by stimulation of trigeminal receptors in the beak and nares, at least in diving ducks.⁷²⁻⁷⁴ During the stress response, blood flow is preferentially distributed to the kidneys, heart, and brain.⁷⁵ This stress response makes safe induction of anesthesia in these birds a challenge. This response may be ameliorated by the use of premedicants such as diazepam or midazolam.

Unidirectional Ventilation: Implications for Anesthesia and Artificial Respiration

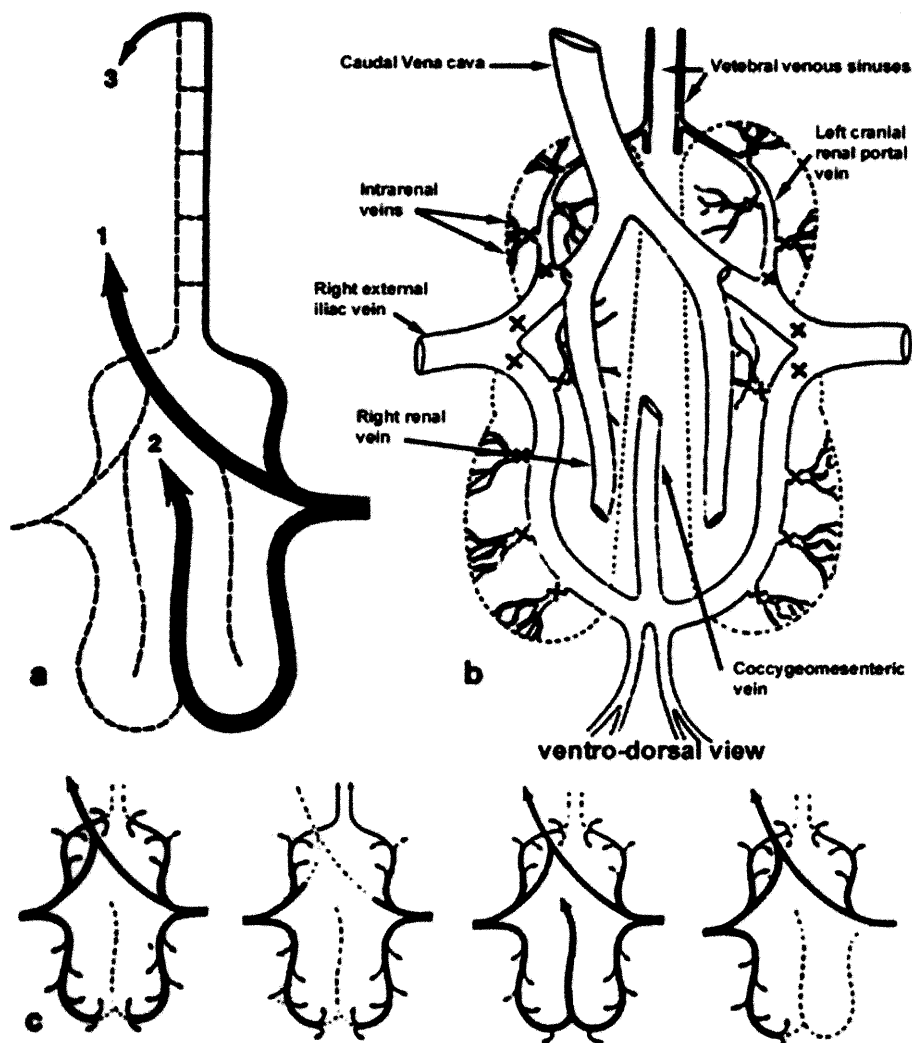

Because of the flow-through nature of the avian respiratory system, birds can be ventilated by flowing a continuous stream of

gas through the trachea and lungs, and out through a ruptured or cannulated air sac.^{76,77} This same technique can be used to induce and maintain anesthesia in birds.^{76,78-80} This technique also offers an effective means by which to ventilate and resuscitate an apneic bird or a bird with an obstructed airway.^{81,82} In one study in which arterial blood gases were compared before and after cannulation of the clavicular air sac in ducks, the arterial blood gases (PaO₂ and PaCO₂) remained unchanged by air sac cannulation.⁸³ Despite the lack of change in blood gases, tidal volume increased significantly, and a doubling of minute ventilation was coupled with a slight but insignificant increase in respiratory frequency. However, a report involving sulfur-crested cockatoos (*Cacatua galerita*) suggests that the clavicular air sac may not be an appropriate route for air sac cannulation and delivery of anesthetic gas in all avian species.⁷⁸ In this latter study, anesthesia could not be maintained when isoflurane was insufflated through the clavicular air sac

Intramuscular Injections and the Renal Portal System

For walking birds, intramuscular injections are most commonly administered in the pectoral muscles and in the leg muscles for flying birds. Because birds have a renal portal system, there has been some concern that injections in the leg muscles might result in rapid elimination of drug through the kidneys and diminished anesthetic response.⁸⁴ The renal portal system may play an important role in those situations in which drug efficacy depends on a constant blood level, as is the case for antimicrobial drugs. In a study of pigeons that were injected with flumequine in the pectoral and leg muscles, significant differences in bioavailability were found between the two injection sites, but whether this was caused by the renal portal system or by differences in blood flow was undetermined.⁸⁵ Although the renal portal system may be an important variable in antimicrobial therapy, its effect on anesthetic drugs injected into the leg muscles is probably unimportant. Injectable anesthetics are given to effect, and if a first dose does not produce the desired result, an additional smaller dose can be given to achieve the desired effect.

Fig. 34.8. Ventral views of renal portal shunts, portal sphincters, and variations in portal blood flow. **a:** The three renal portal shunts as marked on the left kidney: 1, through the portal valve to the caudal vena cava; 2, through the caudal renal portal vein to the caudal mesenteric vein; and 3, through the cranial renal portal vein to the internal vertebral venous sinuses. Shunts 1 and 2 can function individually, or all three collectively, to bypass of the kidney completely. **b:** Numerous combinations of vasoconstriction (marked by crosses) result in highly varied patterns of blood flow. **c:** Selected examples of routes of blood flow through the avian kidney. General Considerations for Anesthesia

Physical Examination

Every bird should be given a thorough physical examination prior to anesthesia. A number of excellent texts describe in detail the techniques for physical examination and what to look for in specific avian species.^{86–88} In general, quiet observation of a bird in its cage provides a great deal of information. A bird's awareness of, and attention to, its surrounding environment, body form and posture, feather condition, and respiratory rate all provide clues to its physical condition. Birds should be removed from their cage and examined, with particular attention given to the nares and mouth. A stethoscope with a pediatric head should be used to auscultate the heart and lungs. At the same time the sharpness of the keel should be determined because this is a good indicator of muscle mass and body fat.

Acclimation

When possible a bird should be allowed to acclimate to the clinic or hospital environment prior to anesthesia. A bird brought into a

new environment will be stressed. Time allows the bird to calm down after the initial physical examination and also gives the veterinarian time to evaluate the results of blood work. It is not unusual that once a bird has acclimated to the new environment, other signs of disease may become apparent that were masked at first presentation.

Fasting

Fasting of birds prior to anesthesia and surgery has been controversial. Arguments against fasting stem from a concern that fasted birds will become hypoglycemic because of their high metabolic rate and poor hepatic glycogen storage.^{89,90} However, because of the hazards associated with regurgitation in minimally fasted birds, some practitioners recommend that avian species, regardless of size, be fasted overnight.⁹¹ A reasonable approach is to hold an avian patient off food long enough for the upper gastrointestinal tract to empty, usually overnight in large birds and 4 to 6 h in smaller birds.⁹² Experience with waterfowl, cranes, and ratites also suggests that in these birds an overnight fast is not deleterious and reduces the incidence of regurgitation-associated

problems. In an emergency a bird with a full crop should be held upright during induction with a finger positioned just below the mandible so as to block the esophagus.⁹² Once the bird is anesthetized, the crop can be emptied by placing a finger covered with gauze over the choanal slits to prevent food from entering the nasal cavity and then milking the food contents out of the crop and esophagus.⁹² At the end of anesthesia the oral cavity should be checked for and cleaned of food material to prevent aspiration.

Physical Restraint

Proper physical restraint is an important part in the handling and anesthetic management of any bird. Improper capture or restraint can cause physical trauma, including wing or leg fractures. Because birds cannot dissipate heat through the skin, they can become stressed and easily overheated with prolonged restraint. Psittacine owners often judge the expertise of a veterinarian by his or her ability to restrain their bird without bruising it around the face. In general, a bird must be restrained so that the wings and legs are controlled and not allowed to flap or kick about. For long-necked birds such as herons and cranes, the neck must also be controlled so as to avoid head, eye, and neck trauma.

Proper restraint is also necessary to protect personnel working around birds. Each avian species has its own unique and effective mechanisms for defense. Birds of prey will use their talons and inflict severe physical trauma on a handler or assistant, and the risk of infection from such wounds is quite real. Although most birds of prey do not bite, some, such as great horned owls, will use their talons and beak to great effect. Psittacines have very strong beaks that can cause severe soft tissue injury. Cranes and herons will use their long, pointed beaks in a spearing manner, and they seem to focus on handlers' eyes. Understanding the physical characteristics and defensive means of birds is crucial to provide restraint that is safe both for the bird and for the people working with the bird.

Injectable Anesthetics

Injectable anesthetics are used frequently to anesthetize birds. Among the many advantages associated with their use are their low cost, ease of use, and the rapidity with which anesthesia can be induced. In addition, expensive equipment is not required for delivery or maintenance of anesthesia, and pollution of the work environment is not an issue. However, inherent disadvantages associated with the use of injectables include great species and individual variation among birds in terms of dose and response, difficulty in delivering a safe volume to small birds, ease in overdosing by any route, difficulty in maintaining surgical anesthesia without severe cardiopulmonary depression, and the potential for prolonged and violent recoveries.⁹⁰

Pharmacological Considerations

Pharmacological principles that apply to mammals also apply to birds. Pharmacokinetics describe the absorption, distribution, biotransformation, and excretion of a drug. Pharmacokinetics are also used to estimate dose and assess the suitability of a route of administration. The fate of a drug in the body, including protein

binding, volume of distribution, biotransformation, and excretion, differs from species to species because the relationship between biotransformation and excretion is determined by metabolic factors and genetics.⁹³ A frequent assumption is that all birds are similar and pharmacologically belong to one group. This assumption can lead either to limited efficacy or to intoxication even among closely related species.⁹³ Veterinarians do have alternative methods available to determine safe, yet effective, doses for drugs used in birds. Allometric scaling and the concepts of physiological time are recognized and accepted alternatives for determining drug doses in lieu of pharmacokinetic data.⁹³⁻⁹⁶ More important, the general principles underlying allometric scaling serve as a rational basis for understanding how drug doses are affected by body mass or metabolic rate. A simple, but specific, example puts these principles and concepts into a clinically relevant perspective. Dosing guidelines for the use of ketamine in birds reflect the allometric concept that drug doses are inversely related to body mass. For example, a recommended dose for ketamine in a small psittacine weighing under 100 g is 0.07 to 0.10 mg/g intramuscularly (IM), whereas a bird weighing over 500 g would receive 0.03 to 0.06 mg/g IM.⁹⁷

There is very little information about the pharmacodynamics of drugs commonly used in birds. It is known that there can be significant differences in response among avian species given the same drug.^{85,98} For example, the commercially available form of ketamine consists of a racemic mixture of the *levo*isomers and *dextro*isomers of ketamine. In great horned and snowy owls this racemic mixture characteristically induces chemical restraint and anesthesia of poor quality.⁹⁸ When great horned owls receive only the *d* form of ketamine, anesthesia induction is smoother and there are fewer cardiac arrhythmias, whereas the *l* form of ketamine is associated with inadequate muscle relaxation, with cardiac arrhythmias, and with excited behavior during recovery.⁹⁸ Whether these differences are due to differing pathways for drug metabolism among birds, production of pharmacologically active metabolites, or differences in types of receptors or receptor sensitivity is not known.

Injection Sites

Commonly used subcutaneous injection sites include the area over the back between the wings, the wingweb, and the skinfold in the inguinal region. The pectoral and thigh muscles can be used for intramuscular injections. The ulnar vein, dorsal metatarsal vein, and jugular vein can be used for intravenous injections, as well as for catheterization. In general the right jugular vein is larger and easier to visualize than the left jugular vein and is an easy vessel to draw blood from or to catheterize.

Drugs

Ketamine, diazepam, and xylazine have been used to induce anesthesia of relatively short duration. Ketamine produces a state of catalepsy and can be given by any parenteral route. Doses range from 10 to 200 mg/kg, depending on species and route of administration. Drugs such as diazepam or xylazine have been combined with ketamine in order to prolong or improve the quality of anesthesia, to provide muscle relaxation, or to provide ad-

ditional analgesia. When used alone, ketamine is suitable for chemical restraint for minor surgical and diagnostic procedures, but is not a suitable general anesthetic for major surgical manipulations.^{99,100} Higher doses of ketamine only serve to prolong its action while decreasing its margin of safety.⁹⁹

Diazepam is an anxiolytic and anticonvulsant with excellent muscle-relaxant properties. As with all anxiolytics, it lacks analgesic properties and should not be viewed as providing additional analgesia when combined with primary anesthetics such as ketamine. Diazepam can be used to tranquilize a bird prior to mask induction with an inhalant anesthetic, thus reducing the stress and struggling associated with anesthetic induction. An important feature of diazepam is that its action is brief and recovery is not prolonged.

Midazolam is a more potent, longer-acting benzodiazepine that has been used in birds. In Canada geese, midazolam (2 mg/kg IM) induced adequate sedation for purposes of radiography, and the effective sedation lasted up to 20 min after injection.¹⁰¹ Mean arterial blood pressure remained stable, and arterial blood gases, which were measured in a select number of birds, were unchanged from baseline values.¹⁰¹ In a study of quail (*Colinus virginianus*), midazolam at a dose of 6 mg/kg injected IM produced heavy sedation in nine of ten birds and mild sedation in one. Time to peak onset of sedation was 10 min after administration and, as judged by heart and respiratory rates, cardiopulmonary function was unaltered.¹⁰² Midazolam appears to be a safe drug that can be used to facilitate induction of anesthesia or to provide a variable period of sedation for minor non-painful procedures such as radiography. In raptors and pigeons the effects of midazolam last for several hours after the termination of anesthesia. Although complications associated with prolonged recovery have not been reported, it can be considered an undesirable feature of any drug.

Xylazine, an α_2 -adrenergic agonist with sedative and analgesic properties, has been used for minor surgical and diagnostic procedures. It has profound cardiopulmonary effects, including second-degree heart block, bradyarrhythmias, and increased sensitivity to catecholamine-induced cardiac arrhythmias. To enhance its sedative and analgesic properties, xylazine is frequently combined with other anesthetic drugs, such as ketamine. When used alone in high doses, xylazine is associated with respiratory depression, excitement, and convulsions in some species.¹⁰³ Hypoxemia and hypercapnia were observed in Pekin ducks given xylazine and a combination of xylazine and ketamine.¹⁰⁴

To hasten recovery or to treat an overdose following the use of an α_2 -adrenergic agonist such as xylazine, an α_2 -adrenergic antagonist such as tolazoline, yohimbine, or atipamezole can be used. Turkey vultures anesthetized with a combination of xylazine and ketamine regained consciousness approximately 4 min after tolazoline (15 mg/kg) was given intravenously (IV).¹⁰⁵ Red-tailed hawks anesthetized with a combination of xylazine and ketamine recovered from anesthesia significantly faster after receiving yohimbine than did birds not receiving the antagonist.¹⁰⁶ In addition, a yohimbine dose of 0.1 mg/kg was effective and found not to cause profound cardiopulmonary changes.¹⁰⁶ In pigeons the effects of anesthesia with a combination of medetomi-

dine, butorphanol, and ketamine were incompletely reversed with atipamezole injected IM 1 h after the ketamine was injected; arousal occurred within 10 min of injection.¹⁰⁷

Propofol has been used in a variety of birds, including chickens, pigeons, barred owls and rheas, red-tailed hawks and great horned owls, canvasback and mallard ducks, barn owls, Hispaniolan parrots, common buzzard and tawny owls, spectacled and king eiders, and wild turkeys.^{108–118} Its effects are characterized by a rapid onset of action, but the speed of recovery can be variable and is species dependent. As is characteristic of the drug, it can produce hypoventilation or apnea and hypoxemia. In chickens and pigeons, propofol produced respiratory depression and apnea, and the lethal dose appears to be close to the induction dose in these species.^{108,109} In red-tailed hawks and great horned owls, propofol not only decreased effective ventilation, but recovery was reported to be prolonged, with some birds exhibiting moderate to severe excitatory central nervous system signs.¹¹¹ In Hispaniolan parrots anesthetized with propofol, recovery times were prolonged when compared with isoflurane anesthesia.¹¹⁶ In wild turkeys induced (5 mg/kg) and maintained (0.05 mg/kg/min) with propofol, apnea was observed for 10 to 30 s after induction, and the respiratory rate was significantly decreased at 4 min after its administration and throughout the period of infusion; two male turkeys developed severe transient hypoxemia, one at 5 and the other at 15 min after induction.¹¹⁸ The average time to standing after discontinuation of propofol infusion was 11 min.¹¹⁸

Surgical anesthesia can be maintained for relatively long periods (1 to 12 h) by using intermediate to long-acting barbiturates or combinations of drugs with intermediate durations of effect. Pentobarbital can be used to produce anesthesia of several hours' duration with a dose of 25 to 30 mg/kg IV.¹¹⁹ Since it requires 10 to 15 min for full onset of action, the drug should be administered initially as a bolus consisting of half the total dose and the remainder titrated over several minutes until the desired plane of anesthesia is achieved.

Phenobarbital is a long-acting barbiturate and produces anesthesia lasting for as long as 1 day when administered at 130 mg/kg.¹¹⁹ Its onset of action is very slow, requiring as much as 30 min before surgical anesthesia is achieved. As is true for pentobarbital, additional doses of phenobarbital can be administered as needed to deepen the plane of anesthesia, but there is a narrow margin between anesthesia and severe cardiac depression and death.

Equithesin is a combination of pentobarbital, chloral hydrate, and magnesium sulfate. It does not produce a surgical plane of anesthesia when used alone, but does produce surgical anesthesia lasting for as long as 90 min when combined with diazepam.⁵⁸

Local Anesthetics

These have been used in birds with unfortunate consequences, including seizures and cardiac arrest.¹¹⁹ The problem is related to the small size of some avian species and inappropriate doses.⁹⁰ For example, 0.1 mL of 2% lidocaine administered IM or subcutaneously (SC) to a 30-g parakeet is equivalent to 67 mg/kg, which is a gross and toxic overdose for any animal. Lidocaine

can be used in birds for local anesthesia, but the dose must not exceed 4 mg/kg, which is a dose that is difficult to achieve in very small birds unless the drug is diluted. Although local anesthetics provide sufficient local analgesia, they do nothing for stress induced by physical restraint and handling of an awake bird.

Opioids

In birds the lack of an anthropocentric type of response to pain does not necessarily mean that they do not perceive pain or that pain does not cause them distress. It may be that the behavior or physiological variables associated with pain in birds have not been adequately characterized, and there are a number of reasons for this. The problem of recognizing pain in birds has been confused by research looking at the effects of opioids in birds. In contrast to studies of the analgesic effects of opioids in mammals, the objective of opioid studies in birds has been to evaluate the effect on learned behavior, not analgesia per se.^{109,120–123} The results of the few studies that have evaluated the analgesic effects of opioids in birds are conflicting. In one study, morphine produced hyperalgesia, whereas, in another, it produced analgesia.^{124,125} The results of one study in chickens indicated that motor deficits associated with the administration of morphine may mask the analgesic effects of the drug.¹²⁶ More recent studies of μ opioid receptor agonists suggest that their analgesic effects can be variable. For example, fentanyl (0.01 and 0.02 mg/kg IM) was rapidly absorbed when given to white cockatoos (*Cacatua alba*) weighing 572 ± 125 g, and its elimination half-life was 1.2 to 1.4 h.¹²⁷ In the same study, fentanyl was given at 0.02 mg/kg IM or 0.2 mg/kg SC and, in terms of response to pain, there was no difference in response times between saline injection and fentanyl at 0.02 mg/kg, even though for 2 h plasma levels were at concentrations considered to be analgesic in humans.¹²⁷ The dose at 0.2 mg/kg provided significant analgesia in some birds, but this dose required a large volume (approximately 2.3 mL per 572-g bird) and caused excitement in some birds.¹²⁷

In African gray parrots, buprenorphine (0.1 mg/kg IM), a partial μ opioid receptor agonist, had no analgesic effects when compared with saline.¹²⁸ These studies suggest that, for analgesia in birds, μ opioids have little clinical efficacy. κ -Receptor agonist opioids, such as butorphanol, appear to be effective analgesics in birds possibly because κ opioid receptors account for 76% of the radiolabeling of pigeon forebrain tissues.¹²⁹ Butorphanol has been shown to produce analgesia in cockatoos and African gray parrots.^{128,130,131}

Inhalant Anesthetics

Inhalant anesthetics, especially isoflurane and sevoflurane, are considered the anesthetics of choice for use in birds, and they offer several advantages for patient management not provided by injectable drugs. Advantages include rapid induction and recovery (especially when inhalant anesthetics with low blood-gas solubility are used, such as isoflurane and sevoflurane); easier control of anesthetic depth; the concurrent use of oxygen with inhalants, which provides respiratory support; and fast recovery that does not depend on metabolic pathways. A disadvantage is that the delivery of the potent inhalants requires special equip-

ment, such as a source of oxygen, a vaporizer, a breathing circuit, and a mechanism for scavenging waste anesthetic gases, although these are widely available in veterinary practices.

Breathing Circuits and Fresh Gas Flows

Non-rebreathing circuits, such as the Bain circuit or Norman elbow, are ideal for use in birds because they offer minimal resistance to spontaneous patient ventilation. An additional advantage to the plastic Bain circuit when used in very small birds is that it is light. When a non-rebreathing circuit is used, oxygen flows should be two to three times minute ventilation, or 150 to $200 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$.

Induction Techniques

The variety of techniques for inducing gas anesthesia in birds are limited only by an anesthetist's imagination. Birds can be induced with commercially available small animal masks or with homemade masks fabricated from plastic bottles, syringe cases, syringes, or breathing-hose connectors. Mask induction techniques can be used in a wide variety of birds of various sizes, from the very small up to, and including, the emu. Mask induction is unsatisfactory in adult ostriches, even if they are debilitated.

Other techniques include the use of plastic bags or chambers. Birds can be induced by inserting their heads into plastic bags (preferably clear plastic) into which oxygen and anesthetic vapor are introduced via a non-rebreathing circuit. Plastic bags have been used to enclose a bird cage completely in order to induce anesthesia in a bird that is difficult to manage.¹³²

An anesthetic chamber can be used to induce anesthesia. A disadvantage to this technique is that the anesthetist is not in physical contact with the bird and cannot get a feel for how the bird is responding to the anesthetic. In addition, birds can injure themselves as they pass through stage II (involuntary excitement) anesthesia.

Whatever inhalant induction technique is used, anesthetists must take precautions to control and eliminate anesthetic-gas pollution in the work environment. If a mask is used, it should fit snugly over the bird's beak and face or over its entire head. If a plastic bag or chamber is used, it should be free of leaks. Once induction is completed, the bag or chamber must be removed from the area without "dumping" the contents into the workplace environment.

Intubation

Any bird larger than 100 g (e.g., a cockatiel) can be intubated.¹³³ However, unique anatomical features that can interfere with intubation, such as the median tracheal septum found in some penguins or the large bills of toucans and flamingos, must be kept in mind while planning an intubation strategy. The glottis is easy to visualize in most birds and, depending on the size of the bird, the larynx and trachea are easily intubated. Some birds are difficult to intubate either because of their unique oropharyngeal anatomy or because of their size. Psittacine species, especially the smaller birds such as parakeets, can be difficult to intubate because of the awkward location of the glottis at the base of the humped, fleshy tongue.¹³⁴

Intubation in small birds is not without risk. Tubes with very small internal diameters can impose significant resistance to ventilation, a feature that becomes an even greater hazard when an endotracheal tube develops a partial or complete obstruction caused by a mucus plug. During anesthesia, especially when an anticholinergic is not used, mucus production can be copious, and because of the drying effects of the inspired cold and dry gases, the mucus becomes thick and tenacious. Obstruction of an endotracheal tube can be detected by observing the bird's pattern of ventilation. As the airway becomes occluded, the duration of the expiratory phase is prolonged. An artificial sigh usually confirms the presence of an obstruction because the air sacs fill in a seemingly normal manner, but they empty slowly or not at all. This problem can be corrected quickly by extubating the bird and cleaning the tube or replacing it altogether. Airway noises may be heard as the tube becomes more obstructed with mucus. An anticholinergic, such as atropine (0.04 mg/kg) or glycopyrrolate (0.01 mg/kg), reduces mucus production and minimizes the formation of mucus plugs.

During intubation, care must be exercised not to traumatize the trachea. The tube should not fit tightly, and if the endotracheal tube has a cuff, it either should not be inflated or must be inflated with extreme care. Since the trachea is composed of complete rings of cartilage an overly inflated cuff can traumatize and even rupture the tracheal mucosa and rings. Damage to the trachea may not become evident until 5 to 7 days after intubation, when the processes of healing and fibrotic narrowing of the trachea cause signs of dyspnea. When an endotracheal tube cuff is over-inflated, the tracheal rings may rupture longitudinally rather than circumferentially.

Minimum Anesthetic Concentration

The minimum alveolar concentration that produces anesthesia in mammals exposed to noxious stimuli is referred to as *MAC*. It is a measure that provides a description of concentration and effect, it can be used to quantify factors that influence anesthetic requirements, and it is a term equally applicable to all inhalation anesthetics.¹³⁵ As defined, MAC is not appropriate for discussions concerning inhalation anesthesia in birds because it presupposes the presence of an alveolar lung. In birds, MAC has been defined as the *minimal anesthetic concentration* required to prevent gross purposeful movement in a bird subjected to a painful stimulus.⁶¹

Although the avian pulmonary system anatomically and physiologically differs from the mammalian pulmonary system, MAC values (Table 34.4) for halothane, isoflurane, and sevoflurane in birds are similar to MAC values reported for mammals.^{61,136–140,141,142} This lends support to the observation that different species or classes of animals do not show large variations in effective concentrations for inhalant anesthetics.¹⁴³

Halothane, Isoflurane, and Sevoflurane

A number of inhalant anesthetics, including chloroform, cyclopropane, ether, methoxyflurane, and halothane, have been used to induce general anesthesia in birds.^{144–147} Although these drugs are historically interesting, this review focuses on halothane,

Table 34.4. Minimal anesthetic concentration (MAC) for halothane, isoflurane, and sevoflurane in birds^a.

Bird	Halothane	Isoflurane	Sevoflurane
Cockatoo	—	1.44% ¹³⁰	—
Chicken	0.85% ¹³⁸	1.25% ¹⁴⁰	2.21% ¹³⁹
Duck	1.05% ¹³⁶	1.32% ¹³⁷	—
Sandhill crane	—	1.35% ⁶¹	—

Superscripts are reference numbers.

isoflurane, and sevoflurane, the most commonly used inhalant anesthetics at this time. Of these three inhalants, isoflurane is preferred for anesthesia in birds. Its introduction has revolutionized avian medicine and surgery because it is well tolerated by birds of all sizes.⁹⁷

Halothane, isoflurane, and sevoflurane, at all end-tidal anesthetic concentrations and in a dose-dependent manner, depress ventilation.^{61,136–140,148} More specifically, as the concentration of anesthetic increases, the partial pressure of carbon dioxide increases significantly. *Anesthetic index* (AI), a measure of the tendency for an inhalant anesthetic to cause respiratory depression and apnea, is derived by dividing the end-tidal concentration of an anesthetic at apnea by the MAC for the anesthetic.¹⁴⁹ The lower the AI is for an anesthetic, the greater is its depressant effect on ventilation. In ducks anesthetized with halothane the AI was found to be 1.51 or lower, whereas the AI for ducks anesthetized with isoflurane was 1.65.^{136,137} These AI values are considerably lower than those reported for dogs, cats, or horses, and suggest that halothane and isoflurane depress ventilation more in birds than in mammals.^{150–152}

The effect of halothane on blood pressure can be variable. In chickens and ducks, increasing concentrations of halothane can cause a decrease in mean arterial blood pressure, or no change.^{136,138,153} In contrast, isoflurane appears to consistently cause a dose-dependent decrease in mean arterial blood pressure, possibly because of isoflurane-associated peripheral vasodilation.^{61,137,153,154} Sevoflurane has been reported to decrease blood pressure in chickens, but only during controlled ventilation did the blood pressure decrease in a dose-dependent fashion, whereas this did not occur during spontaneous ventilation, probably because of the attendant hypercapnia.^{139,140}

In mammals, positive-pressure ventilation depresses mean arterial blood pressure by creating positive intrathoracic pressures that compress the great vessels, thus impeding the venous return of blood to the heart. In sandhill cranes anesthetized with isoflurane, mean arterial blood pressure was actually higher during positive-pressure ventilation than it was during spontaneous ventilation.⁶¹ Such is not the case in chickens anesthetized with sevoflurane.¹⁴⁰

Cardiac arrhythmias frequently occur in animals, including birds, anesthetized with halothane. Cardiac stability is one of the perceived advantages of isoflurane and sevoflurane and is one of the reasons why they have so readily gained wide acceptance in clinical avian practice. However, in a study in which an electric

fibrillation model was used to investigate the myocardial irritant effects of isoflurane and halothane, isoflurane was found to lower the threshold for electric fibrillation more than halothane.¹⁵⁴ The reasons for the discrepancy between clinical experience and the result of this study are not clear, but hypoventilation, which is common during general inhalant anesthesia, may be a contributing factor. Not only does hypoventilation make it difficult to control the plane of anesthesia, it can have a variety of adverse effects on cardiopulmonary function through direct or indirect mechanisms. For example, in ducks held at a constant end-tidal halothane concentration of 1.5% and in which PaCO₂ was varied from 40 to 80 mm Hg, unifocal and multifocal cardiac arrhythmias occurred in six of the 12 ducks.¹⁵⁵ The mean PaCO₂ at which arrhythmias developed was 67 ± 12 mm Hg and in five of six ducks with arrhythmias, the arrhythmias disappeared after carbon dioxide inhalation was terminated.¹⁵⁵ For these reasons, ventilation in birds should be assisted or controlled during general inhalant anesthesia.

Nitrous oxide can be used as an adjunct to general anesthesia in birds, but is not suitable for use as the sole anesthetic.¹⁴⁴ One study suggests that nitrous oxide (50%) may decrease the concentration of isoflurane necessary to maintain a suitable plane of anesthesia by only 11%.¹⁵⁶ As with other anesthetic gases and vapors, nitrous oxide is not uniquely sequestered or concentrated in the air sacs. The considerations for using nitrous oxide are the same as for its use in mammals, such as adequate pulmonary function and delivery of sufficient oxygen to meet a patient's metabolic demands. The minimum fraction of inspired oxygen that should be provided is generally accepted to be 30%. The use of nitrous oxide may pose problems in some avian species. For example, diving birds such as pelicans have subcutaneous pockets of air that do not communicate with the respiratory system, and the use of nitrous oxide in these birds can cause subcutaneous emphysema.¹⁵⁷

Adjuncts to General Anesthesia

Muscle paralytics may prove to be very useful in the anesthetic management of birds, especially during long surgical procedures requiring adequate muscle relaxation and immobility. All too often a bird only appears to be adequately anesthetized, lying still on the surgical table, with complete muscular relaxation, slow respiration, closed eyelids, and relaxed feathers. The bird may accept a surgical scrub and draping, and a skin incision may be completed, when suddenly the patient displays unequivocal signs of being unsuitably anesthetized for surgery by throwing itself about on the table with flopping wings and neck.¹³⁴

Atracurium is a nondepolarizing muscle relaxant with short duration of effect and minimal cardiovascular effects. The neuromuscular and cardiovascular effects of atracurium given to 24 anesthetized chickens have been reported.¹⁵⁸ The effective dose associated with 95% twitch depression in 50% of the birds (ED_{95/50}) was calculated to be 0.25 mg/kg, and the ED_{95/95} was calculated to be 0.46 mg/kg. The duration of action for the 0.25-mg/kg dose was 34.5 ± 5.8 min, whereas it was 47.8 ± 10.3 min at the highest dose of 0.45 mg/kg. Edrophonium (0.5 mg/kg IV) reversed the effects of atracurium. There were small but statisti-

cally significant changes in cardiovascular variables in that heart rate decreased and blood pressure increased after atracurium was administered, but these changes were considered unimportant clinically.¹⁵⁸

Because birds have skeletal muscles that control pupillary diameter, neuromuscular paralytics have been used to produce mydriasis. In a study of three paralytics (d-tubocurarine, pancuronium, and vecuronium) and two autonomic drugs (atropine and phenylephrine) used with or without a surface-acting penetrating agent (either saponin or benzalkonium chloride) and administered to adult cockatoos (*Cacatua sulphurea*), African gray parrots (*Psittacus erithacus*), and blue-fronted Amazon parrots (*Amazona aestiva*), vecuronium produced the most consistent and greatest pupillary dilatation in all three species with the fewest systemic side effects.¹⁵⁹ More recently, in juvenile double-crested cormorants (*Phalacrocorax auritus*), vecuronium alone and in combination with atropine and phenylephrine were evaluated as mydriatics.¹⁶⁰ The cormorants were treated with each of four drug regimens: 1% atropine; vecuronium (total, 0.16 mg/eye); atropine with vecuronium; and atropine plus 2.5% phenylephrine, followed by vecuronium. The regimen of atropine, phenylephrine, and vecuronium provided the most consistent dilation, with larger average pupil size and longer average duration; no side effects from vecuronium were observed in these birds.¹⁶⁰

Monitoring

Birds must be monitored during anesthesia. Physiological variables to monitor include respiratory rate and tidal volume, oxygenation, heart rate and rhythm, body temperature, and muscle relaxation. Both respiratory rate and tidal volume should be monitored during anesthesia in order to assess the adequacy of ventilation and the depth of anesthesia. Respiratory frequency by itself can be misleading as to the adequacy of ventilation and anesthetic depth. High respiratory frequencies in an anesthetized bird do not necessarily indicate that the bird is lightly anesthetized and hyperventilating. More often, high respiratory rates are associated with small tidal volumes and a greater proportion of dead space ventilation rather than effective ventilation.⁶¹

Ventilation can be monitored by watching the frequency and degree of motion of the sternum or movements of the breathing circuit reservoir bag. Capnography can also be used to monitor ventilation in birds, but accurate sampling of airway gas may require adjustments in sampling flow rate or technique.¹⁶¹ When monitoring ventilation in birds, respiratory pauses longer than 10 to 15 s should be treated by lightening the plane of anesthesia and ventilating the bird by either periodically squeezing the reservoir bag or using a positive-pressure mechanical ventilator. Birds can be mechanically ventilated, and although the direction of gas flow through the avian pulmonary system may be reversed, gas exchange is not affected adversely.^{61,162} During positive-pressure ventilation, airway pressure should not exceed 15 to 20 cm H₂O pressure to prevent volotrauma to the air sacs. Ventilation also can be assessed by noting the color and capillary refill time of mucous membranes. The color of the cere, beak, or bill, as well as coloration on the head, can give an indication of the adequacy of cardiopulmonary function.

Pulse oximeters can be used to monitor oxygenation, but the typical pulse oximeter is designed to measure oxygenated and deoxygenated mammalian hemoglobin, not avian hemoglobin. Although pulse oximeters may track trends in oxygenation, they tend to underestimate oxygenation levels at high oxygen saturation levels and overestimate oxygenation levels at lower saturation levels because of the differences between avian and mammalian hemoglobin.¹⁶³

The heart is an electromechanical pump, and the blood vessels are the conduits for its output. The adequacy of pump function can be assessed by monitoring mucous membrane color and refill time as noted earlier, as well as monitoring the ECG and blood pressure, and by palpating peripheral pulses. An ECG is used to monitor the electric activity of the heart. Standard bipolar and augmented limb leads can be used to monitor and record the avian ECG. To assure adequate skin contact for an interference-free signal, ECG clips can be attached to hypodermic needles inserted through the skin at the base of each wing and through the skin at the level of each stifle. An alternative technique is to attach the ECG clips to stainless-steel wires that have been inserted through the prepatagium of each wing and the skin at the lateral side of each stifle. The wire size selected depends on the size of the bird. In birds larger than 500 g, 20- or 22-gauge wire can be used. Appropriately sized hypodermic needles are used to insert the wires through the skin.

Pump function can be assessed by monitoring the pulsations of blood through a peripheral artery or by monitoring blood pressure. Arterial blood pressure in birds larger than 4 kg can be monitored directly, but this technique is not feasible in smaller birds. The Doppler flow probe is an effective device for monitoring blood flow in small birds, and blood flow or blood pressure in either moderately sized or large birds. With the Doppler probe secured in position over a peripheral artery, pulse rate and rhythm can be determined. The probe can be placed over a digital artery, and a sphygmomanometer attached to a cuff placed around the leg can be used to measure arterial blood pressure indirectly.

Body temperature should be monitored for a number of reasons. The stress associated with anesthesia and surgery is minimized when birds are maintained at or near their normal body temperature. During anesthesia, it is not unusual to see major fluctuations in body temperature, but hypothermia is the most common problem, and one that decreases the amount of anesthetic needed to maintain anesthesia, causes cardiac instability, and prolongs recovery. In well-insulated birds (feathers, drapes, and heating pads), hyperthermia can occur and also cause cardiac instability and an increased oxygen demand. Body temperature can be reliably monitored with an electronic thermometer and a long, flexible thermistor probe inserted into the esophagus to the level of the heart. Temperature monitored from the cloaca can vary significantly over time, owing to movements of the cloaca that affect the position of the thermometer or a thermistor probe. Body temperature can be adjusted by inserting or removing pads or blankets between the bird and cold surfaces, using circulating warm-water blankets (not electric heating pads), maintaining a light plane of surgical anesthesia, raising or lowering the environmental temperature, or wetting the bird's legs with alcohol.

According to a report involving Hispaniolan Amazon parrots the most effective method for maintaining body temperature was a forced-air warming device.¹⁶⁴ Even though such a device may not prevent an initial drop in core body temperature, it appears to maintain body temperature within a clinically acceptable range.¹⁶⁴

Recovery

Precautions should be taken to protect birds while they recover from anesthesia. Birds must be kept from flopping uncontrollably, because this can lead to serious neck, wing, or leg injuries. Struggling and flopping behavior can be prevented by lightly wrapping a bird with a towel, but wrapping poses its own hazards. If a bird is wrapped too tightly, sternal movements will be impeded and breathing will be difficult, if not impossible. Wrapping can lead to excessive retention of body heat and cause hyperthermia. If a bird has not been fasted prior to anesthesia, regurgitation can occur during recovery. Keeping a bird intubated during the recovery phase helps to maintain an open airway.

Ratites

Ratites have been raised for commercial purposes for almost 100 years, and there is an extensive base of knowledge concerning the commercial management of these birds. Little information is available about anesthesia because in their native countries where the value of individual birds is low, they are not usually presented for extensive veterinary care. In general, young ratites (ostriches weighing under 30 kg and emus weighing under 18 kg) may be treated with the same considerations as given to other birds because the same problems of hypoglycemia, hypothermia, hypotension, and hypoventilation tend to occur. Hypoglycemia and hypothermia do not appear to be common in adult birds, but restraint and handling are more difficult.

Restraint

Restraint of adult ratites is challenging, so it is important to work with personnel, such as the owner, who are experienced in handling adult birds. Adult ostriches may average 114 kg and stand 6 feet tall. They can move very quickly, peck accurately at objects, and have large-toed feet with which they can strike forward. Most farm-raised birds have been handled, and information about the bird's individual temperament can be obtained from the owner or handler. As with other birds, they can be hooded to facilitate handling. Hoods can be made from surgical stockinette, and the head can be manually restrained (Fig. 34.9). Distracting the bird by allowing it to peck at a shiny object, which is held firmly to prevent ingestion, may be sufficient for completing minor procedures. The ostrich can be herded into a corner or chute by using a solid object such as a sheet of plywood or a large pad, or by holding one wing at the base of the humerus and pushing the bird in front of the handler. It is important always to work from behind or beside the bird to remain out of forward striking range of the feet. If the bird is recumbent, as can occur after sedation, it is best to transport the bird in sternal recumbency with it sitting on its hocks. This position enables control of

Fig. 34.9. Manual restraint, including hooding, of an ostrich.

the feet. In smaller birds, the handler may be able to restrain the bird safely by stepping over its back, grasping the hocks from behind, and folding the legs up to the body.

Injections and Catheter Placement

Intramuscular injections are best given into the large muscle mass of the thigh. Although ratites are reported to have a renal portal system, drugs are effective when given in this location.¹⁶⁵ Intravenous injections can be given into the jugular vein. As is generally true for all birds, the right jugular is more prominent than the left jugular. Routinely placing a catheter (14 gauge, 10 cm) in the jugular vein is recommended in order to prevent hematoma formation from repeated needle sticks. In ostriches, the branchial vein may also be used for injections and catheterization (18 gauge, 3.0 to 4.5 cm).¹⁶⁶ In emus, because of their vestigial wings, the brachial vein is very difficult to use, but the metatarsal vein can be used. The thick, cornified skin on the lower limbs of the ostrich makes it difficult to use the metatarsal vein.

Preoperative Assessment

Performing a good physical examination and preoperative assessment in an adult ostrich can be challenging and is often impossible. It is an unfortunate fact that a bird's state of health cannot be judged reliably by its behavior. Ill adult ostriches may appear to be quite normal and active. Some blood work is needed, preferably a complete blood count and chemistry profile. Acid-base imbalances and dehydration should be corrected before any bird is anesthetized. Normal hematologic and chemistry values have been reported.¹⁶⁷⁻¹⁷⁰ It is important to get an accurate weight. Visual estimation of body weight is difficult because the feathers may conceal a very thin bird. Other preparations for anesthesia will depend on a bird's temperament and the facilities and personnel available. Adult ostriches and emus are routinely fasted overnight, but water is not withheld.

Preanesthetics

Although a wide variety of tranquilizers and sedatives have been used as preanesthetics in ratites (Tables 34.5 and 34.6), a caveat is necessary before discussing the effects of preanesthetics in

ratites.¹⁷⁰⁻¹⁷⁶ Almost all of the information relating drug and effect has been generated from clinical cases. Much of the variability in response to anesthetics is owing to variations in drug requirements imposed by disease conditions, as well as a lack of controlled studies. In point of fact, only one study reports dose effects for anesthetics in ratites.¹⁷⁶ In addition the practical problems of restraint impose restrictions on the acquisition of clinical data. For these reasons the following should be taken as guidelines derived from clinical experience and studies.

For healthy, large ratites, premedication with xylazine (1 to 2 mg/kg IM) appears to facilitate handling, placement of catheters, and induction of anesthesia. This dose of xylazine would produce excessive cardiovascular depression in a sick bird, which emphasizes the importance of an accurate preoperative assessment. Diazepam (0.4 to 1.0 mg/kg IM) is especially effective in sick or debilitated ratites, or may be combined with xylazine in healthy ratites. Midazolam (0.4 mg/kg IM) also appears to be an effective preanesthetic.

Induction of Anesthesia

Ketamine appears to induce the most reliable and smoothest inductions in ratites, especially when combined with diazepam or following xylazine or midazolam premedication (Tables 34.5 and 34.6).¹⁷⁷ Intravenous injection rapidly induces anesthesia and enables anesthetists to titrate the drug dose to achieve a desired effect. However, this may not be possible in fractious birds or where there is little assistance for restraint. Doses for intramuscular injection may be metabolically scaled by using an intermediate value between passerine and nonpasserine birds.¹⁷⁸ Induction with tiletamine-zolazepam, either IM or IV, produces satisfactory results, but recoveries are rough and prolonged.¹⁷⁹ Carfentanil has been used for induction, but induction and recovery are reported to be rough.¹⁷³ In smaller ratites and debilitated birds, mask induction with isoflurane is effective and fairly smooth. In contrast, mask induction in adult ostriches, even if they are debilitated, is not recommended because induction can take as long as 30 to 45 min.

Intubation

Intubation of ratites is similar to that for many other avian species. The larynx is readily accessible, the beak opens widely, and there is no epiglottis. Although the tracheal rings are complete, portions of the trachea are collapsible, so some caution must be used when advancing the endotracheal tube. In an ostrich with a collapsed trachea, intubation was successfully performed following induction with diazepam (0.3 mg/kg IV) and ketamine (7 mg/kg IV).¹⁸⁰ Depending on their size, ostriches can be intubated with endotracheal tubes with internal diameters of 10 to 18 mm, whereas emus generally require endotracheal tubes measuring 9 to 14 mm. Careful inflation of the cuff is usually necessary to enable good ventilation of adult ratites. The tracheal cleft in emus (Fig. 34.1), which is more highly developed in females but present in both sexes, does not complicate intubation. The cleft does make effective positive-pressure ventilation difficult, but this problem can be overcome by placing a tight wrap (e.g., Vetrap) around the distal third of the neck.
