Dedication

The fourth edition of this text is dedicated to the pioneering individuals instrumental in developing the specialty of veterinary anesthesiology and to the practitioners and scientists who continue to advance veterinary anesthesia and the evolving field of pain management. Every veterinarian, technician, and staff member who daily champions the humaneness of patient care in the academic, research, or clinical environment is to be appreciated. We owe much to members of the veterinary profession, as well as to those in allied medical fields, who have focused their life's work on discovering better and safer methods of achieving anesthesia and pain alleviation in the animals that we are privileged to attend and heal.

We dedicate our efforts in bringing this edition to publication to our parents for imparting the values of hard work, loyalty, and patience; to our teachers and colleagues for the belief that scientific knowledge gives us the best chance to know what is real; to our wives for their undying devotion and support of family; and to our children and students for making everything joyful and worthwhile.

William J. Tranquilli

Foreword

Since the initial publication of *Veterinary Anesthesia* in 1973, the science and art of anesthesia and pain management have matured immeasurably. Today, a comprehensive book covering the entire field is beyond the capabilities of any one individual or area of study. As such, and as Founding Diplomates of the American College of Veterinary Anesthesiologists, it has been gratifying to see numerous authors, more than 65 in all, young and old alike, from a wide array of backgrounds and clinical specialties make contributions to this, the fourth edition and newly titled *Lumb and Jones' Veterinary Anesthesia and Analgesia*.

We are indebted to Drs. Tranquilli, Thurmon, and Grimm for assuming editorship of this challenging endeavor. We believe that the fourth edition will continue to serve students, academic colleagues, and practitioners alike as the world's most comprehensive source of information regarding the science and art of anesthesia and pain control in the numerous species that make up the animal world.

William V. Lumb
E. Wynn Jones

Preface

The first edition of *Veterinary Anesthesia* was published in 1973, followed by the second edition in 1984, and the third edition in 1996. The publishing of this, the fourth edition, in 2007 marks this text's thirty-fourth anniversary.

Many changes have occurred in veterinary medicine and anesthesia during this time, with each succeeding edition of this text attempting to update and document these advances. In recent years, the ever-increasing emphasis on the treatment of animal pain has placed veterinary anesthesiology and pain management in a central role in the delivery of humane veterinary care. Accordingly, several chapters focusing on recent advancements in animal pain management have been included in this revision and, most noticeably, are reflected in the new title, *Lumb and Jones' Veterinary Anesthesia and Analgesia*. Where possible, we have endeavored to conserve as much of the previous editions' text as possible so as to continue to provide information on older anesthetic drugs and techniques that might still be employed by veterinarians in various regions of the world. Nevertheless, given the volume of space required to discuss much of the new knowledge and contemporary issues pertinent to veterinary anesthesia and analgesia, retention of much of the previous editions' text was simply not possible. Fortunately, this information, much of which is of historical interest, will forever be available from earlier editions. It should be noted that some chapters' text has been retained from previous editions and, as such, the current authors of these chapters (if not the same) wish to acknowledge the continued valuable contributions of earlier authors to this edition, as well. As in previous editions, the fourth edition provides evidence of numerous advances in our scientific and clinical knowledge pertinent to the provision of anesthesia and analgesia in a multitude of animal species.

This Lumb and Jones' edition has more than 65 contributing authors, offering a wide array of scientific training and clinical experience. As would be expected, many contributors are anesthesiologists, but a number of new authors are specialized in other clinical areas, including clinical pharmacology, surgery, medicine, critical care, cardiology, neurology, urology, ophthalmology, dentistry, radiology, physical rehabilitation, and lab animal medicine. It is hoped that this increased diversity in authorship expertise will provide a comprehensive perspective to the management of anesthesia and pain in patients suffering from an array of clinical conditions and disease. All of the contributing authors have been encouraged to share their personal experiences in an effort to enhance the clinical utility of the information provided. The editors are indebted to the authors for the many hours devoted to the preparation of their individual chapters. Many of these authors have dedicated their careers to the field of veterinary anesthesiology and the humane treatment of animals. In so doing, these indi-

viduals have made numerous and, in some instances, monumental contributions to the advancement of veterinary medicine. Included among these individuals are Drs. W. Lumb, E. W. Jones, C. E. Short, W. W. Muir, W. N. McDonell, E. P. Steffey, R. T. Skarda, S. M. Hartsfield, S. C. Haskins, and P. A. Flecknell. Most recently, this dedication was best exemplified by Dr. Roman Skarda's insistence on his continued contribution to the fourth edition while battling debilitating and painful disease before his eventual passing. These individuals cannot help but provide inspiration to all who have contributed their time and expertise to the completion of this book and to all who benefit from its reading.

Similar to previous editions, this revision can be viewed both as a textbook and as a comprehensive source of scientific knowledge relevant to the clinical management of anesthesia and provision of analgesic therapy. Individuals requiring information on the immobilization and anesthesia of wild, zoo, and laboratory animals also will find chapters devoted to these unique circumstances. In addition to chapters on cardiovascular, respiratory, nervous system, and acid-base physiology, the pharmacology of various classes of drugs employed in the delivery of anesthesia and analgesia has been reviewed and updated. Chapters on anesthetic equipment, monitoring, mechanical ventilation, and regional analgesic techniques are provided. Chapters covering acupuncture, physical rehabilitation, and palliative analgesia of companion animals have been added. Chapters continue to be devoted to the anesthesia of specific species and classes of animals including dogs, cats, horses, swine, ruminants, lab animals, zoo animals, free ranging terrestrial and aquatic mammals, birds, reptiles, amphibians, and fish. Several chapters discussing the unique anesthesia and pain management requirements of companion animals with specific diseases have again been included, as have chapters on specific surgical patients and procedures. New chapters on dental, cancer, orthopedic, and equine colic patients have been included in this edition. As in the third edition, chapters have been organized into sections to aid readers in locating specific information rapidly.

In closing, the editors extend their thanks to all of the anesthesiology faculty and staff at the University of Illinois for their hard work and understanding. Without their support, time would not have been available for the editorial assignments required by such a task.

The editors are also deeply indebted to and thank Erin Gardner and the staff at Blackwell Publishing for their untiring support and encouragement.

GENERAL TOPICS

Chapter 1

History and Overview of Veterinary Anesthesia

John C. Thurmon and Charles E. Short

Introduction

History of Animal Anesthesia

Organized Veterinary Anesthesia in North America

Definitions

Reasons for Administering Anesthesia

Types of Anesthesia

Introduction

The earliest recorded attempts to induce anesthesia appeared to have been performed in humans. Drugs and techniques used included opiates, alcohol, and asphyxiation by compression of the carotid arteries to induce unconsciousness, thus alleviating the pain of surgery. In 1540, Paracelsus produced ether and reported it to have a soporific effect in birds. Despite this discovery, no further progress was made until chemistry was developed and carbon dioxide and several other gases, including oxygen, were discovered.

History of Animal Anesthesia

In 1800, Sir Humphrey Davy suggested that nitrous oxide might have anesthetic properties. Approximately 20 years later, H. H. Hickman (1824) demonstrated that pain associated with surgery in dogs could be alleviated by inhalation of a mixture of nitrous oxide and carbon dioxide. He reasoned that the latter increased the rate and depth of breathing, thus enhancing the effects of nitrous oxide. More recent studies have shown that unconsciousness can be induced in 30 to 40 s in piglets breathing carbon dioxide (50%) alone in oxygen (50%).¹

It was not until 1842 that ether was used for human anesthesia. Two years later, a dentist, Horace Wells (1844), discovered the anesthetic properties of nitrous oxide. Although this finding was neglected for several years, nitrous oxide was reintroduced in humans in 1862. C. T. Jackson, a Boston physician, was the first to employ ether extensively in animals.²

Chloroform was discovered by Liebig in 1831, but it was not until 1847 that it was first used to induce anesthesia in animals by Flourens and in people by J. Y. Simpson of Edinburgh, Scotland. With the introduction of chloroform, reports began to appear in the veterinary literature of its use in animals. Dadd routinely used general anesthesia in animals and was the first in the United States to advocate humane treatment of animals and the application of scientific principles (i.e., anesthesia) in veterinary surgery.³

In 1875, Ore published the first monograph on intravenous anesthesia using chloral hydrate; 3 years later, Humbert described its use in horses. Pirogoff was the first to attempt rectal anesthesia with chloral hydrate in 1847. The rectal administration of chloral hydrate was used later in veterinary practice. Intraperitoneal injection was first used in 1892 in France. Thus, the various routes of administration of general anesthetics to animals were established by the end of the 19th century.

After the initial isolation of cocaine by Albert Niemann of Germany in 1860, Anrep, in 1878, suggested the possibility of using cocaine as a local anesthetic. In 1884, Kohler used cocaine for local anesthesia of the eye, and Halsted described cocaine nerve-block anesthesia a year later. Its use was popularized by Sir Frederick Hobday, an English veterinarian. Thereafter, G. L. Corning was credited for inducing cocaine spinal anesthesia in dogs in 1885. From his description, however, it would appear that he induced epidural anesthesia. In 1898, August Bier of Germany induced true spinal anesthesia in animals and then in himself and an assistant.⁴

While local infiltration was popularized by Reclus (1890) and Schleich (1892), conduction anesthesia was first introduced by Halsted and Hall in New York in 1884. These techniques increased in popularity with the discovery of local anesthetics less toxic than cocaine. These developments enabled Cuille and Sendrail (1901) of France to induce subarachnoid anesthesia in horses, cattle, and dogs. Cathelin (1901) reported epidural anesthesia in dogs, but it remained for Retzgen, Benesch, and Brook to apply this technique in large animal species in the 1920s. Although paralumbar anesthesia was employed in humans by Sellheim in 1909, it was not until the 1940s that Farquharson and Formston applied this technique in cattle. Despite these promising developments with local analgesic techniques in the latter half of the 19th century, and perhaps owing to unfavorable results, general anesthesia was not readily adopted by the veterinary profession until well into the 20th century. It is sad to say, but a "heavy hand," without analgesia/anesthesia, was the stock in trade of many practicing veterinarians.

In small domestic animals, ether and chloroform were commonly administered in the early part of the 20th century. However, general anesthesia became more widely accepted after discovery of the barbiturates in the late 1920s and, in particular, with the development of pentobarbital in 1930. Barbiturate anesthesia received an additional boost with the introduction of the thiobarbiturates and particularly with thiopental in 1934. Because of rough, prolonged recovery, the acceptance of general

anesthesia in large animals was delayed until phenothiazine derivatives were introduced by Charpentier in France in 1950.

General anesthesia of large farm animals was further advanced by the discovery of fluorinated hydrocarbons and the development of large animal anesthetic equipment for their safe administration. Discovery of newer drugs (e.g., tranquilizers, opioids, α_2 -adrenergic agonists, dissociatives, muscle relaxants, and inhalant anesthetics) has further advanced the utility of veterinary anesthesia in large and small animal species.⁵

Organized Veterinary Anesthesia in North America

During the late 1960s and early 1970s, a small group of physician anesthesiologists made it possible for a number of future diplomates of the American College of Veterinary Anesthesiologists (ACVA) to participate in their programs and to learn about the development of new anesthetic drugs and techniques. Among these physicians were Robert Dripps, University of Pennsylvania; Arthur Keats, Baylor University; Mort Shulman and Max Sadoly, University of Illinois; and Edmond I. Eger, University of California Medical College. During this same period, E. W. Jones (Oklahoma State University) and William Lumb (Colorado State University) were making significant contributions to the field of veterinary anesthesiology while at their respective institutions. Jerry Gillespie was also making a unique contribution through his work on respiratory function of anesthetized horses.

Even though there were a number of interested faculty within veterinary colleges and research laboratories, not until 1970 was a major thrust directed at organizing veterinarians. Initially, a society of veterinary anesthesia was perceived. Later this society became the American Society of Veterinary Anesthesia (ASVA). Membership in the ASVA was open to all individuals working in the veterinary profession who had an interest in veterinary anesthesiology. In 1970, the first organizational meeting was held in conjunction with the American Veterinary Medical Association (AVMA) to coordinate the efforts/interest of all those wishing to organize and develop the specialty of veterinary anesthesiology. Their primary goal was to improve anesthetic techniques and to disseminate knowledge whenever and wherever possible. Charles Short was elected the first president of the new society. The ASVA was designed expressly to promote dissemination of information on veterinary anesthesia irrespective of individual training or background. Of major interest was the selection of individuals to speak at the ASVA and other scientific and educational meetings (e.g., the AVMA, the American Animal Hospital Association [AAHA], and the American Association of Equine Practitioners [AAEP]). As the ASVA developed, publication of articles on anesthesiology seemed in order. Bruce Heath accepted editorial responsibilities of articles submitted for the ASVA journal. In 1971, John Thurmon chaired the Ad Hoc Committee to establish the American College of Veterinary Anesthesiologists. The AVMA had established guidelines for the selection of founding-charter diplomates of specialty organizations. The Ad Hoc Committee requirements for charter diplomate status included 10 years of active service in the specialty, significant publications,

intensive training, and being the head of an anesthesiology program or spending a major portion of one's professional time in anesthesia or a closely related subject area. Seven members of the ASVA were found to meet these qualifications. This group would later become the founding diplomates of the ACVA.

Between 1970 and 1975, the constitution and bylaws were drafted and formalized. In 1975, the AVMA Council on Education recommended preliminary approval of the ACVA. This was confirmed by the AVMA House of Delegates in that same year. Thus, the ACVA was officially established in North America. Of importance throughout this process were the insight and efforts of Drs. Lumb and Jones, after which this text is named. They greatly assisted in the establishment of the ACVA because of their sincere interest in the sound principles of veterinary anesthesiology. During this period, several didactic texts were published on animal anesthesiology that helped to establish anesthesia as a stand-alone discipline and specialty within veterinary medicine. The first edition of this text, *Lumb and Jones' Veterinary Anesthesia*, was published in 1973; *Clinical Veterinary Anesthesia*, edited by Charles Short, was published in 1974; and *Textbook of Veterinary Anesthesia*, edited by Larry Soma, was published in 1971.

During the late 1970s, many of the founding diplomates began to establish residency training programs in their respective veterinary colleges. From 1975 to 1980, the ACVA developed continuing education programs, programs in self-improvement, and programs for testing and certification of new diplomates. Along with residency training programs, new faculty positions were created for training veterinary anesthesiologists in a number of colleges of veterinary medicine across North America. In 1980, the ACVA sought and was granted full accreditation by the AVMA, an effort headed by Eugene Steffey, then president of the ACVA.

During the past 3 decades, a number of other organizations around the world have promoted and contributed greatly to the standing of veterinary anesthesia. They include the Association of Veterinary Anaesthetists of Great Britain and Ireland (AVA), as well as the Veterinary Anesthesia and Surgery Association in Japan. These associations were instrumental in organizing the first International Congress of Veterinary Anesthesiology with its stated objective of globally advancing the field of veterinary anesthesiology. The first International Congress of Veterinary Anesthesiology was held in Cambridge, England, in 1982, followed by congresses in Sacramento, California, in 1985; in Brisbane, Australia, in 1988; in Utrecht, the Netherlands, in 1991; in Guelph, Canada, in 1994; in Thessaloniki, Greece, in 1997; in Bern, Switzerland, in 2000; in Knoxville, Tennessee, in 2003; and in Santos, Brazil, in 2006.

Concurrently, organized veterinary anesthesiology was being advanced in Europe. Veterinary anesthesiologists in the United Kingdom established the Association of Veterinary Anaesthetists and awarded the Diploma of Veterinary Anaesthesia to those with specialty training. Later, interests in board specialization became evident in the United Kingdom and many European countries, resulting in the establishment of the European College of Veterinary Anesthesiologists (ECVA). Currently, a number of veteri-

nary anesthesiologists are boarded by both the ACVA and the ECVA. For further information concerning the early history of anesthesia, the reader is referred to a number of sources.⁶⁻⁹

The establishment of the ACVA and the ECVA in recent decades has advanced veterinary anesthesia on a worldwide stage primarily through the increased availability of scientific meetings and literature. Both the ACVA and the ECVA have, as their official scientific publication, the *Journal of Veterinary Anaesthesia and Analgesia*.

Definitions

The term *anesthesia*, derived from the Greek term *anaisthaesia*, meaning “insensibility,” is used to describe the loss of sensation to the entire or any part of the body. Anesthesia is induced by drugs that depress the activity of nervous tissue locally, regionally, or within the central nervous system (CNS). From a pharmacological viewpoint, there has been a significant redefining of the term *general anesthesia*.¹⁰ Both central nervous stimulants and depressants can be useful general anesthetics.¹¹ Several terms are used in describing the effects of anesthetic drugs:

1. *Analgesia* refers to freedom from or absence of pain.
2. *Tranquilization* results in behavioral change wherein anxiety is relieved and the patient becomes relaxed but remains aware of its surroundings. In this state, it may appear to be indifferent to minor pain.
3. *Sedation* is a state characterized by central depression accompanied by drowsiness. The patient is generally unaware of its surroundings but responsive to painful manipulation.
4. *Narcosis* is a drug-induced state of deep sleep from which the patient cannot be easily aroused. Narcosis may or may not be accompanied by analgesia.
5. *Hypnosis* is a condition of artificially induced sleep, or a trance resembling sleep, resulting from moderate depression of the CNS from which the patient is readily aroused.
6. *Local analgesia* (anesthesia) is a loss of sensation in circumscribed body area.
7. *Regional analgesia* (anesthesia) is insensibility in a larger, though limited, body area (e.g., paralumbar nerve blockade).
8. *General anesthesia* is drug-induced unconsciousness that is characterized by controlled but reversible depression of the CNS and analgesia. In this state, the patient is not arousable by noxious stimulation. Sensory, motor, and autonomic reflex functions are attenuated.
9. *Surgical anesthesia* is the state/plane of general anesthesia that provides unconsciousness, muscular relaxation, and analgesia sufficient for painless surgery.
10. *Balanced anesthesia* is induced by multiple drugs. Drugs are targeted to specifically attenuate individual components of the anesthetic state; that is, consciousness, analgesia, muscle relaxation, and alteration of autonomic reflexes.
11. *Dissociative anesthesia* is induced by drugs (e.g., ketamine) that dissociate the thalamocortical and limbic systems. This form of anesthesia is characterized by a cataleptoid state in which the eyes remain open and swallowing reflexes remain

intact. Skeletal muscle hypertonus persists unless a strong sedative, peripheral or central muscle relaxant, or other concurrent medications are administered.

Reasons for Administering Anesthesia

First and foremost, anesthetics alleviate pain and induce muscle relaxation, essential for safe surgery.¹² Other important uses include restraint, safe transportation of wild and exotic animals, various diagnostic and therapeutic procedures, euthanasia, and the humane slaughter of food animals.

Types of Anesthesia

The diverse uses for anesthesia (as it relates to immobilization, muscle relaxation, and analgesia) and the requirements peculiar to species, age, and disease state necessitate the use of a variety of drugs, drug combinations, and methods. Anesthesia is often classified according to the type of drug and/or method/route of drug administration:

1. *Inhalation*: Anesthetic gases or vapors are inhaled in combination with oxygen.
2. *Injectable*: Anesthetic solutions are injected intravenously, intramuscularly, and subcutaneously. Other injectable routes include intrathoracic and intraperitoneal. These latter two routes are not generally recommended.
3. *Oral or rectal*: These routes are ordinarily used for liquid anesthetics or suppositories.
4. *Local and conduction*: Anesthetic drug is applied topically, injected locally into or around the surgical site (field block), or injected around a large nerve trunk supplying a specific region (conduction or regional nerve block). In the latter instance, the injection may be perineural (nerve block) or into the epidural or subarachnoid space (true spinal analgesia).
5. *Electronarcosis, electroanesthesia, or electrosleep*: Electrical currents are passed through the cerebrum to induce deep narcosis. Even though there have been successful studies, this form of anesthesia has never gained popularity and is rarely used in veterinary practice. Electronarcosis should not be confused with the inhumane practice of electroimmobilization.
6. *Transcutaneous electrical nerve stimulation (TENS, TNS, or TES)*: Local analgesia is induced by low-intensity, high-frequency electric stimulation of the skin through surface electrodes.
7. *Hypnosis*: A non-drug-induced trancelike state sometimes employed in rabbits and birds.
8. *Acupuncture*: An ancient Chinese system of therapy using long, fine needles to induce analgesia.
9. *Hypothermia*: Body temperature is decreased, either locally or generally, to supplement insensitivity and decrease anesthetic drug requirement and reduce metabolic needs. It is primarily used in neonates or in patients undergoing cardiovascular surgery.

Pharmacology

Anesthesia is, of necessity, a reversible process. Knowledge of the factors underlying production of anesthesia, and those that may modify it, is essential to the success of the procedure. The dose of anesthetic and the techniques for its administration are based on the average normal healthy animal. Because of the many phenomena that modify the effect of an anesthetic, it is unlikely that any given animal will be exactly average.

Marked variations in response to a standard dose of anesthetic result from the interplay of many factors, especially those related to the central nervous system (CNS) status (excited or depressed) and metabolic activity of the animal, existing disease or pathology, and the uptake and distribution of the anesthetic.

Biological Variation

Since elimination of anesthetics depends on the species and the metabolic processes within the animal, conditions affecting the metabolic rate exert a marked influence on anesthetic effect. Small animals have a higher basal metabolic rate per unit of surface area than large animals; therefore, in general, the smaller the

animal, the larger is the dose per unit of body weight necessary for anesthesia. Animals with large quantities of fat, which is a relatively inactive nonmetabolizing tissue, have a lower basal metabolic rate per unit of body weight and usually require less anesthetic than lean muscular animals in good condition.¹ Animals in poorer condition may also require less anesthetic. Dogs kept on a low food intake causing weight losses of 10% to 20% showed a marked increase in duration of anesthesia after a single anesthetic injection.² In newborns, the basal metabolic rate is low. It gradually increases to its highest point at puberty through early adulthood and then gradually declines. Response to barbiturates varies in dogs of differing ages.² Very young animals and older adult animals are most sensitive, whereas dogs in the age range of 3 to 12 months are least sensitive. These age variations are also related to changes in liver enzyme activity.³ Changes in metabolism with age are not as clear-cut as originally thought. This probably reflects that neither gross weight nor surface area are reliable measures of the active tissue mass of the body. In humans, at least, data on fat-free body weight indicate little change between young and aged adults.⁴ The basal metabolic rate of males is approximately 7% higher than that of females. In females, a rise occurs during pregnancy, owing to the metabolic activity of the fetuses. Conflicting evidence regarding sex differences in susceptibility to anesthetics has been reported.⁵ For example, pregnant rats were most susceptible, nonpregnant females less, and male rats least susceptible to anesthetic effect. In contrast, Kennedy⁶ could find no sex variance in the response of mice to barbiturate anesthesia. Female rats have been shown to be more sensitive to muscle relaxants than males of a similar age.⁷ Apparently, hormones may cause minor differences in an individual's response to an anesthetic.

Pharmacogenetic Differences

Variation in the dose response to drugs because of genetic-related factors can be found in the literature. As examples, the heritable difference in the ability of rabbits to hydrolyze atropine and cocaine,⁸ genetic variations in response to pentobarbital in mice,⁷ and strain sensitivity to nitrous oxide and to non-oxygen-dependent reductive biotransformation of halothane in rats have all been reported.^{7,9} In a few people, plasma cholinesterase has been found to be completely absent or replaced by an inactive variant with resultant prolonged action of succinylcholine.¹⁰ Some breeds of swine are susceptible to malignant hyperthermia.¹¹ Metabolic rate increases with activity; hence, active animals require relatively larger doses of anesthetic agents. Mice

have been shown to be most sensitive to pentobarbital in the early morning. A seasonal response to morphine has been recorded in rabbits, and circadian rhythms have been shown to modify minimum alveolar concentrations for halothane and other inhalant anesthetics by 5% to 10% in rats.⁷

Pharmacokinetics

General anesthesia is produced by the action of an anesthetic on the brain and spinal cord. The agent must therefore achieve access to the central nervous tissue. Although Van Dyke and Chenoweth¹² demonstrated that significant quantities of some inhalation anesthetics are metabolized within the body, for practical purposes they are primarily exhaled. Small amounts are eliminated in feces and urine or diffused through the skin and mucous membranes. Thus, providing respiration and circulation are maintained, inhalants are readily eliminated from the body. In contrast, injectable agents depend on redistribution within the body, biotransformation, principally in the liver, and excretion via the kidneys. With injectable anesthetics, there is less control over the elimination process; for this reason, some consider them to be more dangerous than inhalant anesthetics.

Anesthetics are commonly administered by intravenous injection and occasionally by intramuscular, intrathoracic, intraperitoneal, subcutaneous, and even oral or rectal routes. Intravenous administration bypasses the absorption phase of the drug with the consequences that onset and intensity of action are less variable, titration of dose according to response is facilitated, and the risk of toxicity lessens quickly with the progressive decline of drug concentration in the plasma.¹³

The body may be considered to have multiple compartments (Table 2.1), which are differentiated by blood supply and tissue-blood partition coefficients. After initial intravenous injection, mixing and dilution rapidly occur, and an initial blood concentration of the drug is established. Blood thus becomes the medium by which the drug is delivered to and removed from its site of action. Factors affecting drug concentration and/or availability in the plasma also affect its concentration and availability at the site of action. Binding of drugs to plasma protein, in which form they cannot readily penetrate cellular membranes, and the removal of drugs by tissues that store, metabolize, and excrete them are both important factors that lower the effective concentration of drugs at their site of action.^{13,14} Binding is a reversible fusion of small molecules, such as barbiturates, with protein or other macromolecules, thereby limiting penetration of cellular membranes by molecular size, ionization, and limited lipid solubility. Protein binding varies with the properties of the drug, its concentration, and plasma pH and protein concentration. The fraction of bound drug increases with decreasing drug concentration and vice versa, and is modified by the presence of other drugs that compete for available binding sites. The rate of clearance of drug from the blood, the drug's distribution to the tissues, and availability of drug to produce its desired effects thus may all be modified by the drug concentration, plasma pH and protein, state of body hydration, and minimally by the presence of other drugs.¹⁴

After initial dilution within the vascular system, the drug is distributed to the various tissue compartments according to their

Table 2.1. Body compartments based on tissue perfusion.

Group	Region	Mass (kg)	% Cardiac Output
Vessel rich	Brain	1.4	14
	Liver (splanchnic)	2.6	28
	Heart	0.3	5
	Kidney	0.3	23
Intermediate	Muscle	31.0	16
	Skin	3.6	8

Vessel poor	Residual tissue	11.3	—
Total		63.0	100

From Bard.⁷³ Data on adipose tissue and residual tissue have been added.

perfusion, their capacity for the drug (volume of tissue \times tissue-blood partition coefficient), and the partial pressure gradient of drug between blood and tissue. The vessel-rich group of tissues achieves equilibrium with the blood more quickly than do other tissue groups (Table 2.2).¹⁴ Although fat and muscle groups have similar tissue blood flows per unit of tissue, the higher solubility of most anesthetics (e.g., thiobarbiturates) in fat than in muscle accounts for the greater time required to achieve equilibrium for fat than for muscle. Changes in tissue blood flow, solubility, and blood-tissue partial pressure gradients thus influence uptake and distribution of intravenous anesthetics. Since the plasma concentration of an intravenous anesthetic falls rapidly (Fig. 2.1),¹⁵ and its partial pressure is quickly exceeded by that in the vessel-rich tissues, anesthetic reenters the blood from these tissues to be redistributed to tissues that have greater time constants. This redistribution reduces anesthetic concentration in the brain, anesthesia lightens, and anesthetic accumulates in muscle, fat, and vessel-poor tissues.

The ultimate effect of any general anesthetic is contingent upon its ability to cross the blood-brain barrier. This barrier, like the placenta, has permeability characteristics of cellular membranes and therefore limits the penetration of nonlipophilic, ionized, or protein-bound drugs. Penetration of these barriers is, in fact, so slow that little or no drug of the aforementioned types enters the brain or fetus after a single intravenous bolus dose. The barriers are not, however, absolute, and slow penetration does occur, becoming significant when the level of drug is maintained over a prolonged period.¹³ The high lipid solubility of thiopental relative to pentobarbital accounts for the more rapid onset of, and recovery from, anesthesia induced by the former.¹⁶

Within moments of tissue uptake and redistribution, elimination of the drug begins. The circulation distributes drug to vessel-rich organs able to biotransform and/or excrete it. The liver is the primary site of biotransformation, whereas the kidney is primarily responsible for excretion. Other organs may occasionally be involved, such as in the elimination of morphine via the gastrointestinal tract.¹³ Biotransformation increases the rate of disappearance of the drug from active sites and converts most hypnotics

Table 2.2. Factors influencing rate of tissue equilibration of a drug such as thiopental.

Tissue	Blood Flow (L/min)	Tissue Volume (L)	Thiopental Tissue-Blood Partition Coefficient	Capacity ^a	Time Constant (min) ^b
Vessel-rich group	4.5	6	1.5	9	2
Muscle group	1.1	33	1.5	50	45

From Saidman.¹⁴

and anesthetics from lipophilic nonpolar compounds to polar water-soluble derivatives capable of excretion by the kidneys. Without such conversion, elimination of lipophilic nonvolatile drugs is markedly prolonged owing to reabsorption, after glomerular filtration, into the systemic circulation via the tubular epithelium. Although the metabolites produced by biotransformation are usually less active, in the case of prodrugs (e.g., chlo-

Fig. 2.1. Following an intravenous bolus, the percentage of thiopental remaining in blood rapidly decreases as the drug moves from the blood to the body tissues. Time to attainment of peak tissue levels is a direct function of tissue capacity for barbiturate relative to blood flow. Thus, a larger capacity or smaller blood flow is related to a longer time to reach a peak tissue level. Initially, most thiopental is taken up by the vessel-rich group (VRG) because of its high blood flow. Subsequently, the drug is redistributed to muscle and, to a lesser extent, to fat. Throughout this period, small but substantial amounts of thiopental are removed by the liver and metabolized. Unlike removal by the tissues, this removal is cumulative. Note that the rate of metabolism equals the early rate of removal by fat. The sum of this early removal by fat and metabolism is the same as the removal by muscle. From Eger.¹⁵

ral hydrate) toxic compounds may be produced.¹⁷ The biotransformation rate is determined by the drug concentration at the site of metabolism (e.g., plasma concentration and hepatic blood flow) and by the intrinsic rate of the process. The latter is determined by such factors as enzymatic activity and cofactor availability (e.g., genetics, presence of other drugs, nutrition, or hypoxia).¹³ Most drug metabolism follows first-order kinetics (a constant fraction is metabolized in a given period). In the event that the concentration exceeds the capacity of the biotransformation process (saturation), elimination assumes zero-order kinetics, where a constant amount of drug is eliminated,¹³ and the pharmacological effect is disproportionately prolonged with increasing or multiple doses.¹⁶ Species variations in biotransformation may also be encountered; for example, the duration and effects of lidocaine in humans, dogs, guinea pigs, and rats differ, and the glucuronide conjugation of drugs, such as morphine, salicylic acid, and propofol, in cats markedly differs from dogs.

Excretion subsequent to or independent of biotransformation is primarily a function of the kidney. Renal excretion is the principal process by which predominantly ionized drugs or those of limited lipid solubility are eliminated.¹⁶ The excretion rate is determined by renal blood flow, glomerular filtration, and tubular secretion and reabsorption. Filtered drug passes through the glomerulus. Other drugs and metabolites may require the active transport processes of tubular secretion, which are sensitive to transport inhibitors and hypoxia. Reabsorption is efficient for those drugs (e.g., nonpolar lipophilics) able to penetrate cellular membranes and is modified by pH (drug ionization) and the rate of tubular urine flow.¹³ Intravenous agents used to produce or facilitate anesthesia, such as barbiturates, narcotics, tranquilizers, and nondepolarizing relaxants, are excreted primarily by the kidneys.^{15,18} Although inhalant anesthetics are primarily eliminated by exhalation, their metabolites are excreted largely by the kidney.

Factors Modifying Pharmacokinetics

It is thus apparent that many factors of common occurrence, such as rate of administration and concentration of anesthetic, physical status, muscular development, adiposity, respiratory and circulatory status, drug permeability coefficients, prior and/or concurrent drug administration, fear, recent feeding, and solubility of inhalant anesthetics in bags and hoses may all modify the up-

take, distribution, and elimination of anesthetics. Concentration and rate of injection of a given dose affect anesthetic action, particularly with rapid-acting anesthetics. The more dilute the drug or slower the injection, the less is the effect produced.

Modification of cardiac output, ventilation, ventilation-perfusion ratios, and/or alveolar-capillary diffusion from any cause will influence both the uptake and elimination of inhalant drugs, most especially those of greater solubility. Some common examples causing these modifications include diaphragmatic hernia, pulmonary edema, pulmonary emphysema or atelectasis, and recumbency in large animals.

Permeation of the blood-brain barrier by narcotics and narcotic antagonists is contingent on partition coefficients, ionization, and protein binding, and is therefore influenced by hypocarbia and hypercarbia. For example, during hypocarbia (alkalemia), higher serum morphine concentrations, higher drug distribution in the lipid phase, and increased ratio of free base-acid salt of morphine facilitate penetration of morphine into the canine brain, despite decreased cerebral blood flow.¹⁹

Variation in distribution of blood to the vessel-rich and vessel-poor tissues, to fat, to muscle, and to the alveoli themselves will modify the pattern of induction and recovery. In shock, the proportion of the cardiac output flowing to the brain is increased, and the potential for redistribution is reduced. Owing to reduced blood volume, dilution of the drug is also diminished, as is hepatic and renal blood flow. The reduction in blood volume diminishes both biotransformation and renal excretion. Induction is thus rapid, the dose required is reduced, and recovery is delayed. Even removal of 2% of the body weight in blood tremendously prolongs dogs' recovery time from thiopental anesthesia.² It may thus be concluded that significant hemorrhage, such as might accompany a surgical bleed, will significantly increase sleeping time.

When fear, struggling, or fever occur, increases in cardiac output and decreases in circulation time prolong the time necessary for equilibration of inhalant anesthetic concentration between alveoli and pulmonary capillaries. Muscle and skin blood flow is increased, induction of inhalant anesthesia is delayed, and more anesthetic is required. It is well known that animals showing a period of excitement during induction of inhalant anesthesia always require more anesthetic. This causes a tendency toward overdosing, with its attendant dangers. For this reason, preanesthetic sedation is often advantageous.

Hounds such as the whippet, greyhound, Afghan, borzoi, wolfhound, and saluki have a low fat-to-body mass ratio, a low muscle-to-body mass ratio, and consequent increased blood levels of unbound drug when anesthetized with a barbiturate. Anesthesia with a barbiturate alone is thus characterized by increased sleep times, rougher recoveries, and occasional fatalities. Thin-type muscled or emaciated patients may have similar characteristics.²⁰

According to Dukes,²¹ a large meal of meat may increase the metabolic rate of dogs as much as 90% above the basal level (specific dynamic effect). Carbohydrate and fat also produce this elevation, though to a lesser extent. It is usually 12 to 18 h after the last meal before the basal metabolic rate is attained in carnivorous animals. In contrast, birds are more susceptible to starva-

tion. A 6-h preanesthetic fast may induce hypoglycemia and marked sensitivity to depressant drugs in small birds.²² Certainly it is important to consider that starvation induces low plasma glucose, mobilizes liver glycogen stores, and reduces circulating fatty acids, all of which may alter drug detoxification rates.⁷ In addition to altering the metabolic rate, feeding increases chylomicrons in the blood. It has been shown that thiobarbiturates localize in these, which shortens the anesthesia time.²³ Feeding also increases blood flow to the abdominal viscera and influences overall anesthetic distribution.

With the exception of the gastrointestinal tract, nitrogen is the major gas constituent of closed internal body spaces. Owing to the high blood-gas partition coefficient of nitrous oxide relative to nitrogen and the gases of the intestinal tract, administration of nitrous oxide transfers this gas to internal gas spaces of the body. The volume or pressure of the gases within these spaces may thus increase. Volume increases in highly compliant spaces (e.g., intestinal, peritoneal, and thoracic) and pressure changes in non-compliant spaces (e.g., sinuses and middle ear).¹⁵ In the intestinal loops of dogs anesthetized with halothane-oxygen and 75% nitrous oxide, the intestinal gas volume was shown to increase 1.8 times in 2 h and 2.5 times in 4 h, respectively. In experimental pneumothorax in dogs, the increase was more rapid: A 200-mL pneumothorax was doubled in 10 min, tripled in 45 min, and quadrupled in 2 h. In pneumoencephalograms in dogs, the inhalation of 75% nitrous oxide increased cisternal pressure by 60 torr in 10 min.¹⁵ Consequently, the use of nitrous oxide is contraindicated in patients with pneumothorax, in those undergoing pneumoencephalograms, and in patients with intestinal obstructions requiring prolonged anesthesia.

Most noninhaled drugs are weak acids (barbiturates) or weak bases (narcotics, narcotic antagonists, and muscle relaxants). Once the drug is injected, equilibrium between ionized and non-ionized forms of drug depends on the pH of the blood or tissues and the dissociation constant (pK_a) of the drug. A difference in pH between tissue and blood may thus cause a drug concentration difference. Plasma acidosis, for instance, increases intracellular barbiturate but decreases intracellular narcotic concentration.¹⁴

Drug availability at the site of action or of elimination is also modified by the degree of protein binding. Protein binding is diminished by uremia, hypoproteinemia, and minimally by administration of drugs competing for the binding sites. It may also be impaired by a change in pH or in the nature of the protein secondary to disease, or by dehydration. Decreased binding may make more drug available for specific action, with consequent increased sensitivity to a normal dose.¹⁴

Preanesthetic administration of opioid analgesics generally lowers the metabolic rate, whereas atropine administration causes a slight rise. When they are administered in combination, however, the metabolic rate is usually decreased. Generally speaking, tranquilizers can be expected to lower the metabolic rate.

It has been known for decades that administration of various drugs and pesticides can either stimulate or inhibit hepatic microsomal drug-metabolizing enzymes (enzyme induction and enzyme inhibition). More than 200 drugs are recognized as enzyme

Table 2.3. Examples of drugs capable of producing microsomal enzyme induction.

Hypnotics	Antihistaminics
Barbiturates	Diphenhydramine (Benadryl)
Glutethimide (Doriden)	Steroids
Ethanol	Cortisone
Chloral hydrate	Prednisone
Tranquilizers	Norethynodrel (Enovid)
Chlorpromazine (Thorazine)	Methyltestosterone
Promazine (Sparine)	Anesthetics
Meprobamate (Equanil)	Diethyl ether
Chlordiazepoxide (Librium)	Halothane (Fluothane)
Anticonvulsants	Insecticides
Diphenylhydantoin (Dilantin)	DDT
Methylphenylethylhydantoin (Mesantoin)	Chlordane

From Brown.¹⁷

inducers (Table 2.3). Enzyme levels are maximally enhanced after approximately 5 days of administration of the inducing agent.²⁴ The nature of the induction varies with the type of drug, its dose, and the patient's age, thyroid function, and genetics, to name a few factors.^{16,24} Enzyme induction with accelerated biotransformation reduces the pharmacological activity of drugs normally eliminated by biotransformation, such as certain barbiturates, tranquilizers, hypnotics, and anti-inflammatory drugs. Because inhalation anesthetics undergo minimal biotransformation, their elimination is influenced by enzyme induction less. Although this occurrence has little or no effect on the conduct of clinical anesthesia, it is of significance relative to viscerotoxicity. Inhalant anesthetics are variably metabolized to inorganic fluoride and hexafluoroisopropanol by cytochrome P-450, which, although produced in less than toxic concentrations (<50 µm/L), are potentially toxic to both the liver and the kidney.²⁵ The potential for such toxicity during anesthesia is enhanced by hypoxia. Toxicity associated with biotransformation is also enhanced by reduced liver antioxidants, such as glutathione or vitamin E. In all instances, toxicity of the organohalogens depends primarily on formation of reactive intermediates, especially those produced by non-oxygen-dependent (*reductive*) biotransformation,²⁵ and is contingent on the extent and type of biotransformation, and the metabolic and environmental drug pathways resulting from induction.²⁴ The extent to which such induced metabolic effects influence clinical animal anesthesia is unknown. Inhalant anesthetics (halothane, isoflurane, sevoflurane, and desflurane) are also known to form carbon monoxide and increase anesthetic circuit temperatures when they come in contact with soda lime or Barlyme.²⁶⁻²⁸ The production of carbon monoxide is highest with desflurane and isoflurane and almost nonexistent with halothane and sevoflurane, although sevoflurane causes the greatest increases in anesthetic circuit temperature and can be degraded to a nephrotoxic vinyl ether (compound A).^{29,30} Concentrations of compound A in the anesthetic circuit rarely reach nephrotoxic concentrations even during low-flow anesthesia unless the carbon dioxide-absorbant material has become desiccated.³⁰

Table 2.4. Interactions at tissue receptor sites.

<p>The following agents have neuromuscular blocking properties. They may intensify the effects of nondepolarizing neuromuscular blocking agents (tubocurarine, gallamine, and dimethyl tubocurarine), or they may interact with each other:</p>		
<i>Antibiotics</i>	<i>General Anesthetics</i>

Levarterenol	Halothane	of the heart to catecholamines by Drug 2
Isoproterenol	Thiamylal	

From Abbitt.⁷⁴

Hepatic microsomal enzymes may also be inhibited, with delay of biotransformation. Known inhibitors include organophosphorus insecticides, pesticide synergists of the methylenedioxyphenyl type, guanidine, carbon tetrachloride, chloramphenicol, tetracyclines, and certain inhalation anesthetics.^{16,17} Inhibition has been illustrated by the prolonged plasma half-lives of barbiturates, narcotics, and local anesthetics during halothane anesthesia and by prolonged barbiturate anesthesia after a prior or concurrent chloramphenicol medication.^{17,31}

Relevant drug interactions may also result from protein binding and interaction at receptor sites. To prevent or treat bacterial infections associated with surgery, antibiotics are often administered prior to, during, or immediately after general anesthesia. In many instances, little consideration is given to altered responses that may occur from the interaction between antibiotics and drugs commonly used in the operating room.³² For example, a variety of antibiotics have been shown to cause neuromuscular blockage, the most notable of which are the aminoglycosides (Table 2.4).^{32,33}

The effect of disease on the metabolic rate usually varies with its duration. In the early febrile stage, the rate may be increased;

however, as the disease progresses, toxemia may reduce the rate to low levels. Fever increases the metabolic rate in accordance with van't Hoff's law, which states that for each degree Fahrenheit the temperature rises, the metabolic rate increases by 7%. When animals suffer from toxemia or liver disease, liver functions are often impaired and the ability of the animal to detoxify anesthetics is depressed. Shock lowers the metabolic rate and, because of suppressed cardiovascular function, impairs uptake and distribution of anesthetic agents.

Hepatocellular disease causes reduced protein (primarily albumin) production with consequent limitation of protein binding, increased pharmacological activity of drugs, and unexpected sensitivity to such drugs as thiopental and propofol. Production of specific protein, such as pseudocholinesterase, may also be impaired, with consequent increased duration of action of succinylcholine. Hepatic disease may delay drug biotransformation because of enzyme inhibition or decreased hepatic blood flow.³⁴ Significant amounts of some drugs (e.g., morphine, chloramphenicol, and digitoxin) and/or their metabolites (polar, molecular weight > 300) are likely to be excreted in the bile.¹⁶ Drugs dependent on hepatic elimination must therefore be administered with caution and modified by dose in the presence of hepatic disease.

Distribution and elimination of anesthetic and related drugs can also be impaired by renal disease with increased potential toxicity. Protein binding of organic acids is reduced in uremic patients, causing increased pharmacological activity (sensitivity); examples include pentobarbital, phenylbutazone, and cardiac glycosides. The increase in free-drug fraction in plasma of patients with renal disease correlates with the degree of hypoalbuminemia.¹⁶ Renal disease may also limit excretion and thereby prolong activity of muscle relaxants, such as pancuronium.

The degree by which renal disease actually influences drug protein binding, and therefore overall drug activity and/or excretion, may be modified by fluid therapy (dilution or increased glomerular filtration) and by changes in plasma pH.¹⁵

Hyperthyroidism is accompanied by an elevated metabolic rate and may increase anesthetic requirement, whereas hypothyroidism is generally accompanied by a lowering of the metabolic rate and a reduced anesthetic requirement. Leukemia in some forms increases the metabolic rate, as does long-term severe pain, and thus these pathologies may likewise increase overall anesthetic requirement.³⁵

Irradiation may affect (a) potency, onset, duration of action, and brain levels of injectable anesthetics, and (b) activity of the hepatic microsomal enzyme system.³⁶ Earlier onset of drug action can apparently be caused by radiation-induced modification of the blood-brain barrier. In adult animals, drug action is prolonged, which may be caused by (a) sensitization with a region-specific increase in brain serotonin and/or (b) partial inhibition of hepatic oxidase. Prenatal irradiation may impair the hepatic microsomal enzyme system. The anesthetic effects of barbiturates (thiopental and pentobarbital) decrease immediately after irradiation (1 to 3 h). Later, as irradiation sickness develops (days 10 to 15), sensitivity to anesthetics increases.³⁷

Cellular Effects and Teratogenicity

Interest in mutagenic, carcinogenic, and teratogenic effects of anesthetics peaked after an increase in spontaneous abortions among anesthetists was noted in 1970.³⁸ It is assumed that this increased abortion rate was caused by chronic exposure to trace concentrations of anesthetics. Exposure to such anesthetic concentrations in the first trimester of pregnancy should be avoided. Exposure of rats to nitrous oxide on day 9 of gestation has been shown to cause fetal resorption and skeletal and soft tissue anomalies. Others have also demonstrated that inhalation anesthetics are teratogenic in animals, especially chicks.^{38,39} Corresponding teratogenesis in humans has not been conclusively proved.

Epidemiological studies have suggested an increased incidence of cancer among women, but not men, who work in operating rooms.³⁴ Commonly used anesthetics, with the exception of fluroxene, have not been shown to be potential carcinogens by *in vitro* tests. Both general and local anesthetics can inhibit cell division. Anesthetics also affect such immune phenomena as cellular adherence, phagocytosis, lymphocyte transformation, chemotaxis, and the killing of tumor cells.⁴⁰

Assessment of Anesthetic Actions

General anesthesia has simply been defined as complete unconsciousness.^{41,42} When inducing this state, however, anesthetists require all the following components in patients: unconsciousness, insensitivity to pain, muscle relaxation, and absence of reflex response. The degree to which these are required for specific procedures varies. Anesthetists must therefore select the most suitable drugs and be able to assess the degree to which the varying effects are induced. Anesthesia depth is often difficult to assess, and several experimental measures, including minimum alveolar concentration (MAC) and minimum inhibitory concentration (MIC), have been developed for assessing and comparing anesthetic activity (Table 2.5).^{41,42} Anesthetic drugs that induce adequate anesthesia in one species and operation may be insufficient at similar doses in another species. Signs characterizing a continuum of progressive increases in CNS depression and analgesia may not occur with some drugs and drug combinations. For example, the dissociatives do not induce the typical ocular signs of increasing CNS depression, and higher doses of propofol do not produce more insensitivity to pain commensurate with increased CNS depression. Consequently, veterinarians using modern anesthetic drugs must be familiar with their specific characteristics in order to use them effectively and safely.

Historically, the progressive changes produced by the administration of anesthetic drugs have been classified into four stages. Recognizing the signs characteristic of these stages following administration of most anesthetics enables anesthetists to determine whether the required CNS depression has been achieved or whether it is insufficient or too much.

Stages of General Anesthesia

For descriptive purposes, the levels of CNS depression induced by anesthetics have been divided into four stages depending on neuromuscular signs exhibited by patients (Table 2.6). It should

Table 2.5. Key terms.

Median alveolar concentration (MAC): The end-tidal concentration (in standardized pressure units) of inhaled anesthetic that ablates movement (e.g., withdrawal) in response to surgical incision in 50% of a test population. The MAC is synonymous with MAC immobility. The original acronym MAC stood for minimal alveolar concentration, an end point that measured the concentration of inhaled anesthetic required to block purposeful movement in an individual subject.

Median alveolar concentration awake (MAC-awake): The end-tidal concentration of inhaled anesthetic that prevents appropriate voluntary responses to spoken commands (e.g., to open one's mouth or to raise a hand) in 50% of a test population. This end point measures perceptive awareness rather than memory.

Median alveolar concentration for blunting autonomic responses (MAC-BAR): The end-tidal concentration of inhaled anesthetic that blocks changes in blood pressure and heart rate in response to surgical incision in 50% of a test population.

Minimum infusion rate (MIR): The minimum infusion rate of a drug, administered alone or in combination, required to eliminate reflexes commonly used to assess anesthetic depth (e.g., eyelid, laryngoscope, toe pinch, and tail clamp) in 50% of a test population.

Loss of righting reflexes (LORR): The failure of an animal to regain upright posture when placed on its back. Because this end point measures responses to nonnoxious stimuli, its dependence on anesthetic concentration is closely related to MAC-awake, which can be measured only in humans.

Potency: A measure of relative drug activity that is inversely related to the concentration required to produce a standard effect. A volatile anesthetic that produces a behavioral effect at half the concentration of another anesthetic is said to be twice as potent.

Hypnosis: There are various functional definitions of this term. We use it to connote drug-induced impairment of cognitive functions required for responding appropriately to environmental stimuli, including attention and perception. For a patient in the awake state, administration of inhaled anesthetics can produce a wide range of hypnotic depths, from mild inattention to unresponsiveness to noxious stimuli.

Sedation: There are various functional definitions of this term, which is sometimes used as a synonym for *hypnosis*. We use the term to connote drug-induced hypnosis with anxiolysis, diminished motor activity, and decreased arousal.

be emphasized that no clear division exists between stages, one blending into the next. In addition, variation in response among patients is to be expected. Preanesthetic medication, adequacy of oxygenation, carbon dioxide retention, and physical status of the patients all modify the signs. Patient response is also governed by the anesthetic that is being administered, considerable variation existing between anesthetics.

Stage I. This is termed the *stage of voluntary movement* and is defined as lasting from initial administration to loss of consciousness. Some analgesia may be present in the deeper phases of this stage. In any case, this stage is the most variable. Deviations are

caused by the anesthetic used, from variations in the temperament and condition of the patient, from the manner in which the animal is restrained, and from the rate of induction. Nervous animals are bound to resist restraint. Should the anesthetic necessitate the use of a mask or be irritating to the upper airway, fear with consequent resistance by the patient will be accentuated. Excited, apprehensive animals may struggle violently and voluntarily hold their breath for short periods. Epinephrine release causes a strong, rapid heartbeat and pupillary dilation. Salivation is frequent in some species, as are urination and defecation. With the approach of stage II, animals become progressively ataxic, lose their ability to stand, and assume lateral recumbency. Initially, they can turn or lift the head without support.

Stage II. This is called the *stage of delirium or involuntary movement*. As the CNS becomes depressed, patients lose all voluntary control. This feature marks the change from stage I. By definition, this stage lasts from loss of consciousness to the onset of a regular pattern of breathing. As a result of anesthetic depression of the CNS, reflexes become more primitive and exaggerated. Patients react to external stimuli by violent reflex struggling, breath holding, tachypnea, and hyperventilation. Continued catecholamine release causes a fast, strong heartbeat, cardiac arrhythmias may occur, and the pupils may be widely dilated. Eyelash and palpebral reflexes are prominent. Nystagmus commonly occurs in horses. During this stage, animals may whine, cry, bellow, or neigh, depending on the species concerned. In some species, especially ruminants and cats, salivation may be excessive; in dogs, cats, and goats, vomiting may be evoked. The larynx of cats and pigs is very sensitive at this stage, and stimulation may cause laryngeal spasms. Jaw tone is still present, and attempts at endotracheal intubation are met with struggling and may initiate vomiting in dogs and cats and active regurgitation in ruminants. In view of the exaggerated reflex responses during this stage, stimulation of any kind should be avoided.

Stage III. This is the stage of *surgical anesthesia* and is characterized by unconsciousness with progressive depression of the reflexes. Muscular relaxation develops, and ventilation becomes slow and regular. Vomiting and swallowing reflexes are lost.

In humans, this stage has been further divided into planes 1 to 4 for finer differentiation. Others have suggested the simpler classification of light, medium, and deep. Light anesthesia persists until eyeball movement ceases. Medium anesthesia is characterized by progressive intercostal paralysis, and deep anesthesia by diaphragmatic respiration.⁴³ A medium depth of unconsciousness or anesthesia has traditionally been considered a light plane of surgical anesthesia (stage III, plane 2) characterized by stable respiration and pulse rate, abolished laryngeal reflexes, a sluggish palpebral reflex, a strong corneal reflex, and adequate muscle relaxation and analgesia for most surgical procedures. Deep surgical anesthesia (stage III, plane 3) is characterized by decreased intercostal muscle function and tidal volume, increased respiration rate, profound muscle relaxation, diaphragmatic breathing, a weak corneal reflex, and a centered and dilated pupil. If CNS depression is allowed to increase further, patients will progress to stage IV.

Stage IV. In this stage, the CNS is extremely depressed, and

Table 2.6. Characteristics of the stages of general anesthesia.

		Stage of Anesthesia			
		I	II	III	IV
		Plane			
		1	2	3	4
		Light	Medium		Deep
System Affected	Characteristic Observed				
Cardiovascular	Pulse ^a	Tachycardia	Progressive bradycardia		Weak or imperceptible
	Blood pressure ^a	Hypertension	Normal	Increasing hypotension	Shock level
	Capillary refill	1 s or less		Progressive delay	3 s or longer
	Dysrhythmia probability	+++	++		++++
	Respiratory rate ^a	Irregular or increased	Progressive decrease		Ceased; may gasp terminally
				++	Ceased
	Respiratory depth ^a	Irregular or increased	Progressive decrease		Pale to white
	Mucous membrane, skin color	Normal		Irregular	Ceased
	Respiratory action	May be breath holding	Thoracoabdominal, abdominal		Diaphragmatic
	Cough reflex	++++	Lost		Ceased
	Laryngeal reflex	++++ May vocalize			
	Intubation possible	No	Lost		
	Salivation	Yes			
Gastrointestinal	Salivation	++++			Absent
	Oropharyngeal reflex	++++	Diminished, absent, except in ruminants		
	Vomiting probability	+++	Lost		
	Reflux (regurgitation) potential	None	Very slight		
	Tympany (rumen, cecum)	None	Increases with relaxation		++++
	Pupils	None	Potential increases with duration of anesthesia		
Ocular	Corneal reflex	Dilated	Normal or constricted, progressive dilation		Acutely dilated
	Lacrimation	Normal	Diminishes, lost (horses may persist)		Absent
	Photomotor reflex	Normal	+	Diminishes, absent	Absent
	Palpebral reflex	Normal	+	Diminishes, absent	Absent
	Eyeball position	Normal	+	Diminishes, absent	Absent
	Nystagmus	++++ Especially horses and cows	Ventromedial in dogs and cats or central		
	Jaw tone	++++		+	None
Musculoskeletal	Limb muscle tone	++++	Decreased, minimal		Lost
	Abdominal muscle tone	++++	Decreased, minimal		Lost
	Sphincters (anus, bladder)	++++	++ Decreased, minimal		Lost
	Sensorium	May void	Progressive relaxation		Control lost
Nervous	Pedal reflex	+++	Lost		
	Reaction to surgical manipulation	++++	Decreased		
			Absent		
			None		

^aSurgical stimulation causes increased heart rate, blood pressure, and respiratory rate via autonomic responses that persist in plane 2. Vagal reflexes due to visceral traction persist in plane 3. + to ++++ = degree present.

respirations cease. The heart continues to beat only for a short time. Blood pressure is at the shock level, capillary refill of visible mucous membranes is markedly delayed, and the pupils are widely dilated. The anal and bladder sphincters relax. Death quickly intervenes unless immediate resuscitative steps are taken. If the anesthetic is withdrawn and artificial respiration is initiated before myocardial collapse, these effects may be overcome and patients will go through the various stages in reverse.

The stages just described are best seen when inhalant anesthetics are administered, probably because considerable time is required for an anesthetic concentration to accrue in the CNS. This allows the various signs to become apparent. With some intravenous anesthetics (e.g., dissociatives) or the concurrent use of preanesthetic sedatives, anesthetic-induced depression is difficult to assess, and signs of anesthetic depression are not uniformly apparent.

Signs of Anesthesia

Respiration

Respiratory minute volume typically increases during stage I especially if preanesthetic sedation is not used. As anesthetic depression increases to stage II, respirations become irregular, and breath holding commonly occurs. With the onset of stage III, breathing once again becomes regular. The respiration depth at this time depends on the respiratory threshold to stimulation; surgical manipulation, for instance, stimulates respiration, whereas premedication depresses it. If barbiturates or propofol are used for either preanesthetic sedation or induction, early respiratory depression occurs. During stage III, the intercostal muscles and the diaphragm weaken progressively.⁴⁴ The depth of respiration declines progressively, thoracic movement decreases, respiration becomes largely or entirely abdominal, and the respiration rate may increase. With an overdose, respiration becomes entirely abdominal, and diaphragmatic contraction causes the abdomen to bulge during inspiration and the thorax to collapse. During expiration, the reverse occurs, the anterior excursion of the diaphragm causing the thorax to expand. With progressive overdose, diaphragmatic movements become smaller, respiratory exchange diminishes further, and respirations are gasping and ultimately cease. In dogs, oral and cervical movements (tracheal tugging) may be observed during this stage.

Circulation

Although blood pressure may be monitored by indirect methods or by direct arterial catheterization, veterinarians often do not measure pressure, but must depend on the pulse rate or bleeding at the surgical site, and on induction of momentary blanching by compressing an exposed mucous membrane (such as the conjunctiva, oral mucosa, or tongue) to give some indication of the circulatory status of patients. The mucous membranes may show pallor as a result of hemorrhage or shock and cyanosis caused by hypoxia. In rodents, feet, ears, and muzzles are observed for such signs; in poultry, it is necessary to examine the comb and/or wattles; in rats and rabbits, the color of light reflected from the eye is helpful.

During stages I and II, the pulse is strong and accelerated. Arrhythmias sometimes occur during stage II. In stage III, the pulse rate is regular and usually slightly accelerated. During inhalant anesthesia, progressive bradycardia occurs. Pain stimulation in light stage III may induce tachycardia or even arrhythmias. As the anesthesia depth increases, blood pressure declines, and the pulse weakens.

Ocular Signs

These include eyeball position and movement, photomotor reflexes and pupillary size, lacrimation, and palpebral, corneal, and conjunctival reflexes. Although ocular signs are often helpful, they can be quite variable in most species and should never replace observation of respiratory and circulatory signs.⁴⁵ Eyeball movement is especially valuable in horses, in which nystagmus occurs with the onset of stage II and continues through light surgical anesthesia. In cattle, eyeball rotation is very consistent and a reliable indicator of anesthetic depth whether anesthesia is produced by inhalation anesthetics, barbiturates, or combinations of central muscle relaxants, dissociatives, and α_2 -agonists (Fig. 2.2). In light and medium surgical anesthesia in dogs, cats, and pigs, their eyeballs are generally turned downward. The eyelids during this time are usually closed, and the third eyelid overlays the medial portion of the cornea. The palpebral reflex becomes sluggish in all species when surgical anesthesia is attained. The pupillary size is modified by the degree of light and by premedication with such drugs as morphine and atropine. The pupils are dilated during stage II but thereafter constrict. In deep (stage III, plane 4) anesthesia or stage IV, pupillary dilation indicates overdose. Reflex constriction of the pupil on exposure to light stimuli (photomotor reflex) is lost on transition from light to medium surgical anesthesia.

Lacrimation is no longer observed in the deeper stages of surgical anesthesia. In horses, lacrimation is a consistent sign of light surgical anesthesia. Because the eyes may also be open in deep anesthesia, the cornea appears dull and is subject to the adverse effects of drying. To protect against this hazard, ointment should be applied to the eyes or they should be taped closed after anesthesia has been induced. The palpebral reflex, which is a blink induced by touching the eyelids, becomes sluggish or is lost as medium surgical anesthesia develops. Blinking induced by gently touching the cornea (corneal reflex) is variable, but is usually lost shortly after the palpebral reflex. In horses, the corneal reflex persists into deeper anesthesia.

Pharyngeal and Upper-Airway Reflexes

Suppression of these reflexes is of particular importance for endotracheal intubation and for induction of anesthesia in animals, such as ruminants, with full stomachs. Coughing and laryngospasm in response to intubation are lost in light surgical anesthesia, but may persist into medium anesthesia in cats. The intensity of these responses varies with the animal species concerned: especially intense in the cat, and relatively mild in cattle and horses. The swallowing and vomiting reflexes disappear with the onset of stage III; like the laryngeal reflexes, the swallowing reflex persists into medium anesthesia in cats.

Fig. 2.2. Eyeball position during induction and maintenance of general anesthesia of cows. **A:** Position of the cow's eye when awake and positioned in lateral recumbency. Induction of anesthesia is accompanied by a progressive ventral rotation of the eyeball, becoming partially obscured by the lower eyelid. **B and C:** As the depth of anesthesia is increased, the cornea becomes completely hidden by the lower eyelid. **D:** At this time, surgical anesthesia is present. Applying traditional methods of assessing anesthetic depth, the cow would be in stage III, plane 2 to 3. Increasing the depth of anesthesia causes the eye to rotate dorsally, with the cornea becoming centered between the palpebra. **E:** At this time, deep surgical anesthesia with profound muscle relaxation and central nervous system depression is present. Eye reflexes have been lost, and the cornea will appear dry and wrinkled. Maintaining this extreme depth of anesthesia can rapidly end in death of the patient. Decreasing the depth of anesthesia is accompanied by eyeball rotation occurring in reverse order. From Thurmon and Benson.⁷⁵

Other Signs of Anesthesia

After an initial increase during stage II, muscle tone progressively declines, as indicated by relaxation of the abdominal muscles, decreasing efficiency of the intercostal muscles, and reduced resistance to passive flexion of the limbs. In lean animals with shorthaired coats, abdominal muscle relaxation may be such that the profile of viscera is readily apparent. The contour of the rumen may become visible in some ruminants. In cats, detectable extensor tone, in response to passive flexion of the limb by pushing on the digits, persists into medium surgical anesthesia. Generally, limb muscles are relaxed in light anesthesia, whereas abdominal muscles are not well relaxed until anesthesia is deep. The tone of the anal sphincter of horses is a good indicator of relaxation in this species. During stage II, the sphincter is tight, but as anesthetic depth increases, the sphincter relaxes so that in deep surgical anesthesia it may gape to such an extent that feces can be observed in the anal canal. Concomitant with progressive dilatation, the anal sphincter gradually loses ability to contract in response to mechanical stimulation in medium to deep surgical anesthesia. Deliberate anal dilation induces an increase in respiratory rate; this respiratory reflex is lost during early stage III.

In dogs, response to opening the jaw is considered to be a useful sign by many veterinarians. During transition from stage II to stage III, passive opening of the mouth may elicit yawning,

which is a response especially likely in barbiturate anesthesia. Resistance to opening the mouth fully is lost in medium anesthesia. The digital (pedal) reflex, in which the limb is flexed in response to painful stimulation of the digits or interdigital region, is also a useful guide to the depth of anesthesia in dogs, cats, and rats. This reflex is lost as the transition from light to medium surgical anesthesia occurs. Head shaking in response to ear pinching is a helpful sign in cats, rabbits, and guinea pigs, and is lost with the onset of surgical anesthesia. In cattle and cats, the ear-flick reflex in response to tactile stimulation of the hairs within the pinna remains until a medium level of anesthesia is present. Twitching of the whiskers in response to ear pinching is lost as light anesthesia progresses to medium. Response to painful stimulation by pinching the tail of rodents and snakes and the wattles or combs of birds is a useful indicator of the onset of surgical anesthesia. The anal reflex remains until a deeper plane of anesthesia is achieved in birds and is often referred to as the *vent reflex* in this species.

Signs of Anesthesia Recovery

As anesthetic drugs are eliminated from the CNS, the degree of anesthesia lightens and reverse progress through the stages of anesthesia occurs. Induction techniques are usually selected and performed to minimize the duration of stage II, in which excite-

Table 2.7. Classification of physical status^a

Category	Physical Status	Possible Examples of This Category
I	Normal healthy patients	No discernible disease; animals entered for ovariohysterectomy, ear trim, caudectomy, or castration
II	Patients with mild systemic disease	Skin tumor, fracture without shock, uncomplicated hernia, cryptorchidectomy, localized infection, or compensated cardiac disease
III	Patients with severe systemic disease	Fever, dehydration, anemia, cachexia, or moderate hypovolemia
IV	Patients with severe systemic disease that is a constant threat to life	Uremia, toxemia, severe dehydration and hypovolemia, anemia, cardiac decompensation, emaciation, or high fever
V	Moribund patients not expected to survive 1 day with or without operation	Extreme shock and dehydration, terminal malignancy or infection, or severe trauma

^aThis classification is the same as that adopted by the American Society of Anesthesiologists.

ment and motor activity may occur. During recovery, however, stage II can be prolonged. Every effort should be made to avoid stimulation of the animal at this time. This stage of recovery is of particular concern when large animals are anesthetized. Horses are especially subject to excitement and struggling during this period. The use of short-acting anesthetics and postoperative sedation can do much to minimize recovery delirium.

During recovery, the question arises of how best to judge the recovery from anesthesia, particularly when so many modifying factors must be considered. Experienced anesthetists find themselves relying less on classic signs of anesthesia and more on a patient's response to stimuli. Needless to say, effective anesthesia is not only that which just obliterates a patient's response to painful stimuli without excessive depression of vital functions, but also that from which recovery is relatively rapid and uneventful.

Patient Evaluation and Preparation

A thorough history should be recorded and a complete physical examination performed before anesthesia. Every animal should be categorized regarding its physical health, pain and stress status, and anesthetic risk (Table 2.7). Appropriate medical and nursing issues should be reviewed and provided before producing anesthesia.

Preanesthetic Evaluation

The purpose of the preanesthetic patient evaluation is to determine a patient's physical status. In general, *physical status* refers to the presence or absence of disease, severity of pain (if present), and the level of stress. Specifically, the term refers to a patient's medical condition, including the degree of pain and stress and the overall efficiency and function of organ systems. The goal is to determine any deviations from the norm that will affect anesthetic uptake, action, elimination, and safety. Organ systems of greatest concern are the nervous, cardiopulmonary, hepatic, and renal. Knowledge of the physical status is an aid to selection of anesthetic drugs and techniques and arriving at a preanesthetic prognosis. Physical status is one of the best determinants of the likelihood of cardiopulmonary emergencies occurring during the anesthetic period. As such, it is much better than arbitrary predic-

tors such as age. It is axiomatic that the sicker a patient (the poorer the physical status) is, the greater is the likelihood of adverse events or death. Physical status is determined by (a) history, including an assessment of pain; (b) inspection (attitude, condition, conformation, temperament, stress, or distress); (c) palpation, percussion, and auscultation; and (d) laboratory determinations and special procedures (e.g., radiographs). Any abnormalities should be noted. Those that can be corrected should be. If no further improvement can be reasonably corrected by medical treatment, the patient's overall risk and prognosis can be determined.

The history and physical examination are the best determinants of the presence of disease. Laboratory tests should be done on the basis of the physical exam and history. The use of extensive laboratory screening of patients has not been found to improve the outcome of surgical patients in either human or veterinary medicine. Laboratory screenings frequently fail to uncover pathological conditions, they detect abnormalities that do not necessarily improve patient care or outcome, and they are inefficient in screening for asymptomatic disease. Moreover, abnormalities that are detected seldom have any impact on anesthetic protocol or surgical management.⁴⁶

The use of multiple chemical and enzymatic analyses of blood and urine in surgical patients has become common with the advent of automated analyzers and their availability to veterinarians. Their use, as previously noted, has not appreciably improved the outcome of veterinary surgical patients. Frequently, when an abnormal value is reported, surgery is delayed and the test rerun, adding to the total cost of the procedure, with little patient benefit. It should be remembered that reference ranges compare the test result with a set of values from a group of similar animals in a defined state of health (determined by physical examination). The reference range, *normal*, is presumed to be within ± 2 standard deviations of the mean. A common error, however, is to assume that the upper and lower limits of this presumed normal range represent a rigid cutoff point between a state of health and disease or normal and abnormal function. Indeed, 5% of normal animals fall outside this range. Furthermore, a test result in the normal range (within 2 standard deviations of the mean) implies that function is normal, but does not account for normoglycemic diabetics or animals with cirrhosis that have normal hepatic en-

zymes and bilirubin values. Because 5% of nondiseased animals fall outside the normal range as previously defined, 1 of 20 healthy animals tested will fall outside the range. If multiple tests are performed, the frequency of abnormal test results in nondiseased animals increases with the number of tests done. As the number of tests increases, the likelihood of an abnormal result in a nondiseased animal increases. In a ten-test profile of independent parameters, there is a 40% chance of at least one test result being outside the reference range. Reference ranges do provide useful standards by which extreme test values can be recognized. However, there is no consistent relationship between the extremeness of test results and the presence of a disease. Frequently, there is overlap in the distribution of measured test values between healthy and diseased populations. This is caused in part by the statistical nature of the reference ranges, the inherent spectrum of disease (latent to fulminant), and the variable rate of disease progression and host response that the test measures. Thus, test results must be carefully interpreted in light of the physical examination and the history and not rigidly interpreted on an empirical basis of simply being more than 2 standard deviations from the mean of the reference population.⁴⁷

A thorough preanesthetic evaluation of patients is essential for successful anesthesia and subsequent surgery. Every effort should be made to detect factors that may modify anesthetic action and safety, emphasizing concurrent diseases, current or projected painful conditions, and stress status. Although such evaluation is important in all patients, it is especially important in critically ill patients. In addition to body weight and vital signs, the following should be included: The history should include previous and current health; presenting complaint, its severity, and its duration; concurrent symptoms of disease (e.g., diarrhea, vomiting, exercise intolerance, ascites, rales, dyspnea, and polyurea-polydipsia); pregnancy; exposure to drugs; prior anesthetic history; and recent feeding. Especially important to consider are the status of cardiopulmonary function, the potential of acid-base or electrolyte imbalance, the possibility of a full or distended stomach or of hepatic or renal disease, and the prior or concurrent administration of drugs (e.g., organophosphates, diuretics, digitalis preparations, anticonvulsants, corticosteroids, aminoglycoside antibiotics, sulfonamides, and nonsteroidal anti-inflammatory drugs).

All body systems should be examined and any abnormalities identified. The physical examination and medical history will determine the extent to which laboratory tests and special procedures are necessary. In all but extreme emergencies, packed cell volume and plasma protein concentration should be routinely determined. Contingent on the medical history and physical examination, additional evaluations may include complete blood counts; urinalysis; blood chemistries to identify the status of kidney and liver function, blood gases, and pH; electrocardiography; clotting time and platelet counts; fecal and/or filarial examinations; and blood electrolyte determinations. Tests should not be run unless it is suspected their results could cause a change in anesthetic management. Radiographic and/or fluoroscopic examination may also be indicated, especially in animals, such as primates, calves, sheep, and rodents, that are susceptible to chronic respiratory infections.

Following examination, the physical status of the patient should be classified as to its general state of health according to the American Society of Anesthesiologists (ASA) classification and the information recorded (Table 2.7). This mental exercise forces the anesthetist to evaluate the patient's condition and proves valuable in the proper selection of anesthetic drugs. Classification of overall health is an essential part of any anesthetic-record system. The preliminary physical examination should be done in the owner's presence, if possible, so that a prognosis can be given personally. This allows the client to ask questions and enables the veterinarian to communicate the risks of anesthesia and allay any fears regarding management of the patient.

Pain

Pain and the biological responses to it are part of a highly integrated warning system directed toward maintaining homeostasis and preventing further injury.⁴⁸ Pain, along with heart rate, respiratory rate, temperature, and blood pressure, should be considered the fifth clinical sign routinely assessed prior to medical treatment. The pain system includes sensors, neural pathways, and processing centers that are responsible for detecting, transmitting, and activating animals' biological and behavioral responses to noxious events. Pain warns animals of potential tissue damage and protects them from further injury. Animal pain has been defined as "an aversive feeling or sensation associated with actual or potential tissue damage," broadening the dictionary definition to include behavioral changes, neuroendocrine activation, and the "stress response."⁴⁸ The latter definition is the basis for why pain perception alone is not considered to fully represent the pain experience and helps to explain the relationship between painful experiences and pain behaviors in animals. Nociception is the neurophysiological process whereby noxious mechanical, chemical, or thermal stimuli are transduced into electrical signals (action potentials) by high-threshold pain receptors (nociceptors) located on the peripheral terminals of very thin, noninsulated or minimally insulated (myelinated) C and A- δ nerve fibers, respectively.⁴⁸ These electrical signals are subsequently transmitted to the superficial and deeper layers of the dorsal horn of the spinal cord, modified (modulated), and projected to the brain (perception). The free nerve endings of afferent sensory pain fibers encode noxious stimuli, depending on the modality, intensity, duration, and location of the stimulus. The intensity of the stimulus producing pain is considerably greater than that required to elicit innocuous sensations and is the most important factor determining the severity of pain. In the absence of tissue damage, pain is considered to be *physiological* or "ouch" pain, which warns and protects animals from tissue damage. *Pathological* pain occurs when tissues or nerves are damaged and has been "clinically" categorized based on the most likely mechanism responsible (e.g., inflammation, neuropathy, and cancer).⁴⁸ Unlike physiological pain, pathological pain can be produced by stimulation of large myelinated A- β nerve fibers, which normally do not transmit painful sensations. Severe injuries and chronic pathological pain states can change (dynamic plasticity) the intensity of the stimulus required to initiate pain (hypersensitivity). The develop-

ment of tissue hypersensitivity (nociceptor sensitization) can be responsible for the development of increased sensitivity to noxious stimuli (hyperalgesia) and painful sensations arising from normally nonpainful perceptions (allodynia).

Tissue damage and inflammation can result in the activation and release of intracellular components from damaged cells, inflammatory cells (lymphocytes, neutrophils, and macrophages), and the primary nerve fiber itself. The local release and spread of ions (hydrogen and potassium), prostaglandins (prostaglandin E₂), bradykinin, cyclooxygenase, neurotrophic growth factors and cytokines (interleukin 1, interleukin 6, and tumor necrosis factor α [TNF- α]) sensitize pain fibers to subsequent painful and nonpainful stimuli.⁴⁸ Mast cell degranulation increases the local concentration of 5-hydroxytryptamine (5-HT or serotonin) and histamine. Together these substances produce a “sensitizing soup” that lowers the threshold of nociceptors and activates “silent” nociceptors (10% to 40% of the total nociceptor population), amplifying the pain response and producing a zone of primary hyperalgesia.⁴⁸ Local vasodilation and plasma extravasation further amplify the inflammatory response and spread hypersensitivity to surrounding tissues, and hypersensitivity to non-painful stimuli occurs.

More severe tissue trauma or nerve damage produces electrical signals that continuously bombard dorsal horn neurons, producing a cumulative effect and activation of alternate receptors on dorsal horn neurons, resulting in central sensitization. Central sensitization occurs when the cumulative effects of frequent (chronic) or severe peripheral nociceptor input releases excessive quantities of CNS neurotransmitters (substance P, neurokinin A, and brain-derived neurotrophic factor), including glutamate, which activates *N*-methyl-D-aspartate and other receptors, resulting in an increase in sensitization (*windup*) of neurons in the dorsal horn of the spinal cord.⁴⁸ Sensitization of dorsal horn neurons can last for hours and is believed to be responsible for pain outside the area of tissue injury (secondary hyperalgesia) and allodynia. Central sensitization is fundamentally different from peripheral sensitization in that the former enables low-intensity stimuli to produce pain sensations. When pain is chronic, central sensitization enables sensory fibers that normally transmit non-painful stimuli (low-threshold A- β fibers) to produce pain as a result of changes in sensory processing in the spinal cord. Central sensitization increases the responsiveness of dorsal horn neurons to sensory inputs (allodynia), expands receptive field, and is believed to be responsible for the discomfort and agony produced by severe injury. Chronic pain, therefore, can be responsible for activity-dependent plasticity and long-term structural changes (neuroplastic) within the CNS, leading to the development or modification of memory patterns that change animal behavior. Together the development of windup and central sensitization represent a process that exists as a consequence of continuous, unrelenting, and untreated pain causing stress and distress. The diagnosis and treatment of pain, therefore, require an appreciation of its consequences, a fundamental understanding of the mechanisms responsible for its production, and a practical appreciation of the analgesic drugs that are available. Semiobjective and objective behavioral, numerical, and categorical methods

3. Pain management is individualized for each patient
4. Practice utilizes preemptive pain management
5. Appropriate pain management is provided for the anticipated level and duration of pain
6. Pain management is provided for the anticipated level and duration of pain
7. Patient is reassessed for pain throughout potentially painful procedure
8. Patients with persistent or recurring disease are evaluated to determine their pain management needs
9. Analgesic therapy is used as a tool to confirm the existence of a painful condition when pain is suspected but cannot be confirmed by objective methods
10. A written pain management protocol is utilized
11. When pain management is part of the therapeutic plan, the client is effectively educated

have been developed for the diagnosis of pain and, among these, the visual analogue scale (VAS) has become popular. A trained observer rates pain along a 10-cm line from no pain to worst possible pain and, based on this rating, prescribes appropriate therapy. Ideally, pain therapy should be directed toward the mechanisms responsible for its production (multimodal therapy), with consideration, when possible, of initiating therapy before pain is initiated (preemptive therapy). The American Animal Hospital Association (AAHA) has developed standards for the assessment, diagnosis, and therapy of pain that should be adopted by all veterinarians (Table 2.8).

Stress

Animals feel pain, which affects their physiology, quality of life, and interactions with their environment. Pain normally serves a protective function by warning animals of real or impending tissue damage but, when severe or chronic, is responsible for temporary periods of dramatic increases in sympathoadrenal and neuroendocrine activity, which is commonly referred to as the *stress response*. Both acute and chronic pain can produce stress.⁴⁹ Untreated pain can initiate an extended and potentially destructive series of events characterized by neuroendocrine dysregulation, fatigue, dysphoria, myalgia, abnormal behavior, and altered physical performance. This type of response has been termed the *sickness syndrome*. Even without a painful stimulus, environmental factors (loud noise, restraint, or a predator) can produce a state of anxiety or fear that sensitizes and amplifies the stress response. *Distress*, an exaggerated form of stress, is present when the biological cost of stress negatively affects the biological functions critical to survival. Pain, therefore, should be considered in terms of the stress response and the potential to develop distress.

Normally, the stress response is an adaptive pattern of neural, behavioral, endocrine, immune, hematologic, and metabolic changes directed toward maintaining or restoring homeostasis.⁴⁹ Most stress is temporary because the stressor is removed. During threatening circumstances, the stress response prepares animals for an emergency reaction and fosters survival (fight or flight). Acute pain can produce significant stress in dogs and cats. Pain induced by surgical or accidental trauma evokes characteristic responses typified by activation of the sympathetic branch of the autonomic nervous system, secretion of glucocorticoids (primarily cortisol), hypermetabolism, sodium and water retention, and altered carbohydrate and protein metabolism (Table 2.9). Increased central sympathetic output causes increases in heart rate and arterial blood pressure, sweating, piloerection, and pupil dilatation. The secretion of catecholamines from the adrenal medulla and spillover of norepinephrine released from postganglionic sympathetic nerve terminals augment these central effects. Increased concentrations of circulating catecholamines augment glycogenolysis and gluconeogenesis and promote insulin resistance. Corticotrophin-releasing factor (CRF) is released from the hypothalamus, amplifying the startle response, anxiety, fear and, in some animals, rage. CRF serves as an excitatory neurotransmitter releasing cortical norepinephrine, dopamine, and 5-HT, with resultant behavioral changes, including hyperresponsiveness, hyperarousal, vigilance, and agitation. Mild to moderate acute pain caused by tissue trauma may activate the immune response. Severe acute pain produces behavioral, autonomic, neuroendocrine, and immunologic responses that upset homeostasis and can lead to self-mutilation and immune incompetence. Chronic pain produces sustained increases in circulating concentrations of cortisol, epinephrine, norepinephrine, and glucagon, suppressing both the humoral and cellular immune response. The systemic release of endogenous opioids (endorphin and enkephalin) may contribute to immunosuppression. The messengers of the immune system are cytokines (interleukin 1, interleukin 6, and TNF- α). The acute-phase response can be triggered by severe stress from any cause. The main feature of the acute-phase response is the release of proteins from the liver that act as inflammatory mediators and scavengers in tissue repair. They include C-reactive protein, fibrinogen, macroglobulin, and antiproteinases. Excessive production of these proteins can contribute to the development or maintenance of the systemic inflammatory-response syndrome (SIRS). The peripheral blood white cell count generally reflects a stress leukogram typified by an elevated number of immature polymorphonuclear leukocytes (left shift) and reduced numbers of lymphocytes. Stress induced by chronic pain often produces morphological changes that are typical of long-term aversive stimuli and include a failure to thrive, poor hair coat, weight loss, and acceleration of aging. Ultimately, changes in an animal's behavior may be the most noninvasive and promising method to monitor the severity of an animal's pain and associated stress.

Patient Preparation

Too often, operations are undertaken with inadequate preparation of patients. Some foresight here is beneficial. With most types of

Table 2.9. Consequences and indicators of the stress response.

Neurohumoral response
Pituitary

Self-mutilation

CNS, central nervous system.

general anesthesia, it is best to have patients off feed for 12 h previously. It should be recalled that some species are adversely affected by fasting. Birds, neonates, and small mammals may become hypoglycemic within a few hours of starvation, and mobilization of glycogen stores may alter rates of drug metabolism and clearance. The latter may be a factor in ruminants. In contrast, feeding dogs increases their metabolic rate for up to 18 h. Induction of anesthesia in animals having a full stomach should be avoided, if at all possible, because of the hazards of aspiration. Distension of the rumen in sheep and larger ruminants has been shown to impair ventilation, with consequent hypoxemia and hypercapnia.⁵⁰ In horses, a full stomach may rupture

during induction and casting. Although limitation of food does not empty the rumen, the possibility of regurgitation is perhaps reduced if water is withheld for 12 to 24 h prior to induction.

In most species, especially in the young and aged, water is usually offered up to the time that preanesthetic agents are administered. It should be remembered that many older animals suffer from renal disease. Although these animals remain compensated under ideal conditions, the stress of hospitalization, water deprivation, and anesthesia, even without surgery, may cause acute decompensation. To withhold water from these animals, even for short periods, may prove hazardous. Ideally, a mild state of diuresis should be established with intravenous fluids in nephritic patients prior to the administration of anesthetic drugs. In any case, it is good anesthetic practice to administer intravenous fluids during anesthesia to help maintain adequate blood pressure and urine production, and to provide an available route for drug administration.

Systemic administration of antibiotics preoperatively is a helpful prophylactic measure prior to major surgery or if contamination of the operative site is anticipated. However, the potential interaction of antibiotics with anesthetic or related drugs should receive careful consideration, and antibiotics ideally are given 1 or 2 h before anesthetic induction begins. In surgery of the colon, rectum, and anus, preoperative enemas administered 1 or 2 days prior to surgery will remove fecal material and facilitate manipulation. On the other hand, an enema just prior to surgery may complicate the situation, because feces will be fluid and the operative site may easily become contaminated.

Dehydrated animals should be treated with fluids and appropriate alimentation prior to operation; fluid therapy should be continued as required. The delay occasioned by administration of fluids is more than compensated for by the animal's increased ability to withstand the stress of anesthesia and surgical trespass. An attempt should be made to correlate the patient's electrolyte balance with the type of fluid that is administered. Anemia and hypovolemia, as determined clinically and hematologically, should be corrected by administration of whole blood or blood components and balanced electrolyte solutions. Patients in shock without blood loss or in a state of nutritional deficiency benefit by administration of plasma or plasma expanders.⁵¹

Several conditions may severely restrict effective ventilation. These include upper-airway obstruction by masses or abscesses, pneumothorax, hemothorax, pyothorax, chylothorax, diaphragmatic hernia, and gastric or rumen distention. Affected animals are often in a marginal state of oxygenation. Oxygen administration by nasal catheter or mask is indicated if the patient will accept it. Alternatively, a tracheotomy may be performed under local anesthesia prior to induction. Intrapleural air or fluid should be removed by aspiration prior to induction, because the effective lung volume may be greatly reduced and severe respiratory embarrassment may occur on induction. Although no attempt should be made to insert an endotracheal catheter in these patients prior to anesthesia, this must be done immediately after induction. Anesthetists should be prepared to carry out all phases of induction, intubation, and controlled ventilation in one continuous operation.

In laboratory animals, especially rats, guinea pigs, mice, and rabbits, chronic respiratory disease may be endemic. In calves, sheep, and swine, lung lesions are common. In primates, tuberculosis may be encountered. Animals having such infections should receive specific therapy prior to anesthesia, and, should resolution not occur, local or regional anesthesia should be strongly considered.

Decompensated heart disease is a contraindication for general anesthesia. If animals must be anesthetized, an attempt at compensation through appropriate inotropes, antiarrhythmic drugs, and diuresis should be made prior to anesthesia. If ascites is present, this fluid should be aspirated to reduce excessive pressure on the diaphragm.

In cases of hepatic or renal insufficiency—for instance, in many bacterial and viral infections of mice, dogs, or primates, or in parasitism of calves, sheep, and rabbits—the mode of anesthetic elimination should receive strong consideration, with inhalation anesthesia preferred. Under experimental conditions, animals with clinical or subclinical disease of any body system should be identified and treated before inclusion.

Just prior to induction, it is desirable to encourage defecation and/or urination by giving animals access to a run or exercise pen. If this attempt is unsuccessful, catheterization or bladder compression may be necessary prior to surgery. Once an animal is anesthetized, the bladder can be emptied by slow, steady compression through the abdominal wall or by catheterization. An empty bladder is an advantage in abdominal surgery because urine may contaminate the operative field.

During anesthesia, patients should, if possible, be restrained in a normal physiological position. Compression of the chest, acute angulation of the neck, overextension or compression of limbs, and compression of the posterior vena cava by large viscera can all lead to serious compromise. Complications include hypoventilation, nerve and/or muscle damage, and impaired venous return. Horses are especially susceptible to myopathy and/or neuropathy caused by excessive extension, abduction, or compression and ischemia of the muscles. Such complications are more likely to occur when good relaxation is achieved or when blood pressure is depressed and recumbency is prolonged in a lateral position. Such a position also adversely affects ventilation-perfusion ratios and thereby the efficiency of gas exchange within the lungs. The inefficiency of respiratory exchange may be greater in one position than another.⁵² In some cases, a periodic change in position may be beneficial during long surgical procedures.

Tilting anesthetized patients alters the amount of respiratory gases that can be accommodated in the chest (functional residual capacity [FRC]) by as much as 26%.⁵³ In dogs subjected to hemorrhage, tilting them head-up was detrimental, producing lowered blood pressure, hyperpnea, and depression of cardiac contractile force.⁵⁴ When dogs were tilted head-down, no circulatory improvement occurred. In pentobarbital-anesthetized dogs lying on a horizontal table, sternal recumbency and left and right lateral recumbency positions consistently produced the least overall change in cardiopulmonary function (D. W. DeYoung and W. V. Lumb, unpublished data, 1971). The supine position was the

least physiological of the level positions assessed. Prone and supine head-down positions (60°) produced the greatest physiological derangement.

In all species, the head should be extended to provide a free airway and to prevent kinking of the endotracheal tube. In ruminants, it is desirable to have the head tilted down to enable drainage of saliva. Downward tilting of the hindquarters and abdomen (below the thorax), with minimal compression of the abdomen, limits reflux of rumen contents. On induction, if active regurgitation begins with large volumes of ruminal contents flowing into the pharyngeal cavity, pressure should be applied immediately by externally grasping the esophagus dorsal to the trachea to prevent further flow. Alternatively, an endotracheal tube can be inserted into the esophagus and the cuff rapidly inflated, directing the flow through the tube away from the laryngeal opening while an endotracheal tube is properly placed to protect the airway from contamination. Precautions should also be taken to prevent accumulation of rumen gases during anesthesia. This may be done by passage of a large-bore stomach tube. During emergence from anesthesia, it is desirable to position ruminants in sternal recumbency. When large species are restrained in recumbency, viscera, restraining ropes, and bands may restrict respiration or compress nerves or muscle groups severely. During restraint in dorsal recumbency, abdominal viscera may compress the large veins and restrict venous return. In all instances, thorough padding beneath the animal is mandatory.

Selection of an Anesthetic

The ideal anesthetic is one that

1. Does not depend on metabolism for its termination of action and elimination
2. Enables rapid induction, quick alteration in anesthesia depth, and rapid recovery
3. Does not depress cardiopulmonary function
4. Does not irritate any tissue
5. Is inexpensive, stable, nonflammable, and nonexplosive
6. Requires no special equipment for administration

No anesthetic drug possesses all of these qualities. Therefore, selection of an anesthetic is a compromise based on appraisal of the situation. Factors to be considered include

1. The patient's species, breed, and age
2. The patient's physical status
3. The time required for the surgical (or other) procedure, its type and severity, and the surgeon's skill
4. Familiarity with the proposed anesthetic technique
5. Equipment and personnel available

In general, veterinarians will have greatest success with drugs they have used most frequently and with which they are most familiar. The art of administration is developed only with experience; therefore, change from a familiar drug to a new one is usually accompanied by a temporary increase in anesthetic risk. Clarke,⁵⁵ speaking of anesthesia in people, stated, "The outstanding fact is that thorough familiarity with a technique is equivalent

at least to a 30 percent increase in efficiency and safety. If a person has mastered a technique, it is not worth his while changing to a new and unfamiliar one unless the change promises some big advantage."

Often the length of time required to perform a surgical procedure and the amount of help available during this period dictate the anesthetic that is used. Generally, short procedures are done with short-acting agents, such as thiobarbiturates, propofol, alphaxalone-CD, and etomidate, or with combinations using dissociative, tranquilizing, and/or opioid drugs. Where longer anesthesia is required, inhalation or balanced anesthetic techniques can usually be safely used.

Species differences may prevent the use of some drugs. For example, procaine is frequently lethal for parakeets and, in high doses, morphine can be excitatory in cats. On the other hand, once adjusted for species dose requirements, most agents can be used interchangeably among species. Anesthesia in the very young is attended with increased risk owing to size limitations, limited muscular and adipose tissue in which anesthetic may be redistributed, and immature metabolic and excretory mechanisms. For this reason, the use of barbiturates in very young patients is generally not recommended.

Aged animals are often poor anesthetic risks because of decreased vitality and the possibility of decreased cardiac, hepatic, and renal function (reserve), which may not be apparent on casual examination. Drugs should be chosen and administered in doses that minimally depress these systems and that can be easily metabolized and eliminated or reversed with specific antagonists. The same is true of patients in poor physical condition, because the liver and kidneys usually are somewhat affected.

General anesthesia is to be avoided, if at all possible, in animals with renal failure. Local, regional or epidural anesthesia should be used where possible. If general anesthesia must be used, induction with a short-acting anesthetic such as propofol or etomidate, a potent opioid, or very low doses of a thiobarbiturate and inhalant anesthetic is preferred.

A cardiac murmur per se is not a contraindication to general anesthesia unless the murmur is accompanied by untreated cardiac decompensation (no exercise tolerance). However, such patients may have less cardiac reserve and require more careful supervision during anesthesia. Patients with heartworm infestation and congenital lesions of the heart and great vessels also fall into this category. Balanced techniques using less depressant drugs such as dissociatives, opioids, etomidate and isoflurane are preferred.

Brachycephalic dogs, because of their pendulous soft palate and restricted respiratory passages, may have difficulty in breathing even when awake. This is particularly true in hot, humid weather. During anesthesia, the degree of airway obstruction is compounded, and these animals often have severe respiratory stridor unless a patent airway is maintained via endotracheal intubation. It is wise to use short-lasting agents that are rapidly eliminated (e.g., propofol) so that a prolonged recovery period is avoided and patient control of the airway recovers rapidly.

In large animals such as horses and cattle, anesthetics should be selected to provide rapid recovery with minimal emergence

struggling. Emergence struggling is usually more of a problem in equine anesthesia, whereas general anesthesia in ruminants is complicated by the hazards of rumen tympany, regurgitation, and aspiration. These latter complications make the use of regional anesthesia desirable where appropriate. In the event general anesthesia is used, endotracheal intubation is mandatory. Regional anesthesia with the patient in the standing position has the advantage of preventing compression of abdominal viscera and is therefore less likely to impede respiratory and cardiovascular function.

The overriding consideration in choosing an anesthetic protocol is patient safety. This is based on

1. Patient factors likely to influence responses to anesthesia, uptake, distribution, and elimination
2. The physical status of the animal
3. The specific needs of the species
4. The specific needs in the case, including the relative requirements for sedation, immobilization, analgesia, relaxation, and safety

Secondarily, the anesthetic protocol should be one that provides convenience to the surgeon so that the procedure can be completed efficiently, insures patient comfort, allows for appropriate monitoring, and can be administered with confidence by the veterinarian.

Operative Risk

Operative risk refers to uncertainty and the potential for misadventure or adverse outcome as a result of anesthesia and surgery. It should be emphasized that physical status, anesthetic risk, and operative risk are entirely different. To determine anesthetic risk, many factors must be considered, including the degree of skill of the anesthetist, the anesthetic to be employed, and the physical status of the patient. To determine operative risk, the foregoing must be appraised and, in addition, the operation to be performed and the skill of the surgeon must be taken into consideration. Operative risk, then, is determined by factors associated with the patient, anesthesia, and surgery.^{55–59} Patient factors affecting risk include physical status, temperament, age, species and breed, and overall physical fitness. Perioperative morbidity and mortality increase with the severity of preexisting disease. Geriatric and pediatric patients are at increased risk because of limited ability to respond to stress because of decreased functional reserves in the former and incomplete development in the latter. Depressed or overly apprehensive or fractious patients are often unstable and difficult to safely induce and maintain. In such patients, careful consideration should be given to preanesthetic management and choice of drugs. Species and breed characteristics can contribute to operative risks. Examples include the increased risk of airway obstruction in brachycephalic dogs, malignant hyperthermia in some strains of swine, increased incidence and severity of myositis in heavy draft horses, and increased incidence of regurgitation and aspiration in ruminants.

Surgical factors that can increase risk include the nature of the procedure itself (i.e., duration, complexity, organ involvement,

operating conditions, and emergency). Major surgical procedures and procedures that are complex are associated with increased morbidity and mortality as compared with minor and simple procedures. Involvement of major organs increases risk; CNS, cardiac, and pulmonary procedures have the highest risk, followed by the gastrointestinal tract, liver, kidney, reproductive organs, muscles, bone, and skin. Emergency procedures are more risky because of poorer patient status, that is, unstable or severely compromised patients, decreased ability to prepare or stabilize the patient, and lack of preparation by the surgical and anesthetic team. *Operating conditions* refer to the physical facilities and equipment and support personnel available. The aggressiveness of the surgical team, experience with the procedure, and frequency of performance are also important. Lastly, the duration of the procedure and fatigue must be considered because patients cannot be operated on indefinitely. The incidence of morbidity and mortality increases with the duration of anesthesia and surgery. Thus, efficiency of the surgical team is important in reducing risk. A related factor is fatigue.⁶⁰

Anesthetic factors that can affect risk include the choice of anesthetic drugs to be used, the anesthetic technique, and the duration of anesthesia. The choice of anesthetic can adversely affect the outcome, but more commonly the agents are not so much at fault as the manner in which they are given. Many adverse physiological effects of anesthesia and surgery are time related. Experience of the anesthetist with the protocol is important to its safe administration. Fatigue increases risk because it decreases vigilance. Thus, efficiency of patient monitoring and timely recognition and response to potentially life-threatening events are decreased. It is worth noting that human error remains the number one reason for anesthesia-related mishap and is a major contributor to anesthetic risk (Table 2.10).^{61–71}

Record Keeping and Monitoring

“For every mistake that is made for not knowing, a hundred are made for not looking.”

Anonymous

Death of a patient from any cause is always unpleasant, but a fatality during anesthesia and surgery is even more so because of the obvious practitioner involvement. One will occasionally hear a veterinarian state that he or she has never lost an animal because of anesthesia. This is conceivably true, though highly unlikely if a sizable number of animals have been anesthetized. Obviously, the criteria for anesthetic mortality in this instance must be defined. It is human nature for a veterinarian to forget the disagreeable and to excuse a fatality by blaming it on something over which he or she has no control. Not all deaths in the perioperative period are anesthetic deaths. Deaths may be caused by (a) anesthesia; (b) surgery; (c) anesthesia primarily, with only a minor surgical contribution; (d) surgery primarily, with only a minor anesthetic contribution; (e) the patient’s disease primarily; or (f) indeterminate causes. Deaths related to anesthesia should be recognized and identified. Examples of deaths that are attributable to anesthetic management are (a) death during induction,

^cAbdominal surgeries only.

^dAbdominal surgeries excluded.

(b) explosion (rare at this time), (c) pulmonary aspiration, (d) failure to secure the airway, (e) hypoxia, (f) anesthetic overdose, (g) technical mismanagement of the anesthetic system, and (h) maladministration of fluids and air embolism.⁷²

As long as anesthetics are administered, the hazard of death can never be eliminated completely; it can, however, be minimized, particularly if one is willing to investigate and to learn from mistakes. Once an anesthetic fatality has occurred, the sequence of the perioperative events preceding the death should be reviewed, their significance should be evaluated, and a necropsy

should be performed to piece together its pathogenesis and etiology. Armed with this information, the practitioner can then take steps to prevent a recurrence of this tragedy.

Unfortunately, there is little recorded information concerning mortality in animals anesthetized in clinical practice. This may be because (a) busy practitioners do not have time to collect the necessary data, (b) there is no economic gain to be derived from such collection, or (c) there is lack of interest on the part of individuals best able to obtain these data. To obtain meaningful data concerning anesthesia, certain information must be collected and

definite criteria established. A record must be made for each animal anesthetized, with the owner's name and the case number written on it. Among the items that should be recorded are

1. Species, breed, age, gender, weight, and physical status of the animal
2. Surgical procedure or other reason for anesthesia
3. Preanesthetic agents given
4. Anesthetic agents used and method of administration
5. Person administering anesthesia (veterinarian, technician, student, or lay personnel)
6. Duration of anesthesia
7. Supportive measures
8. Difficulties encountered and methods of correction

Tabulation of these data will provide not only extensive information on anesthesia, but also the incidence of surgical diseases in various species, age groups, and breeds.

Moribund patients are poor anesthetic risks, and if a single agent is used to anesthetize them, the mortality rate for this agent may appear to be disproportionately high. When one is discussing anesthetic mortality, therefore, it is necessary to categorize the physical status of a patient prior to anesthesia to assess risk. The ASA has developed a five-division classification of physical health and therefore anesthetic risk (Table 2.7). A modification of this classification of anesthetic risk can relate severity of patient disease to the occurrence of death. As expected, the mortality rate increases sharply as physical status deteriorates. There are various reasons that animals with poor physical status undergo anesthesia. In some instances, anesthesia and surgery are performed to secure diagnoses on animals that would likely have died within hours. Although data are available to define mortality based on patient disease and surgical procedure, percentage figures derived from large patient populations are not necessarily applicable to individual patients or hospitals.

It is necessary that each step of anesthetic administration, along with the patient's response, be recorded in an anesthetic record (Fig. 2.3). Minimally, the pulse and respiratory rate should be monitored at 5-min intervals and charted at 10-min intervals. Trends in these parameters thus become apparent before a patient's condition severely deteriorates, so that remedial steps may be taken.

The diplomates of the American College of Veterinary Anesthesiologists (ACVA) have proposed guidelines (1994) for anesthetic monitoring, with the intention of encouraging high-quality care of anesthetized veterinary patients (Table 2.11). The ACVA recognizes that some of the methods may be impractical in certain clinical settings and that anesthetized patients can be monitored and managed without specialized equipment. The ACVA does not suggest that using any or all of these methods can ensure successful patient outcome or that failure to use any or all of these methods causes poor outcome. These suggestions are offered only to assist veterinarians in determining priorities for monitoring and record keeping during anesthesia, surgery, and recovery. These suggestions may be revised as warranted by developing knowledge and technology. The aspects of anesthetic management addressed by the ACVA guidelines that deserve careful

attention include patient circulation, oxygenation, and ventilation. Methods of monitoring each of the physiological processes are listed in Table 2.11 in approximate order of simplest, most economic, and least invasive, to the most complex, expensive, and invasive. Circulation can be assessed by palpation of peripheral pulse, palpation of heartbeat by chest wall, auscultation of heartbeat (stethoscope, esophageal stethoscope, or other audible heart monitor), use of an electrocardiogram, use of noninvasive blood flow or blood pressure monitor (e.g., a Doppler ultrasonic flow detector or an oscillometric flow detector), or use of an invasive blood pressure monitor (an arterial catheter connected to a transducer or aneroid manometer). Oxygenation can be assessed by observation of mucous membrane color, pulse oximetry (non-invasive estimation of hemoglobin saturation), oxygen analyzer in the inspiratory limb of the breathing circuit, blood-gas analysis (arterial oxygen partial pressure), or hemoximetry (measurement of hemoglobin saturation in the blood). Ventilation can be assessed with observation of chest wall movement, observation of breathing-bag movement, auscultation of breath sounds, audible respiratory monitor, respirometry, capnography (measurement of carbon dioxide in end-expired gas), or blood-gas monitoring (arterial carbon dioxide partial pressure).

The ACVA further recommends that an anesthetic record should be compiled for each patient to maintain a legal record of significant events and to enhance recognition of trends in monitored parameters (Fig. 2.3). The record should include all drugs administered, noting the dose, time, and route of administration. Monitored parameters should be recorded regularly (at least every 10 min) during anesthesia. Responsible individuals should be aware of the patient status at all times during anesthesia and recovery and be prepared to alert the veterinarian about changes in the patient's condition. If a veterinarian, technician, or other responsible person cannot remain with the patient continuously, a responsible person should check the patient's status regularly (at least every 5 min) during anesthesia and recovery. The responsible person may be present in the same room although not necessarily solely occupied with the anesthetized patient (e.g., the surgeon may also be responsible for overseeing anesthesia). In either of these situations, the use of audible heart and respiratory monitors is suggested. In the best of situations, a person, solely dedicated to managing and caring for the anesthetized patient, remains with the patient continuously until the end of the anesthetic period.

Insurance Claims and Anesthesia Risk

Claims presented to the American Veterinary Medical Association Professional Liability Insurance Trust from 1976 through 1982 and from 1999 to 2003 based on anesthetic, surgical, and medical incidents reflect changing trends in veterinary practice and owner concern for optimal patient care (Table 2.12). It should be noted that the percentage of anesthesia claims decreased by over 50% for both dogs and horses from 1982 to 2003, reflecting the increasing sophistication and safety of veterinary anesthesia during the last 20 years. For more recent data on anesthetic-related claims, the reader is referred to the American Veterinary Medical Association Liability Insurance Trust.

Fig. 2.3. Example anesthetic record. The anesthetic record provides written documentation of the anesthetic drugs and techniques used to produce general anesthesia and suggests methods for monitoring the patient throughout anesthesia. The patient's physical status and pain should be assessed before and after any procedure. Other drugs, fluids, surgical and medical techniques, and the personnel involved should be recorded.

Table 2.11. American College of Veterinary Anesthesiologists' suggestions for monitoring.

<p>Circulation Objective: to ensure that blood flow to tissues is adequate Methods:</p> <ol style="list-style-type: none"> 1. Palpation of peripheral pulse 2. Palpation of heartbeat through the chest wall 3. Auscultation of heartbeat (stethoscope, esophageal stethoscope, or other audible heart monitor) 4. Electrocardiogram (continuous display) 5. Noninvasive blood flow or blood pressure monitor (e.g., Doppler ultrasonic flow detector or oscillometric flow detector) 6. Invasive blood pressure monitor (arterial catheter connected to transducer/oscilloscope or to anaeroid manometer) <p>Oxygenation Objective: to ensure adequate oxygen concentration in the patient's arterial blood Methods:</p> <ol style="list-style-type: none"> 1. Observation of mucous membrane color 2. Pulse oximetry (noninvasive estimation of hemoglobin saturation) 3. Oxygen analyzer in the inspiratory limb of the breathing circuit 4. Blood-gas analysis (arterial oxygen partial pressure) 5. Blood-gas monitoring (arterial carbon dioxide partial pressure) <p>Anesthetic Record Objective: to maintain a legal record of significant events and to enhance recognition of trends in monitored parameters Methods:</p> <ol style="list-style-type: none"> 1. Record all drugs administered to each patient, noting the dose, time, and route of administration 2. Record monitored parameters (minimum: heart rate, respiratory rate) regularly (minimum: every 10 min) during anesthesia <p>Personnel Objective: to ensure that a responsible individual is aware of the patient's status at all times during anesthesia and recovery, and is prepared either to intervene when indicated or to alert the veterinarian in charge about changes in the patient's condition Methods:</p> <ol style="list-style-type: none"> 1. If a veterinarian, technician, or other responsible person cannot remain with the patient continuously, a responsible person should check the patient's status regularly (at least every 5 min) 2. A responsible person may be present in the same room, although not necessarily solely occupied with the anesthetized patient (e.g., the surgeon may also be responsible for overseeing anesthesia) 3. In either of the foregoing situations, the use of audible heart and respiratory monitors is suggested 4. A responsible person, solely dedicated to managing and caring for the anesthetized patient during anesthesia, remains with the patient continuously until the end of the anesthetic period

Aftercare

Although in most instances recovery from anesthesia is uneventful, patients should be kept under observation during the recovery period to prevent untoward sequelae. In animal hospitals and laboratory-animal facilities, it is wise to have a recovery room for this purpose, because all of the necessary equipment, drugs, and materials can be kept in one place, and it is less difficult to observe several animals. In some instances, the prep room may also serve as the recovery room; alternatively, recovery and intensive

care functions may be combined. Such facilities should be conveniently located for nursing staff.

Small Animals

Following removal from the operating room, the animal should be placed in its cage in lateral recumbency.

While the animal remains unconscious or immobile, monitoring deemed necessary in the operating room should be continued. In any case, vital signs should be recorded at 10-min intervals

Table 2.12. Trends in claims involving anesthesia, surgery, and medicine presented to the American Veterinary Medical Association (AVMA) Professional Liability Insurance Trust.

Species	Total No. of Claims	Anesthesia (%)	Surgery (%)	Medicine (%)

until the animal regains consciousness. Continued supervision is especially important until extubation and the return of coughing and swallowing reflexes. A blanket, pad, or even newspaper should be placed under and over the patient to conserve body heat. In very small or newborn animals, the ambient temperature should approximate body temperature. Incubators designed for babies are helpful in maintaining body temperature and are used routinely in many laboratories where birds, rodents, and primates are anesthetized. In newborn pigs, an environmental temperature of 90°F has been found desirable. Otherwise, shivering occurs with increased oxygen and energy requirements, and hypoglycemia may result. During recovery, birds should be housed at 100°F; mice, hamsters, and small primates at 95°F; rats, guinea pigs, and rabbits at 90°F; and cats, dogs, and similar carnivores at 77° to 86°F.⁷ Depending on environmental temperatures, heat lamps, heating pads, or warm-water blankets may be required. If fluid therapy is used, fluids should be warmed to body temperature.

During recovery, the patient's tongue should be pulled forward to preclude its blocking the pharynx. In brachycephalic breeds or in animals in which respiratory function is compromised, an endotracheal tube should remain in place until upper-airway reflexes and jaw movements return. In such animals, sternal recumbency, if practical, is preferred. Care is necessary to assure freedom of the airway from blankets or paper. The water pan should always be removed from the cage to prevent accidental drowning in the event a semiconscious patient should place its nose and mouth or endotracheal catheter in the container. Food and water may be offered as soon as a patient can stand.

Predisposition to postoperative respiratory failure may result from continuing drug-induced respiratory depression, postextubation spasm or glottic edema, other respiratory obstructions, diffusion hypoxia, mechanical splinting associated with pain and/or dressings, and persistent hypoventilation and/or atelectasis during anesthesia. Careful evaluation of respiration during the immediate postanesthetic period is therefore essential. If hypoventilation is identified, predisposing causes should be corrected and, if necessary, supportive respiratory therapy should be initiated. Since postoperative hypotension may be caused by a

persistent drug effect, hemorrhage, and inadequate volume, adequacy of cardiovascular function should also be carefully and frequently evaluated.

Under no circumstances should an anesthetized animal be placed in the same cage with a conscious one, because the former cannot protect itself. Cannibalism has been known to occur (e.g., among pigs and rats), particularly where the anesthetized patient had an open wound!

When preanesthetic sedation has not been used, animals may thrash and struggle, bruising themselves severely and even breaking teeth during the recovery period. Coursing breeds, such as greyhounds, Russian wolfhounds, and Afghans, are particularly prone to this phenomenon. The judicious use of tranquilizers or opioids in small doses quiets animals in this condition. Plastic-covered sponge-rubber mats or other suitable pads in recovery cages also afford protection.

After administration of large doses of barbiturates, some animals will have a prolonged recovery period. Special attention must be given these animals to prevent hypostatic congestion and subsequent pneumonia. They should, of course, be kept warm and turned frequently. In addition, prophylactic antibiotic therapy may be desirable and a protective ophthalmic ointment placed in the eyes to prevent corneal drying. Intravenous electrolyte solutions in moderate amounts prevent dehydration.

Constrictive bandaging of the head or throat must be avoided because of the danger of asphyxiation. Occasionally, cats that have been tightly bandaged around the abdomen show evidence of posterior paralysis on recovery. This condition is apparently caused by decreased circulation to the hindquarters. Removal of the bandage may quickly resolve paralysis.

It is unwise to send anesthetized animals home, because owners generally cannot cope with any unusual situation that may arise. In addition, the owners may become alarmed by the signs of their animal's approaching consciousness and may demand service unnecessarily.

Large Animals

Like smaller animals, large animals should be removed to a recovery room (stall). The room should be padded to minimize injury during emergence from the anesthetic and recovery of righting reflexes. Availability of oxygen and suction is essential. If a padded floor and pads are unavailable and bedding material such as straw must be used, this should be covered with a tarpaulin so that it is kept clear of the external nares or end of the endotracheal tube and the eyes. Using pads beneath the head and limbs is essential. In horses especially, bony prominences must be protected from abrasion. It is an excellent practice to bandage and pad all limbs prior to anesthesia and to keep these protections in place until recovery is complete. A horse's head is especially subject to trauma during recovery, with resulting abrasions, edema, and even facial paralysis. It should therefore be protected with a pad or a padded hood. Halters or headstalls should be used when necessary and should be padded.

Whenever possible, horses should be allowed to lie quietly in a darkened environment neither restrained nor disturbed. The possibility of emergence struggling and of attempts to stand before coordination is fully recovered is thus less likely. If an endotracheal tube has been used, it should remain in situ until the re-

turn of upper-airway and swallowing reflexes necessitates its removal. Food and water should be removed from the stall until recovery is complete. If straw or other bedding material is used, the animal is observed to prevent it from eating. When eye reflexes have fully returned, and nystagmus is absent, horses are usually able to stand. While animals attempt to rise, a steady influence exerted by the handlers in holding up the head and in upward traction on the tail may be helpful.

Some horses, despite preanesthetic sedation, struggle during recovery from anesthesia. Additional sedation or manual restraint may be required. A tail rope or a halter to restrain the head and neck is usually sufficient. Alternatively, a sedative (e.g., xylazine) may be administered. Control by medication is preferable, although recovery may be prolonged with large doses. Small amounts of xylazine (100 mg per 1000-pound horse) have proved useful in alleviating pain and calming recovery without unduly lengthening it. Some veterinarians restrain a horse either on the operating table or by ropes and hobbles until they judge the animal is able to stand. Such a practice predisposes animals to struggling and injuries.

When recovery rooms are not available, it may be necessary to permit recovery in the operating room. Operating rooms having a padded floor, or a padded floor with table that lowers to floor level, are suitable. Restraint with straps on the operating table until recovery is complete is undesirable, especially for horses; struggling is likely, and abrasions and nerve injuries are common. Rupture of the colon has been attributed to such restraint in several instances. If a cart is available to transport the animal, a grassy plot is a desirable location for recovery.

Ruminants are handled in a manner similar to that used for horses. Struggling and resulting trauma are usually not problems. Instead, it is necessary to minimize possible regurgitation and aspiration of rumen contents, and ruminal tympany. The endotracheal tube with cuff inflated should therefore remain in position as long as possible. Use of a speculum to prevent damage to, or constriction of, the tube is helpful. During recovery, ruminants should be placed in sternal recumbency. If their flexed limbs are abducted slightly, the animals can usually be propped in this position. Padded bolsters, other supports, or even bales of hay can be used to assist in maintaining this position. The head should be down and extended and the end of the endotracheal tube unobstructed. When anterior epidural anesthesia has been used, the hind legs should be hobbled to a degree sufficient to prevent abduction until muscle control is regained.

Recovering large animals should be protected from temperature extremes. In the absence of heating or air conditioning, the use of blankets, heaters, or fans may be necessary. If an outside recovery area is used, animals should be shaded from direct sunlight in hot weather and blanketed in cold weather. When recovery is prolonged, animals should be turned frequently, and warmed fluids should be administered intravenously. Vital signs should be continually and routinely monitored until the return of coughing, swallowing, and righting reflexes.

Introduction

The prevention and control of pain are central to the practice of anesthesia. It is essential that anesthetists have an understanding of the physiological processes leading to the perception of pain and the responses of patients to this process. Ultimately, *anesthetic patient management* is the control of pain and maintenance of homeostasis in the face of noxious stimuli. The perioperative analgesic protocol has an impact on patient well-being that often extends far beyond the immediate anesthetic period. Appropriate pain management is not only integral to an anesthetic plan; it is a fundamental component of good medical practice.

In human medicine, several organizations are dedicated to improving the understanding and treatment of acute and chronic pain. Despite the efforts of these organizations, it has taken an inordinate amount of time for the human medical profession to accept that pain is a matter to be taken seriously. A landmark paper by Marks and Sachar¹ exposed both the indifference of physicians to the pain of terminally ill people and the knowledge deficits of medical professionals about effective pain control. Unfortunately, it is still commonplace for physicians to be considered the individuals that effect a cure, while nurses care for patients and try to alleviate pain

and suffering. The fact that many physicians and institutions have ignored the importance of patient pain has not been lost on the public or regulatory agencies, prompting the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) to mandate in the year 2000 that human hospitals elevate pain to the fifth vital sign (along with temperature, pulse, respiration, and blood pressure). The new requirements for assessing and controlling pain in people assert that “appropriate pain management is good medicine because it results in quicker clinical recovery, shorter hospital stays, fewer readmissions, and improved quality of life, leading to increased productivity.”² Thirty years have passed since Marks and Sachar put in print what ordinary people already knew: Despite all of our resources and the modern technology devoted to medical care, attention to pain management and patient comfort fell short of the mark. It took almost 30 years for JCAHO to finally regulate the delivery of appropriate pain management care.

The similarities between human and veterinary medicine are impressive. Numerous dedicated individuals over the last several decades have worked to improve our understanding and treatment of animal pain, yet the paradigm shift to comprehensive and effective perioperative analgesia has been slow. Lloyd Davis³ had exposed the myth approximately 35 years ago that opioids could not be given to cats, yet it is still relatively common to hear that opioids will induce mania in cats. Bernie Rollin, 25 years ago, established the moral imperative to minimize and treat pain in research animals and has been speaking and writing about the issue ever since.⁴ In what may be considered a watershed paper, Hansen and Hardie⁵ blew the whistle on academic veterinary practice, much as Marks and Sachar did, by exposing the lack of provision of effective analgesics to dogs and cats that had undergone major surgical procedures. Several surveys from within the veterinary profession indicate that pain management is improving, but is far from ideal.^{6–10} In 2003, the American Animal Hospital Association (AAHA) followed JCAHO’s initiative and elevated pain to the fourth vital sign in animals (in addition to temperature, pulse, and respiration). Although the AAHA is a voluntary organization of small animal veterinary hospitals, the actions taken to improve the recognition and treatment of pain are a watershed in veterinary medicine. These 11 AAHA standards emphasize patient evaluation, appropriate treatment, and effective communication with clients about the degree of patient pain and discomfort, treatment options, and possible side effects. Pain is easy to overlook in animals; thus, efforts to increase our vigilance to assessing, preventing, and alleviating pain will serve to improve the quality of care that can be delivered to animals.

The Definition of Pain

Pain is an unpleasant sensory and emotional experience (perception) associated with actual or potential tissue damage or is described in terms of such damage. The inability to communicate in no way negates the possibility that an individual is experiencing pain and is in need of appropriate pain relieving treatment.

Pain arises from the activation of a discrete set of receptors and neural pathways by noxious stimuli that are actually or potentially damaging to tissues. Pain is a conscious awareness of acute or chronic discomfort occurring in varying degrees of severity resulting from injury, disease, or emotional distress as evidenced by biological or behavioral changes or both. It is a subjective experience accompanied by feelings of fear, anxiety, and panic. Pain elicits protective motor actions, results in learned avoidance, and may modify species-specific traits of behavior, including social behavior.^{11,12} *Acute pain* is the result of a traumatic, surgical, or infectious event that begins abruptly and is relatively brief. It is generally alleviated by analgesic drugs. *Chronic pain* is pain that persists beyond the usual course of an acute disease or beyond a reasonable time for an injury to heal, or that is associated with a chronic pathological process that persists or recurs for months or years (e.g., osteoarthritis). Chronic pain is seldom permanently alleviated by analgesics, but may respond to a combination of analgesics, tranquilizers or psychotropic drugs, physical therapy, environmental manipulation, and behavioral conditioning. Acute pain is a symptom of disease, whereas chronic pain, in and of itself, is a disease.¹³ Acute pain has a biological function in that it serves as a warning that something is wrong and leads to protective behavioral changes. Chronic pain does not serve a biological function and imposes severe detrimental stresses. Because pain is a perception, it is always subjective.

In people, pain experience has three dimensions—sensory-discriminative, motivational-affective, and cognitive-evaluative—which are subserved by physiologically distinct systems.^{14,15} The *sensory-discriminative* dimension provides information on the onset, location, intensity, type, and duration of the pain-inducing stimulus. This aspect is subserved primarily by the lateral ascending nociceptive tracts, thalamus, and somatosensory cortex. The *motivational-affective* dimension disturbs the feeling of well-being of the individual, resulting in the unpleasant experience of pain and suffering, and triggers the organism into action. This dimension is closely linked to the autonomic nervous system, and cardiovascular, respiratory, and gastrointestinal responses are associated with it (although these can also occur reflexly). This dimension is subserved by the medial ascending nociceptive tracts and their input into the limbic system. The *cognitive-evaluative* dimension encompasses the effects of prior experience, social and cultural values, anxiety, attention, and conditioning. These activities are largely caused by cortical activity, although cortical activation is dependent on reticular activity. The cognitive-evaluative dimension of the pain experience in lower mammals may be the only one that differs significantly from that in people. To discuss pain physiology and its management requires a review of the definitions commonly used to describe this perception.

Definitions

Agology. The science and study of pain phenomena.

Allodynia. Pain caused by a stimulus that does not normally provoke pain.

Analgesia. The absence of pain in the presence of stimuli that would normally be painful.

Analgesics. Drugs that produce analgesia.

Anesthesia. The absence of all sensory modalities.

Anesthetics. Drugs that induce regional anesthesia (i.e., in one part of the body) or general anesthesia (i.e., unconsciousness).

Cancer pain. Pain that is caused by primary tumor growth, metastatic disease, or the toxic effects of chemotherapy and radiation, such as neuropathies caused by neurotoxic antineoplastic drugs.¹⁶

Causalgia. A syndrome of prolonged burning pain, allodynia, and hyperpathia after a traumatic nerve lesion, often combined with vasomotor and sudomotor (sweating) dysfunction and later trophic changes.

Central pain. Pain associated with a lesion of the central nervous system.

Chronic pain. Pain that persists for longer than the expected time frame for healing or pain associated with progressive nonmalignant disease (such as osteoarthritis).¹⁶

Deafferentation pain. Pain caused by loss of sensory input into the central nervous system, as occurs with avulsion of the brachial plexus or other types of peripheral nerve lesions, or caused by pathology of the central nervous system.

Dermatome. The sensory segmental supply to skin and subcutaneous tissue.

Distress. The external expression through emotion or behavior (i.e., fear, anxiety, hyperactivity, or aggression) of suffering.^{17–19}

Dysesthesia. An unpleasant abnormal sensation, whether spontaneous or evoked.

Hyperalgesia. An increased response to a stimulation that is normally painful.

Hyperesthesia. An increased sensitivity to stimulation, excluding special senses.

Hypoalgesia. A diminished sensitivity to noxious stimulation.

Hypoesthesia. A diminished sensitivity to stimulation, excluding special senses.

Inflammatory pain. Spontaneous pain and hypersensitivity to pain in response to tissue damage and inflammation.²⁰

Neuralgia. Pain in the distribution pathway of a nerve or nerves.

Neuritis. An inflammation of a nerve or nerves.

Neuropathic pain. Spontaneous pain and hypersensitivity to pain in association with damage to or a lesion of the nervous system.²⁰

Neuropathy. A disturbance of function or a pathological change in a nerve.

Nociception. The reception, conduction, and central nervous processing of nerve signals generated by the stimulation of nociceptors. It is the physiological process that when carried to completion results in the conscious perception of pain.

Nociceptive pain. Transient pain in response to noxious stimuli.²⁰

Nociceptor. A receptor preferentially sensitive to a noxious stimulus or to a stimulus that would become noxious if prolonged.

Nociceptor threshold. The minimum strength of stimulus that will cause a nociceptor to generate a nerve impulse.

Noxious stimulus. One that is actually or potentially damaging to body tissue. It is one of intensity and quality that are adequate to trigger nociceptive reactions in an animal, including pain in people.

Pain (detection) threshold. The least experience of pain that an individual can recognize. The point at which an individual just begins to feel pain when a noxious stimulus is being applied in an ascending trial or the point at which pain disappears in a descending trial. The pain-detection threshold is relatively constant among individuals and species. In most cases, it is higher than the nociceptor threshold.

Pain tolerance. The greatest level of pain that an individual will tolerate. Pain tolerance varies considerably among individuals, both human and animal. It is influenced greatly by the individual's prior experience, environment, stress, and drugs.

Pain-tolerance range. The arithmetic difference between the pain-detection threshold and the pain-tolerance threshold.

Paresthesia. An abnormal sensation, whether spontaneous or evoked. Paresthesias are not painful (as opposed to dysesthesias).

Radiculalgia. Pain along the distribution of one or more sensory nerve roots.

Radiculitis. An inflammation of one or more nerve roots.

Radiculopathy. A disturbance of function or pathological change in one or more nerve roots.

Reactions. A combination of reflexes designed to produce widespread movement in relation to the application of a stimulus. Reactions are mass reflexes not under voluntary control and therefore do not involve the cerebral cortex.

Reflexes. Involuntary, purposeful, and orderly responses to a stimulus. The anatomical basis for the reflex arc consists of a receptor, a primary afferent nerve fiber associated with the receptor, a region of integration in the spinal cord or brain stem (synapses), and a lower motor neuron leading to an effector organ such as skeletal muscles (somatic reflexes), smooth muscles, or glands (visceral reflexes).

Responses. Willful movement of the body or parts of the body. A response cannot occur without involvement of the somatosensory cerebral cortex. A decerebrate animal can give a reaction but not a response. Reflexes and reactions may or may not be perception linked (i.e., the stimulus perceived as painful). Because responses require a functioning somatosensory cortex, the initiating stimulus must first be perceived.

Somatic. Usually used to describe input from body tissues other than viscera.

Suffering. An unpleasant emotional state that is internalized and not expressed outwardly. It is described as an undesirable mental state or as an unpleasant emotion that people or animals would normally prefer to avoid. Suffering can refer to a wide range of intense and unpleasant subjective states, such as fear and frustration. It can be of either physical or psychological origin. Suffering can be provoked by pain or by pain-free non-tissue-damaging external stimuli such as denial of the fulfillment of an animal's natural instincts or needs, such as maternal deprivation, social contacts, and so on.

Neuroanatomy of Nociceptive Pathways

Nociceptors and Stimuli

Nociception is the reception of signals from activation of *nociceptors*, which are receptors that detect tissue-damaging (*noxious*) stimuli. *Pain* implies that noxious stimuli have been perceived at the cortical level. Activating stimuli for nociceptors can include mechanical, thermal, or chemical stimuli. Some nociceptors respond only to one of these modalities, whereas others are sensitive to a variety of them (polymodal nociceptors). Nociceptors are naked (nonencapsulated) nerve endings, widely distributed in skin and deep tissues. These represent the peripheral termini of nociceptive primary afferent neurons that possess lightly or unmyelinated, small-diameter axons. Activation of fast-conducting (5 to 30 m/s), *A-δ fibers* are associated with sharp, pricking pain (as reported by humans). Slow-conducting (0.5 to 2.0 m/s), unmyelinated *C fibers* are associated with a slower, burning type of pain.^{21–23} Both types of nociceptive fibers innervate the skin (*superficial pain*) and deep somatic or visceral structures (*deep pain*). The distinction between superficial and deep pain is not just an arbitrary one based on “outside” and “inside.” Each is associated with an anatomically and functionally segregated central pain pathway; they are differentially susceptible to injury, and they are examined separately in a neurological exam.

Pain research has revealed the presence of a particular functional type of nociceptor referred to as a *silent nociceptor*.^{24–26} The high threshold of this nerve ending ensures that under normal circumstances it is relatively insensitive to any stimuli. Following release of tissue-inflammatory mediators, however, the threshold is markedly reduced, and these previously silent nociceptors can be activated by a variety of thermal and mechanical stimuli. The presence of silent nociceptors is one mechanism by which inflammation produces primary hyperalgesia.

Divergence in Nociceptive Pathways

In addition to the connections of ascending nociceptive pathways with somatosensory cortex for conscious perception, pain pathways exhibit variable degrees of connectivity with a number of subcortical regions of the brain and through these connections elicit a variety of nonconscious responses.^{21,26–29}

A behaviorally important aspect of nociception (and other sensory modalities) is the degree to which it affects mental alertness. This relationship between sensation and consciousness is orchestrated in the *reticular formation* (RF), a loose aggregate of nuclei in the central core of the brain stem, extending from diencephalon through medulla oblongata. Functions of the RF include regulation of heart and respiratory rates, selective attention to stimuli, and maintenance of consciousness and cortical alertness. The RF is critical to the regulation of the level of consciousness through its rostral projections to the diencephalon, which, in turn, diffusely excites the cerebral cortex. The RF receives input from all afferent pathways, although the degree to which these connections are made is variable, depending on the pathway. Stimuli—but most especially noxious stimuli—increase alertness and autonomic functions, such as heart and respiratory rates.

Nociceptive information is simultaneously directed to the *hypothalamus*, which is the brain's coordinator of elaborate autonomic responses and the primary integrator of physiological and emotional responses. Input from nociceptive pathways to the hypothalamus produces activity in the sympathetic nervous system and the pituitary gland and thus increases circulating epinephrine/norepinephrine and glucocorticoids. The catabolic and other endocrinologic manifestations of this activation can have negative effects on health.

Both the hypothalamus and the RF have projections to other parts of the so-called *limbic system*, a group of cortical and sub-cortical regions that produce the behavioral, cognitive, and physiological changes that people describe as emotions. Comments on the role of emotion in pain responses are presented below.

Nociceptive pathways send collateral projections to the *mesencephalon (midbrain)*. One set of nuclear targets in the midbrain consist of motor neurons that coordinate orienting movements of the head and eyes toward the noxious stimulus (the visual grasp reflex). Other neurons that form the *periaqueductal grey matter* of the midbrain activate important descending pain modulatory systems.

Nociception: Ascending Spinal Pathways

Multiple nociceptive pathways that have been described in the spinal cord of domestic animals are present in all funiculi of the cord and with a confusing degree of overlap in their functions. None of these pathways are exclusive for transmission of nociception (all have fibers conducting tactile information). For clinical purposes, only two need be understood fully: the spinocervicothalamic and spinoreticular tracts.

The *spinocervicothalamic tract* is concerned with the transmission of *superficial pain* and tactile sensations and is regarded as the primary conscious pain pathway in carnivores.^{30,31} The primary afferents of this pathway synapse in the dorsal horn, from which secondary afferents then mediate local reflexes and project cranial in an ipsilateral tract in the dorsal part of the lateral funiculus. The axons in this tract ascend to spinal cord segments C1 and C2, where they synapse in the *lateral cervical nucleus* (Fig. 3.1). The fibers arising from this nucleus will then decussate and project through the brain stem to the thalamus. Some collaterals of the ascending fibers will terminate in the RF. From the thalamus, fibers project to the somatosensory cortex.

The sensations transmitted by the spinocervicothalamic tract are *touch* and *superficial pain*. This pathway is *discriminative* in that the location of the painful stimulus can be precisely determined by the animal, which is a quality linked to the high degree of somatotopy exhibited by this pathway. Clinically, function of the spinocervicothalamic tract is tested by lightly pinching the skin with fingers or a mosquito hemostat. This stimulus is applied *lightly* and *briefly* so as to activate the spinocervicothalamic pathway preferentially.

The *spinoreticular tract* is primarily concerned with transmission of *deep-pain* and *visceral sensations*.^{22,32,33} The primary afferents of this pathway enter the cord and immediately diverge to

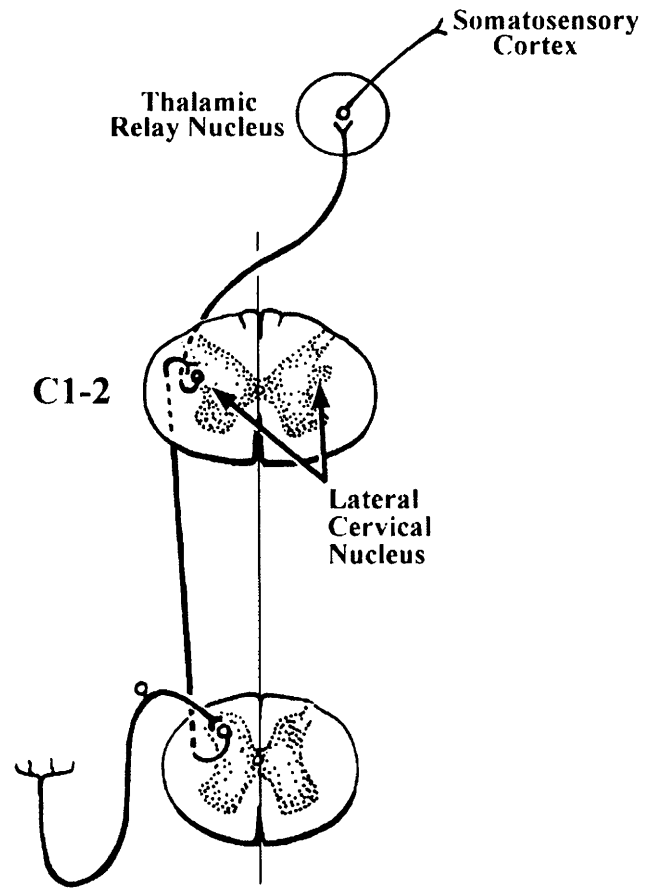

Fig. 3.1. Spinocervicothalamic tract.

send collaterals several segments rostral and caudal to the segment of entry. This spreading of information across several spinal cord segments enables these afferents to participate in intersegmental reflexes (various manifestations of withdrawal and postural reflexes in response to painful stimuli). Second-order neurons are found in the dorsal horn. Axons of projection neurons in this system are present diffusely in the lateral and ventral funiculi. These projections are *bilateral*; decussation of axons in this system occurs diffusely throughout the long axis of the spinal cord (Fig. 3.2).

Most ascending projections of the spinoreticular tract that reach the brain stem do not project directly to the thalamus; rather, they terminate in the RF. Therefore most deep pain that is consciously perceived arrives at the cortex via diffuse reticular projections to the thalamus. Activation of this pathway increases arousal and activates the limbic system, a connection that in humans is associated with emotional responses to pain. There is ample reason to believe that animals, too, experience emotional aspects of pain. As a consequence of the multisynaptic and diffuse nature of this pathway, somatotopy is not well defined, and sensations brought to consciousness by the spinoreticular tract are *poorly localized*: that is, the animal experiences pain and arousal, but cannot readily pinpoint the source.

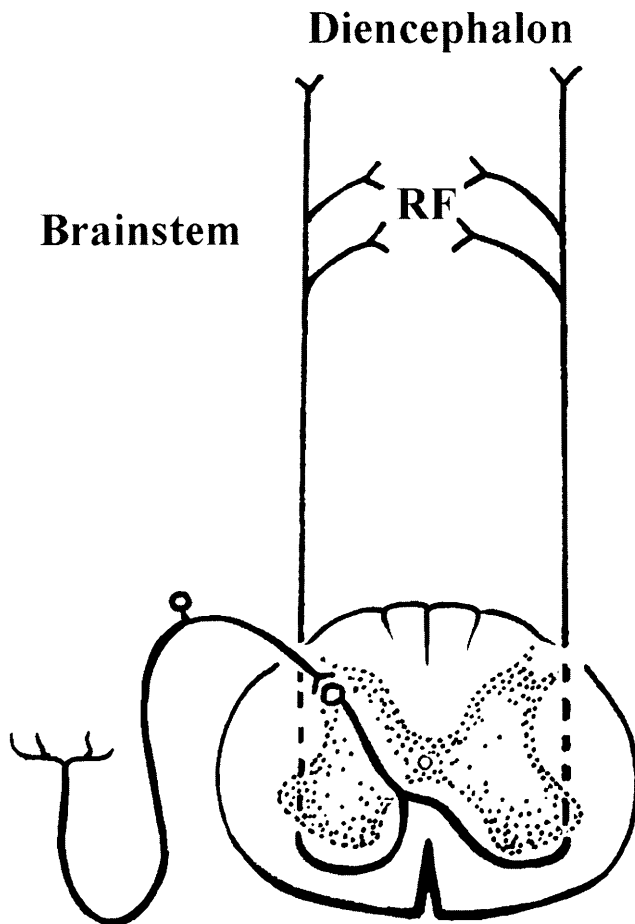

Fig. 3.2. Spinoreticular tract.

Visceral pain is particularly poorly localized (see the later comments on referred pain). Visceral afferent fibers travel in sympathetic nerves, have large overlapping receptor fields, and respond primarily to stretch, ischemia, dilation, or spasm (direct trauma to viscera—including surgical trauma—is a surprisingly ineffective stimulus for nociceptors).^{22,34,35} Whereas in somatic structures the ratio of A- δ to C fibers is about 1:2, that ratio in viscera is about 1:10.³⁵ By extension, then, pain of visceral origin tends to be dull, aching, or burning. Primary afferents from viscera follow autonomic nerves (e.g., the vagus and sympathetic nerves) to the central nervous system (CNS).

The deep-pain pathway is tested in the neurological examination by application of a hemostats across the base of a toenail (taking care to exclude skin), a manipulation that stimulates nociceptors in the periosteum of the third phalanx.

Trigeminal System

For the head, nociception and tactile information are transmitted by the trigeminal system.^{29,36} Cell bodies of primary afferent fibers reside within the *trigeminal* (semilunar) *ganglion*. Their central processes enter the pons with the trigeminal nerve and course caudal along the lateral surface of the medulla (Fig 3.3). A nuclear column lies medial to the spinal tract throughout its

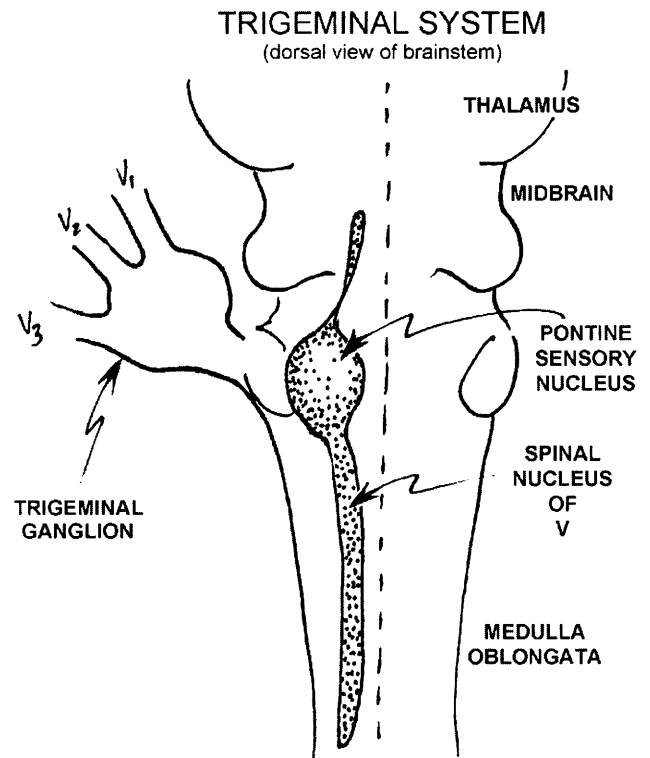

Fig. 3.3. Trigeminal afferent tract.

length. At its rostral extent in the pons, this group of cell bodies comprises the *pontine sensory nucleus*. More caudally, the column is known as the *spinal nucleus of V*. The pontine and spinal nuclei of V contain somata of the second-order neurons in this system. There is a rostral-to-caudal segregation of function in these nuclei; the pontine nucleus is primarily concerned with discriminative tactile and proprioceptive stimuli, and the rostral part of the spinal nucleus of V sends somatosensory information to the cerebellum. The majority of neurons in the spinal nucleus of V, however, are concerned with nociception. Many of these will project to motor nuclei of cranial nerves to participate in reflex arcs (e.g., corneal and palpebral reflexes), and many more will project to the RF to affect autonomic responses and increase arousal. Fibers for conscious perception, however, cross the midline of the medulla diffusely and join the contralateral quintothalamic tract, adjacent to the medial lemniscus. The quintothalamic (aka trigeminal lemniscus) tract projects to the thalamus, and, from there, nociceptive information reaches the somatosensory cortex via the internal capsule.

Nociception: Concepts and Perception (Pain)

Human pain has been described as having three facets, each reflecting the different targets of this sensory information.³⁷ The sensory-discriminative aspect of pain is concerned with identifying its onset, location, intensity, and character, and is primarily a function of the somesthetic cortex. Behavioral, emotional, and

autonomic responses constitute the motivational-affective facet of nociception, and arise in large measure from the connections nociceptive pathways make with the RF, hypothalamus, and the limbic system. Finally, responses to nociception that are a result of experience, attention, and cultural conditioning are described as cognitive-evaluative. These responses are generated by higher cortical functions (awareness, memory, and reasoning).

Painful stimuli are not emotionally neutral events. There is, after all, adaptive value in having an aversion to noxious stimuli; the strong connections of pain pathways to the limbic system ensure that the organism (whether human or animal) will have a negative emotional reaction to pain, which is a feature that is referred to as the *affective component of pain*. This may seem oddly obvious to normally functioning organisms like veterinarians—pain hurts, after all, so why wouldn't you want to avoid it? Reflect for a moment on the myriad of other stimuli constantly made available to the conscious brain; the majority of sensory experiences are emotionally neutral. Feel the surface of this paper: Your fingers relay a vast amount of sensory information, but unless you give yourself a paper cut (a noxious stimulus) or have developed a fetish for paper (resulting in pleasurable feelings as a result of learned associations), you don't have an emotional response to this sensation.

Pain *hurts*, then, because the nociceptive pathways make connections to the limbic system, which assigns an emotional value to it. There are, in fact, documented human cases where brain injury interrupts this valuation process; these patients can feel pain, can identify it, its character, and location accurately, and yet feel no aversion to the stimulus (an extraordinary condition called *asymbolia for pain*).

Suffering is the state of emotional distress associated with events that threaten an organism. Pain need not be the only cause of suffering, although it is probably safe to say that it is the primary one in nonhuman animals. It has been stated that animals do not suffer, because they cannot generate the same *anticipation* of pain and its outcome. Although the ability to anticipate a painful event and put it in a complex context (i.e., How bad is this going to hurt? How long will it hurt? Am I going to die? Who's going to take care of my family?) probably *is* limited in domestic animals, this ability very likely is only partly responsible for the emotional state people associate with suffering. Anticipation is really a feature of the cognitive-evaluative aspect of pain. That this aspect is not well developed in animals is probably defensible on a purely anatomical basis. However, suffering is clearly an *emotional* state. It is probably therefore firmly rooted in the connections between nociceptive pathways and the limbic system, the generator of behavior and emotion. Suffering is a part of the motivational-affective facet of nociception, and there is ample neuroanatomical evidence that the connections between nociceptive pathways and the limbic system are at least as well developed in animals as in people.

Pain Modulation

There is a tendency to conceive of somatosensory pathways as electrical circuits that respond to stimuli in predictable ways and

that consistently produce a sensory perception that is a faithful recording of the stimulus in the periphery. This is a useful model, of course, but it grossly oversimplifies the actual condition, wherein activity in the CNS can *modulate* somatosensory processing. This ability to alter activity in sensory systems is especially well developed in nociceptive pathways. *The ability of a given stimulus to produce a perception of pain is a highly labile property and can be modified in the periphery, in the spinal cord, in the brain stem, and in higher centers.*

Modulation in the Periphery (Nociceptors)

Nociceptor threshold is not a constant. As was described above, the presence of so-called *silent nociceptors* is one example of how conditions in the cellular environment of the naked nerve ending can change the sensitivity of the receptor to stimulus. The high threshold of silent nociceptors ensures that, under normal circumstances, they are relatively insensitive to any stimuli, but, on exposure to inflammatory mediators, this threshold is markedly reduced, and previously silent nociceptors can be activated.^{24–26}

Similarly, many inflammatory mediators (e.g., prostaglandins and leukotrienes), collectively referred to as *nociceptor sensitizers*, will lower the threshold of other populations of nociceptors.^{24,38,39} Thus, in damaged or inflamed tissue, stimuli that would normally be subthreshold may produce activity in nociceptive afferents. Likewise, certain inflammatory mediators (e.g., bradykinin and serotonin) or substances released by damaged cells (e.g., potassium ions and adenosine triphosphate) directly stimulate nociceptors and can thus be considered *nociceptor activators*. Interestingly, stimulated free-nerve endings can release substances directly into the surrounding tissues. Notable among these is *substance P*. Substance P (which is also an important neurotransmitter in central nociceptive pathways) dilates blood vessels and degranulates mast cells, both of which contribute to inflammation and increased sensitization of local nociceptors. All of these events contribute to the development of *primary hyperalgesia* (resulting from the increased responsiveness of nociceptors to noxious stimuli) and a related phenomenon, *allodynia* (wherein normally nonnoxious stimuli, such as those that elicit a touch sensation, become capable of activating nociceptors). Administration of nonsteroidal anti-inflammatory drugs (NSAIDs) is intended to obviate the expression of hyperalgesia and allodynia in injured—and specifically *inflamed*—tissue.

Modulation in the Dorsal Horn

Considerable processing of nociceptive information occurs in the dorsal horn, although precisely what happens there is debated. One of the fundamental concepts of dorsal horn processing is that one population of second-order neurons is dedicated to nociception (nociceptive-specific cells) and an additional, smaller group receives input from primary afferents conducting both noxious and nonnoxious tactile information.^{22,25,40} It is suspected that the nociceptive-specific neurons are primarily involved in discriminative nociception (i.e., localization). The second group, referred to as wide-dynamic-range or *WDR neurons*, responds both to noxious and nonnoxious stimuli, and is likely to be recruited in

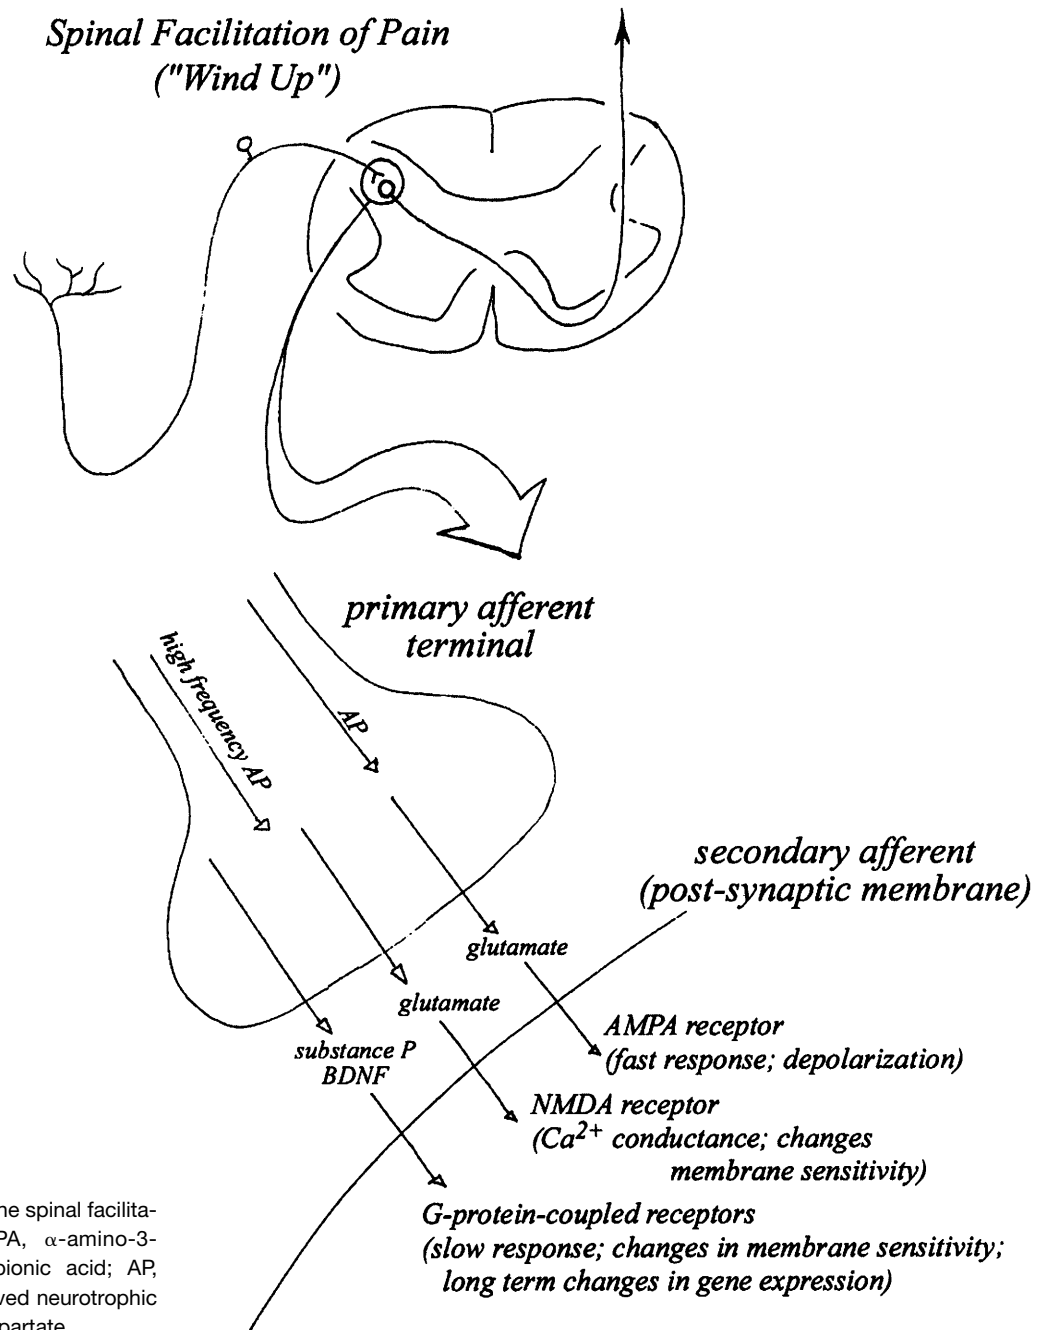

Fig. 3.4. Processes involved in the spinal facilitation of pain or windup. AMPA, α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; AP, action potential; BDNF, brain-derived neurotrophic factor; and NMDA, *N*-methyl-D-aspartate.

pathways that exhibit less somatotopy (i.e., are less discriminative). The WDR neurons appear to be relatively insensitive to tactile information, discharging at one rate in response to innocuous touch stimuli, while responding more vigorously (at a greater frequency) to noxious stimulation. These neurons also receive information from both somatic and visceral structures, which is a feature believed to underlie the phenomenon of *referred pain*.⁴¹ In referred pain, noxious stimuli originating in viscera are perceived as originating instead from a somatic region (body wall or skin). This perception is thought to result from the fact that information from that region of viscera converges on WDR neurons and path-

ways that also convey information from somatic structures. Since we (and presumably other organisms) are much more familiar with sensations arising from our skin and body wall, the pain is interpreted to originate in these somatic structures.

The WDR neurons are probably the cells most important in the expression of *spinal facilitation of pain*, or *windup* (Fig. 3.4). Windup occurs with rapid, continuous firing of primary nociceptive afferents, probably most especially small-diameter, unmyelinated fibers (C fibers).^{38,42,43} The high-frequency volley of action potentials in the primary afferent terminal stimulates release of increased amounts of glutamate and is also associated with release

of substance P and brain-derived neurotrophic factor.^{43,44} The increased exposure to glutamate in the synaptic cleft activates N-methyl-D-aspartate (NMDA) receptors (inactive except under conditions of persistent membrane depolarization) on the postsynaptic membrane. This particular variety of glutamate receptor is unique in that it exhibits a calcium conductance; its activation is therefore associated with influx of calcium ions onto the postsynaptic neuron, leading to a series of intracellular cascades that ultimately results in upregulation of receptors.^{42,45} Substance P and brain-derived neurotrophic factor are neuromodulatory neurotransmitters that bind with G-protein-coupled receptors. These, too, activate intracellular signaling cascades that increase the membrane's sensitivity to subsequent stimulation.

The net effect of these events is that high-frequency action potentials in the primary afferent neuron “train” the second-order neurons to respond more vigorously to subsequent stimulation. This change can last from hours to days (and longer) after the causative event ends. Effectively, then, prolonged noxious stimuli produce greater sensitivity to subsequent stimuli. What is especially significant about this phenomenon is that general anesthesia does not prevent windup, as it does not prevent generation of action potentials in the primary afferents. This observation has been used as a compelling argument for the use of analgesics preoperatively or intraoperatively as a preemptive strike against the development of windup during surgeries (e.g., orthopedic procedures) likely to activate C fibers. In 1965, Melzack and Wall⁴⁶ developed a concept of spinal cord pain modulation that they called the *gate control theory*. The specifics of the neuronal interactions in the original gate control theory have since been shown to be inaccurate, and many contemporary pain researchers object to the continued use of the term “gate control theory.” Nonetheless, the term is in very wide use among professionals educated in medicine, and the model, however inaccurate in its details, is useful as a basis for understanding the modulatory influences of tactile information on nociceptive information at the level of the spinal cord. The gate control theory was developed primarily to explain the common observation that nonnoxious tactile stimulation (e.g., vibration and massage) can reduce the perception of pain. That this is so is evident in our common pain experiences. For example, when you “bark your shin,” your first impulse is to rub the injured region. To do so lessens the perceived pain.

In a simplified form, the gate control theory may be summarized as follows: Both nociceptive-specific C fibers and nonnociceptive (tactile) A-β fibers converge on WDR neurons of the dorsal horn. The nonnociceptive fibers also make connections with interneurons whose effects on transmission neurons of the dorsal horn are inhibitory. When A-β fibers are activated by tactile stimuli, they weakly stimulate the WDR projection neurons and simultaneously stimulate the inhibitory interneurons. These inhibitory neurons reduce transmission in the nociceptive pathways either by (a) inhibiting activity in the WDR projection neurons (postsynaptic inhibition) or (b) inhibiting release of neurotransmitter from the C-fiber terminals in an axoaxonic connection (presynaptic inhibition). Whatever the mechanism, the end result is that ascending transmission of nociception is decreased.⁴¹

The gate control theory, regardless of the exact circuitry, explains the observation that certain kinds of tactile stimuli can reduce perception of pain. These stimuli can take the form of heat or cold application, massage, vibration, or transcutaneous electrical nerve stimulation, a pain therapy used in human medicine, among others. Additionally, the described modulation at the level of the dorsal horn may be at least partly responsible for the effectiveness of acupuncture for relief of pain.

Suprasegmental Modulation

Activity in spinal nociceptive pathways is also strongly influenced by antinociceptive systems that originate in the brain stem.^{21,41,44,47} The midbrain (mesencephalon) and medulla both possess a series of midline nuclei that modulate the transmission of nociception. Input from higher cerebral centers and collaterals from ascending nociceptive pathways, particularly those conveying deep pain (spinoreticular tract), activate these nuclei. Among the nuclei that give rise to descending pain modulatory pathways, of particular note are the mesencephalic *periaqueductal gray matter* (PAG) and the *nucleus raphe magnus* of the rostroventral medulla.

The PAG receives input from ascending nociceptive tracts and higher centers (including limbic structures and cerebral cortex) and sends axons to the nucleus raphe magnus, to other medullary reticular nuclei, and, to a much lesser extent, to the dorsal horn of the spinal cord. These axons release multiple neurotransmitters, most notably *endorphins*, which are transmitters with powerful antinociceptive properties. The PAG input to the nucleus raphe magnus activates (through disinhibition) the monoaminergic pathways that arise here and descend the cord to modulate nociception at the level of the dorsal horn (Fig. 3.5). The primary neurotransmitters of the nucleus raphe magnus and other medullary nuclei are serotonin and norepinephrine. Activity in these systems will recruit a pool of interneurons whose neurotransmitters (endorphin, enkephalin, and dynorphin) inhibit transmission in spinal cord pain pathways at the level of the dorsal horn.

Neuropathic Pain

This is pain that is caused by injury to the nervous system. Damage leading to neuropathic pain can result from a variety of insults, including trauma (e.g., amputation and crushing injury), vascular injury (e.g., thromboembolic disease), endocrinopathy (e.g., diabetes mellitus), or infection (e.g., postherpetic neuralgia). Neuropathic pain resulting from these many different causes is probably not a single uniform entity. Several mechanisms are thought likely to contribute to neuropathic pain; not all of these necessarily underlie any given case of neuropathic pain, although they are not mutually exclusive.^{38,48,49}

Hyperalgesia and allodynia are both commonly associated with neuropathic pain. *Dysesthesias*, which are unpleasant, abnormal sensations often characterized as tingling or “electric,” are sometimes described by affected people, although neuropathic pain is most usually described as having a burning, lancinating quality. In the peripheral nervous system, injury to pri-

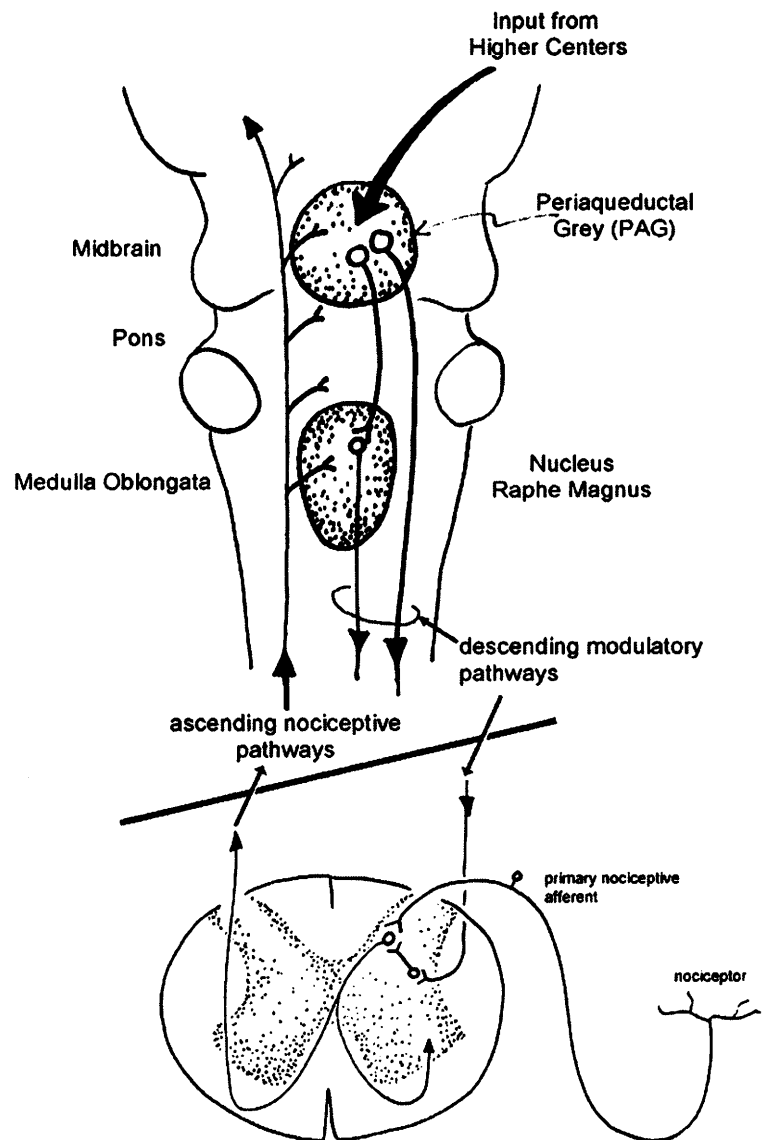

Fig. 3.5. Descending inhibitory pain pathways.

many afferents (up to and including the dorsal root ganglia) can cause neuropathic pain. The pathomechanisms producing this pain are not clearly understood and, like all facets of neuropathic pain, are likely to be multiple. In at least some cases, the damaged primary afferent produces an increased frequency of spontaneous action potentials (most neurons do this to some extent, but normal nociceptive afferents typically do so at a very low rate), a phenomenon called *ectopic discharge*.^{38,48} Damaged primary afferents are also apt to develop collateral sprouting, perhaps in response to neurotrophic factors released by damaged tissues. Aberrant collaterals of nociceptive neurons may spread into adjacent skin or other tissues, where their activation can produce an abnormal perception of pain.³⁸ One line of inquiry has revealed a phenomenon of electrical coupling between somatosensory and sympathetic fibers in the periphery (including the dorsal root ganglia). This coupling, called *sympathetically maintained pain*, activates nociceptive pathways (and pain perception) with activity in sympathetic neurons.^{38,48}

Centrally, the alterations described in the discussion of windup (spinal facilitation of pain) are likely to play a role in the development of sustained, neuropathic pain, inasmuch as the upregulation of receptors on postsynaptic membranes can persist for a prolonged time.^{43,45} Since activation of NMDA glutamate receptors is a key part of spinal facilitation of pain, use of NMDA antagonists shows potential as a therapy for neuropathic pain. Additionally, there is evidence that tactile (i.e., nonnociceptive) A- β afferent fibers sprout collateral connections in the dorsal horn (again, probably in response to neurotrophic factors released by injured nervous tissue), making aberrant connections with projection neurons that are normally associated with nociception.⁴⁸ Activity in these fibers will therefore produce activity in nociceptive pathways, leading ultimately to the perception of increased pain.

There is also ample evidence that the repertoire of neurotransmitters and/or receptors within the dorsal horn undergoes changes in response to injury.^{49,50} Some researchers have docu-

mented a decrease in γ -aminobutyric acid (an inhibitory neurotransmitter) in animal models of neuropathic pain. Experimental techniques that increase levels of γ -aminobutyric acid in the spinal cord are associated with an attenuation of allodynia, which is characteristic of neuropathic pain.

A particularly frustrating aspect of neuropathic pain is the extent to which it is refractory to opioids. This is likely because of a loss of opioid receptors, which is a phenomenon that has been reported in the dorsal root ganglion and the dorsal horn.⁴⁸ Simultaneously, cholecystokinin and its receptors appear to be upregulated by nervous tissue injury; cholecystokinin has documented opioid antagonist activity.⁴⁸

Neuropathic pain is a well-recognized problem in human medicine, and there is observational evidence that it is a significant cause of postinjury morbidity in animals, as well. Therapies to effectively reverse the development of neuropathic pain will rely on a clear understanding of the cellular biology and neurophysiology that underlie it.

Response to Pain and Injury

Nociceptive stimulation of medullary centers of circulation and ventilation, hypothalamic centers of neuroendocrine function (primarily sympathetic), and limbic structures produces suprasegmental reflex responses. These include hyperventilation, increased hypothalamic neural sympathetic tone, and increased release of catecholamines and other endocrine hormones. Increased neural sympathetic tone and catecholamine secretion add to that induced segmentally to further increase cardiac output, peripheral resistance, blood pressure, cardiac work, and myocardial oxygen consumption. In addition, there is increased secretion of cortisol, adrenocorticotropic hormone, glucagon, cyclic adenosine monophosphate, antidiuretic hormone, growth hormone, renin, and other catabolic hormones, and a concomitant decrease in the anabolic hormones insulin and testosterone. These responses, characteristic of the stress response, cause increased blood glucose, free fatty acids, blood lactate, and ketones, as well as an increased rate of metabolism and oxygen consumption. These responses cause substrate mobilization to central organs and injured tissues, and lead to a catabolic state and negative nitrogen balance. The magnitude and duration of these changes parallels those of the degree of tissue damage and may last for days when weight loss and muscle wastage become clinically obvious.^{17,51-54}

These nociceptive responses also occur in anesthetized or unconscious patients because the nociceptive neural activity is not obtunded at the spinal and brain-stem levels. Nevertheless, the patients are pain free because the nociceptive activity does not terminate or impinge on a functioning cerebral cortex. It has been proposed that these responses can be obtunded or largely prevented by the preoperative administration of analgesic agents (so-called preemptive analgesia).⁵⁵ More specifically, when evoked potential responses to somatic stimulation are abolished by epidural or intrathecal local anesthetics, the stress response is inhibited. Peripheral nerve blockade alone is not as effective at blocking the stress response. Systemic opioids have little effect

on the stress response. Epidural or intrathecal opioids when used alone appear to obtund the stress response, but not nearly as effectively as do local anesthetics. Norepinephrine, epinephrine, adrenocorticotropic hormone, and cortisol increased intraoperatively corresponding to surgical manipulation in dogs anesthetized with isoflurane alone for ovariohysterectomy, and remained elevated postoperatively. These endocrine responses were prevented by the preoperative administration of the α_2 -agonist medetomidine.⁵⁶ Administration of analgesics (e.g., morphine or xylazine) has been shown to decrease plasma catecholamine concentrations in cats after onychectomy.⁵⁷

Intense anxiety and fear, which are an integral part of the pain experience and response, greatly enhance the hypothalamic responses through cortical stimulation. Pain-free anxiety can cause greater cortisol and catecholamine responses than those resulting directly from nociceptive impulses reaching the hypothalamus.^{58,59} In addition, anxiety causes cortically mediated increases in blood viscosity, clotting time, fibrinolysis, and platelet aggregation.⁶⁰⁻⁶³ Pain-induced responses are summarized in Table 3.1.⁶⁴

These reflex responses induced by tissue damage and pain, although immediately protective for short-term survival of the organism, can be deleterious if prolonged. Indeed, in the hospital setting, and specifically in a surgical environment, they may be more deleterious than beneficial. More specifically, the stress response increases cardiac output, cardiac work, and oxygen consumption at a time when cardiac reserve is diminished. Intense vasoconstriction, especially of the splanchnic beds, leads to ischemia, tissue hypoxia, and release of myocardial toxins. Renal failure may ensue as a result of intense vasoconstriction and the release of arginine vasopressin (antidiuretic hormone) and aldosterone. In many patients with severe posttraumatic or postsurgical pain, these neuroendocrine responses are of sufficient magnitude to initiate and maintain shock.⁶⁵

Attenuation of the stress response through adequate pain relief and supportive therapy should improve patient outcome and promote healing. For example, in a recent report, the continuous-rate infusion of butorphanol (13 $\mu\text{g}/\text{kg}/\text{h}$) for 1 day following abdominal surgery in horses decreased plasma cortisol concentrations and improved behavior scores when compared with horses that did not receive butorphanol.⁶⁶ Similarly, dogs undergoing forelimb amputation that received a constant-rate infusion of ketamine during and after surgery in addition to standard analgesics had significantly lower pain scores 12 and 18 h after surgery and were more active on postoperative day 3 as compared with dogs that did not receive ketamine.⁶⁷ Pain can be managed initially through systemic administration of analgesics, primarily opioids, α_2 -adrenergic agonists, local anesthetic nerve blocks, lidocaine administered intravenously, ketamine, and NSAIDs. Long-term (up to 12 h) control of pain may include epidural or spinal administration of many of these agents in combination with local anesthetics. Local and regional nerve blocks (e.g., intercostal, brachial plexus, or intra-articular) can play an important role in the perioperative period and as a part of a balanced anesthetic protocol.⁶⁸ Preventive analgesia has been shown to be highly effective in preventing windup and in decreasing postoperative pain as measured by a reduced requirement for analgesics.^{55,69}

Table 3.1. Neuroendocrine and metabolic responses to pain.

Segmental and suprasegmental reflexes
Increased sympathetic tone
Vasconstriction: skin and viscera
Increased systemic vascular resistance and preload
Increased stroke volume, heart rate, and cardiac output
Increased arterial pressure and myocardial work
Increased metabolic rate and oxygen consumption
Decreased gastrointestinal and urinary tone
Increased skeletal muscle tone
Endocrine responses
Increased adrenocorticotropic hormone, cortisol, antidiuretic hormone, and growth hormone
Cyclic adenosine monophosphate, catecholamines, renin, and angiotensin II
Aldosterone, glucagon, and interleukin I
Decreased insulin and testosterone
Metabolic responses
Hyperglycemia
Glycogenolysis and gluconeogenesis
Increased muscle protein metabolism
Increased lipolysis
Water and electrolytes
Retention of water and sodium ions
Increased potassium-ion excretion
Decreased extracellular fluid
Ventilation
Central hyperventilation
Segmental hypoventilation
Splinting and bronchospasm
Diencephalic and cortical responses
Anxiety and fear increase sympathetic responses
Blood viscosity and clotting time
Fibrinolysis and platelet aggregation
Psychological effects
Overall effects of pain
Prolonged recovery
Slower return to normal behaviors

Preemptive analgesia clearly has beneficial effects in the immediate perioperative period, including being able to maintain anesthesia with less inhalant agent (less cardiopulmonary depression) and improved recovery from anesthesia and surgery. Based on survey studies from human medicine, the overall impact of preemptive analgesia on patient pain and outcome variables is somewhat less clear.^{70–74} Large-scale clinical studies evaluating the role of preemptive analgesia in overall patient outcome have not been published in the veterinary literature to date. Nevertheless, the clinical benefits of preemptive analgesia likely outweigh the costs. As such, analgesics should be administered to all animals undergoing a surgical or invasive diagnostic procedure unless there are compelling reasons to do otherwise. In addition, NSAIDs may be useful in relieving pain caused by the continued release of algogenic substances from injured and inflamed tissues. Nonpharmacological treatments, such as supportive bandages and splinting, should not be overlooked.

Communicating and Measuring Pain in Veterinary Patients

As previously mentioned, pain is an extremely complex multidimensional experience with both sensory and affective (emotional) elements. Obviously, there are distinct populations, including human neonates, nonverbal adults, and animals, that cannot express their pain overtly. However, all mammals possess the neuroanatomical and neuropharmacological components necessary for transduction, transmission, and perception of noxious stimuli; therefore, it is commonly assumed that animals experience pain even if they cannot exactly perceive or communicate it in the same way people do.⁷⁵

All pain is subjective. No one can “feel” another person’s pain. Even after identical surgical procedures, people do not experience the same quality and intensity of pain. In view of that, how can we determine with any degree of certainty what an animal feels? Put simply, in humans, pain is what the patient says it is; and, in animals, pain is what humans say it is. Clearly, there is more room for error when humans assess pain in an animal, because all judgments are subjective and, if the humans “get it wrong,” a great disservice is done to the animal. It can be stated that pain has been treated effectively only if it can be measured. Veterinarians can measure many specifics in our patients, including blood pressure, temperature, and arterial oxygen partial pressure, all of which are expressed in quantifiable, completely objective units, but what is the unit of pain? There is none. Lord Kelvin stated in 1883, “I often say that when you can measure what you are speaking about and express it in numbers you know something about it; but when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meager and unsatisfactory kind.”⁷⁶

With that in mind, there is presently no gold standard for assessing pain in animals. Many different scoring methods that include physiological variables (in an attempt to identify objective measures) and behavioral variables have been published, but few have been rigorously validated. The issue of pain assessment in animals is especially complex because consideration must include differences in gender, age, species, breed, strain, and environment. Assessment systems must also take into account the different types and sources of pain, such as acute versus chronic or neuropathic pain and visceral compared with somatic pain. For example, if a pain scale were developed to evaluate acute postoperative pain in dogs following routine abdominal surgery, such as ovariohysterectomy, then the scale might be inappropriate for assessing pain after orthopedic surgery or pain associated with chronic osteoarthritis in that species. There is no question that as more studies focus on species-specific pain behaviors and the different types of pain, the ability of the veterinary community to recognize and treat pain in animals will improve. Nevertheless, the assessment of pain in animals will remain a subjective and inaccurate undertaking for the foreseeable future. Despite that prediction, one fact remains certain: Ignoring pain simply because there is difficulty measuring it condemns animal patients to undue suffering.

Behavioral responses to pain vary greatly between species, and

these differences may be linked to an animal's survival mechanisms. For example, because rats and mice are prey animals, overt signs of pain or injury draw the attention of predators, so the rodents have evolved to where they instinctively disguise their pain. The subtle signs of pain exhibited by these species, such as abdominal pressing and back arching, can be easily missed by an inexperienced observer.^{77,78} Because of behavioral distinctions, pain-assessment tools must be species specific. There are also behavioral variations within a species: Few veterinarians would disagree that Labrador retriever dogs react differently from the Arctic breeds in the postoperative period!

It is now apparent that every animal is unique with respect to number, morphology, and distribution of opioid receptors; and these differences are genetically determined. This, as well as each individual's own endogenous ability to inhibit pain transmission and perception, may explain some of the variation in pain tolerance and the range of responses to analgesic drugs. From the work of Holton and others with dogs⁷⁹ and Roughan and Flecknell⁷⁸ with rats, it is obvious that creating meaningful pain-assessment tools is a painstaking and time-consuming task.

Pain-Assessment Tools in Veterinary Medicine

Acute Pain

Most studies in dogs and cats have focused on assessing acute postoperative pain. Not all of the systems used have been validated or rigorously tested, however; and the key question for a busy practitioner is "How well do these scoring systems perform in clinical practice?"

Objective Measures

In both cats and dogs, the correlation between easily measured physiological variables (heart rate, respiratory rate, blood pressure, and pupil diameter) and pain scores have been evaluated.⁸⁰⁻⁸² No study found a consistently reliable objective measure, which is not surprising as these parameters can be affected by many factors other than pain. For example, an opioid alone causes mydriasis in cats but miosis in dogs. Pupil size is also affected by fear and ambient light. In a tightly controlled research setting, blood pressure looked promising as an indirect indicator of pain in cats, but, in a clinical environment, this variable was an unreliable indicator of pain.^{83,84}

Changes in plasma cortisol and β -endorphins are components of the "stress response" to anesthesia and surgery, and much effort has been expended trying to correlate these hormones with pain in laboratory and clinical analgesia trials. Plasma cortisol was not a useful pain marker in dogs and is extremely unreliable in cats.^{80,84-87} Mechanical nociceptive threshold testing with various devices (palpometers and algometers) has proved to be useful for evaluating both primary (wound) and secondary (remote area) hyperalgesia in cats and dogs.^{81,88,89} Changes in wound sensitivity have correlated with visual analog scoring in cats, suggesting that assessing wound tenderness is a valuable tool and should be incorporated into an overall assessment protocol.⁸⁹ Force plate gait analyses have been widely used to assess lame-

ness in dogs objectively. This technique has also been used to evaluate response to different surgical procedures and to assess the efficacy of a variety of analgesics. Conzemius et al.⁹⁰ have demonstrated that pressure platform gait analysis can be used successfully in cats and may provide a method of assessing pain after procedures such as onychectomy.

Scoring Systems

Because animals cannot self-report, all scoring systems that depend on a human observer must, by definition, be subjective to some degree and leave room for error, which could be either underassessment or overassessment of the animal's pain. Any system used must be valid, reliable, and sensitive.⁹¹ Without strictly defined criteria and the use of well-trained and experienced observers, many scoring systems are too variable, which is one of the main criticisms of multicenter clinical trials. One scoring system may show an analgesic agent to be effective, and another shows that same analgesic to be ineffective. If a system is insensitive, then these differences are inevitable and result in large interobserver variability.

Simple descriptive scales. These are the most basic pain scales. These usually have four or five descriptors from which observers choose, such as *no pain*, *mild pain*, *moderate pain*, *severe pain*, or *very severe pain*. Although simple to use, these scales are extremely subjective and do not detect small changes in pain behavior.

Numerical rating scales. These are essentially the same as simple descriptive scales, but assign numbers for ease of tabulation and analyses; for example, absence of pain is assigned the number 0 and very severe pain the number 5. This system implies equal difference or weighting between each category, which is not the case. These are discontinuous scales; therefore, a dog experiencing pain that is "just in" category 2 is in quite different condition from a dog that is also in category 2 but almost in category 3. A further development of the simple descriptive and numerical rating systems is a categorized numerical rating system where certain behaviors are chosen and assigned a value. For example, vocalization can be divided into none (score = 0), crying but responsive (score = 1), and crying but nonresponsive (score = 2); other categories may include movement, agitation, and posture.⁹²

Visual analog scale. In an attempt to improve on discontinuous scales, the visual analog scale (VAS) has been widely used in veterinary medicine (Fig. 3.6). This tool consists of a continuous line (usually 100 mm long) anchored at either end with a description of the limits of the scale, for example *no pain* or *no sedation* at one end and *severe pain* or *asleep* at the other end. An observer places a mark on the line at the point that he/she thinks correlates with the degree of pain in the animal under observation, and this point is later translated into a number by measuring the distance to the mark from zero. The VAS can be improved by adding a descriptor that says "Worst possible pain for *this* procedure," because the worst pain associated with a castration is likely to be different from the worst pain after a thoracotomy. Without training and experience, the VAS results in wide interobserver variation.

Fig. 3.6. The visual analogue scale used to assess pain in animals.

Holton and others⁹¹ compared the use of simple descriptive, numerical rating, and visual analogue scales for assessing pain in dogs after surgery. The results showed significant observer variability—as high as 36%—with all three scales. These researchers suggested that the numerical rating scale was most suitable if a single, trained observer performed all assessments, which again emphasizes the difficulty in conducting reliable multicenter trials.

Lascalles and others⁸⁸ have reported the use of a dynamic and interactive visual analog scale (DIVAS) as an extension of the classic VAS system in dogs. With the DIVAS system, animals are first observed from a distance undisturbed and then approached, handled, and encouraged to walk. Finally, the surgical incision and surrounding area are palpated, and a final overall assessment of sedation and pain is made. This approach overcomes some of the deficiencies of purely observational systems; for example, a dog may lie very still and quiet *because* a wound is painful, and this would go undetected unless the observer interacted with the animal. The DIVAS system has also been used to assess postoperative pain in cats and, when performed by one individual unaware of treatments, it detected differences between analgesics (meperidine and carprofen) and between treated (analgesia) and untreated (no analgesia) cats.^{93,94} So far, the scoring systems discussed in this section are regarded as *one-dimensional* in that they assess only intensity of pain.

Considering the complexity of pain, it is not surprising that simple, subjective, one-dimensional systems have not proven ideal. In humans, multidimensional systems, such as the McGill Pain Questionnaire, that account for not only intensity but also sensory and affective (emotional) qualities of pain have provided a more comprehensive assessment of a patient's pain. Multidimensional systems are particularly important when self-reporting is not possible, but reports must incorporate components that are proven to be sensitive and specific to pain (e.g., facial expressions in infants) in the species being studied.⁹⁵

It is now accepted that quantitative measurements of behavior are the most reliable methods for assessing pain in animals and that, if the methodology used to develop and validate these systems is rigorous, they can be more objective with minimal observer bias.⁹⁶ Knowledge of normal behavior for the individual being evaluated is essential. Deviations from normal behavior suggest pain, anxiety, or some combination of stressors. Developing these quantitative systems is a daunting task; Fox et al.⁹⁷ identified 166 possible pain behaviors associated with ovariohys-

terectomy in bitches. The importance of noninteractive (videotaped in absence of caregivers) and interactive behaviors has also been demonstrated.^{97,98} In these studies, dogs that had undergone surgery without analgesics spent more time sleeping than control animals did, but also showed increased cage-circling activity, lip licking, and flank gazing. These activities would be easy to miss in a busy clinical setting, however. Although reduced after surgery (with and without analgesics), tail wagging and positive interactions still occurred in the presence of a caregiver; and, during cursory examinations, the dog could easily be scored as *not painful*.

Sporadic observation of animal behavior may not reveal signs of pain. Some signs may be masked by behavior that is stereotypical of the species being observed. For instance, a dog may wag its tail and greet an observer at the cage door despite being in pain. Cats may simply hide in the back of their cages and demonstrate no behaviors that would suggest to a casual observer that they are painful. Behavioral changes indicating pain may not be what are expected. A cat sitting quietly in the back of the cage after surgery may be in pain; however, pain would not be recognized if the caregiver expects to see more active signs of pain, such as pacing, agitation, or vocalizing.

The University of Melbourne Pain Scale (UMPS) has been developed to incorporate objective physiological data (heart rate, respiratory rate, pupil size, and rectal temperature) and behavioral responses (activity, response to palpation, posture, mental status, and vocalization). By assigning numbers to each factor, a score between 0 and 27 is derived.⁹⁹ This scale has been tested on dogs following ovariohysterectomy and demonstrated good agreement between different assessors. It could differentiate between dogs that were anesthetized but not subjected to surgery and those undergoing surgery. With some refinement to detect smaller differences, the system shows promise for clinical use.

To date, the most vigorously validated scale for assessing acute postoperative pain in dogs is the Glasgow composite measures pain scale.⁷⁹ The original 279 words or expressions that could describe pain in dogs have been reduced to 47 well-defined words placed in one physiological category and seven behavioral categories. The behavioral categories comprise evaluations of

- Posture
- Comfort
- Vocalization
- Attention to the wound
- Demeanor and response to humans
- Mobility
- Response to touch

Each descriptor is well defined to avoid misinterpretation. Assessment involves both observation from a distance and interaction with the patient (e.g., palpation of the wound). Frequent assessments are necessary because pain is not a static process, and the benefits of intervention with analgesics must be evaluated. In a busy practice, time-consuming assessments are the biggest drawbacks to effective pain management. For this reason, a short form of the Glasgow composite pain scale, which takes only a few minutes to perform, has been developed (Fig. 3.7).

SHORT FORM OF THE GLASGOW COMPOSITE PAIN SCALE

Dog's name _____

Hospital Number _____ **Date** / / **Time**

Surgery Yes/No (delete as appropriate)

Procedure or Condition _____

In the sections below please circle the appropriate score in each list and sum these to give the total score.

A. Look at dog in Kennel

Is the dog?

(i)		(ii)	
Quiet	0	Ignoring any wound or painful area	0
Crying or whimpering	1	Looking at wound or painful area	1
Groaning	2	Licking wound or painful area	2
Screaming	3	Rubbing wound or painful area	3
		Chewing wound or painful area	4

In the case of spinal, pelvic or multiple limb fractures, or where assistance is required to aid locomotion do not carry out section B and proceed to C
Please tick if this is the case then proceed to C.

B. Put lead on dog and lead out of the kennel. C. If it has a wound or painful area including abdomen, apply gentle pressure 2 inches round the site.

When the dog rises/walks is it?

(iii)	
Normal	0
Lame	1
Slow or reluctant	2
Stiff	3
It refuses to move	4

Does it?

(iv)	
Do nothing	0
Look round	1
Flinch	2

Total Score (i+ii+iii+iv+v+vi) = _____

Fig. 3.7. Short-form pain questionnaire. The short-form composite measure pain score (CMPS-SF) can be applied quickly and reliably in a clinical setting and has been designed as a clinical decision-making tool that was developed for dogs in acute pain. It includes 30 descriptor options within 6 behavioral categories, including mobility. Within each category, the descriptors are ranked numerically according to their associated pain severity, and the person performing the assessment chooses the descriptor within each category that best fits the dog's behavior or condition. It is important to perform the assessment procedure as described on the questionnaire, following the protocol closely. The pain score is the sum of the rank scores. The maximum score for the 6 categories is 24, or 20 if mobility is impossible to assess. The total CMPS-SF score has been shown to be a useful indicator of analgesic requirement, and the recommended analgesic intervention level is 6/24 or 5/20.¹⁷⁰

Suggestions for Creating an Acute-Pain Scoring System

Each practice should choose or design a pain-scoring system that meets its own specific needs, and finding one that suits may require trial and error. The system chosen should be user friendly and readily used by veterinarians and animal-care staff. It should also be an integral part of an animal's postoperative evaluation. After temperature, pulse, and respiration are checked, pain, which has been coined the "fourth vital sign," should also be assessed and treated, if necessary. A scale should include both non-interactive and interactive components and rely heavily on changes in behavior.

Considerations in Establishing a Pain Scale

Pain scales should not be used to deny analgesic therapy to an animal that is likely to be in pain following a procedure. Rather, the pain scale should be used to determine whether analgesic therapy needs to be increased or can be tapered off.

Therapy should not be based on rigid minimum scores.

Individual behaviors suggestive of animal pain or distress should overrule results of pain scoring.

If a procedure is likely to be painful, but the pain score is too low to prompt treatment, a test dose of analgesic should be administered and the patient's response observed.

Critically ill or compromised animals may be unable to show behaviors required to bring about treatment.

Consider low-dose opioid therapy in a painful animal that is slightly obtunded. Increased awareness of surroundings, but not agitation, suggests a beneficial effect of analgesic therapy.

If a practitioner is unsure that a patient is in pain, but tissue trauma has occurred, treat for pain conservatively and observe results.

How Often Should Animals Be Assessed?

Acute Pain

The health status of the animal, extent of surgery/injuries, and anticipated duration of analgesic drugs determine the frequency and interval of evaluations. In general, evaluations should be made at least hourly for the first 4 to 6 h after surgery, provided the animal has recovered from anesthesia, has stable vital signs, and is resting comfortably. Animals not recovering as anticipated from anesthesia/surgery and critically ill animals require much more frequent evaluations until they are stabilized. Patient response to analgesic therapy and expected duration of analgesic drug(s) administered help to determine frequency of evaluations. For example, if a dog is resting comfortably following the postoperative administration of morphine, it may not need to be reassessed for 2 to 4 h. Animals should be allowed to sleep following analgesic therapy. Vital signs can often be checked without unduly disturbing a sleeping animal. In general, animals are not awakened to check their pain status; however, that does not mean they should not receive their scheduled analgesics.

Continuous, undisturbed observations, coupled with periodic interactive observations (open the cage, palpate the wound, etc.) are likely to provide more information than occasionally observing the animal through the cage door. It is regrettable that contin-

uous observations are not practical for most clinical situations. In general, the more frequent the observations, the more likely that subtle signs of pain will be detected.

Chronic Pain

Without doubt, chronic pain affects an animal's quality of life. Because of the nature of chronic pain, such as that associated with osteoarthritis in dogs and cats, the accompanying behavioral changes can be insidious and easily missed. Indeed, many owners assume these changes are inevitable with advancing age.

Preliminary data based on owner interviews revealed changes in 32 types of behavior in dogs with chronic pain.¹⁰⁰ This study also indicated that the owners are the best evaluators of their pet's pain. The Glasgow University Health-Related Dog Behavior Questionnaire has identified some key indicators of chronic pain, including, but not limited to, decreases in mobility, activity, sociability, and curiosity, and increases in aggression, anxiety, daytime sleeping, and vocalizing.¹⁰⁰

Chronic pain is undoubtedly a clinical problem in cats, but is not well documented. Compared with dogs, very little is known about degenerative joint disease in cats, but radiographic evidence in geriatric cats suggests the incidence may be as high as 90%.¹⁰¹ Because of a pet cat's lifestyle, lameness is not a common owner complaint; but changes in behavior, including decreased grooming, reluctance to jump up to favorite places, and soiling outside the litter box, should prompt veterinarians to look for sources of chronic pain. It is common for owners not to realize how debilitated their pet is until they see dramatic improvements following treatment. Radiographic lesions in the lumbosacral area have been correlated with neurological disease.¹⁰¹

Management and Control of Pain

Because the anatomical structures and neurophysiological mechanisms leading to the perception of pain (nociception) are remarkably similar in humans and animals, it is reasonable to assume that, if a stimulus is painful to a person, is damaging or potentially damaging to tissues, and induces escape and emotional responses in an animal, it must be considered to be painful to that individual.^{102,103} That animals exhibit signs of distress and learned avoidance behavior, and vocalize in response to noxious (painful) stimuli, is further evidence of their capacity to suffer from pain. Pain may not always be overtly expressed and may be evidenced only by subtle changes in behavior or posture. A degree of anthropomorphism is appropriate and desirable, especially in situations that are known to cause pain in people.^{104,105} A consensus statement from an international workshop on animal and human pain concluded that animals feel pain, but that it is unclear whether animals feel pain with the same qualities and intensities as humans. Furthermore, it is unclear at what taxonomic level noxious stimuli are associated with pain, but it is likely that all vertebrates and some invertebrates experience pain.¹⁰⁶ It is worth noting that humans have differing thresholds and sensitivities to pain, and it is likely that the experience of pain caused by given procedure or injury is quite varied. Thus, the consensus statement that it is unclear whether animals feel

pain with the same quality or intensity as humans does nothing to minimize the importance or clinical relevance that animals feel pain. (Similarly, the variability in pain response between people does not negate the fact that pain exists and is unpleasant.)

Just as antibiotics are administered prophylactically to prevent infection, it is appropriate to administer analgesics to prevent pain where it is likely to occur. The commonly stated reasons for withholding analgesics (e.g., to avoid opioid-induced respiratory depression or because pain relief would increase activity leading to self-injury) are seldom valid and should be carefully examined before a decision is made to withhold analgesic drugs. Accurate selection and dosing of analgesic drugs provide relief of pain without severe respiratory depression. Where pulmonary function is compromised, monitoring for signs of respiratory depression and tailoring analgesic therapy to the individual patient will prevent hypoventilation or apnea. Appropriate splinting, bandaging, or confinement will prevent self-injury. Animals should not have to endure pain because of real or imagined sequelae to its relief. Pain-induced alterations in metabolism, endocrine, and cardiopulmonary function are well recognized and of serious consequence to animals.

Analgesia in the strictest sense is an absence of pain but clinically is the reduction in the intensity of pain perceived. The goal should not be to eliminate pain completely, but to make the pain as tolerable as possible without undue depression of patients. Analgesia in the clinical setting may be induced by obtunding or interrupting the nociceptive process at one or more points between the peripheral nociceptor and the cerebral cortex. Nociception involves four physiological processes that are subject to pharmacological modulation. *Transduction* is the translation of physical energy (noxious stimuli) into electric activity at the peripheral nociceptor. *Transmission* is the propagation of nerve impulses through the nervous system. *Modulation* occurs through the endogenous descending analgesic systems, which modify nociceptive transmission. These endogenous systems (opioid, serotonergic, and noradrenergic) modulate nociception through inhibition of the spinal dorsal horn cells. *Perception* is the final process resulting from successful transduction, transmission and modulation, and integration of thalamocortical, reticular, and limbic function to produce the final conscious subjective and emotional experience of pain.¹⁰⁷

Transduction can be largely abolished by use of local anesthetics infiltrated at the site of injury or incision, or by intravenous, postthoracotomy intrapleural, or postlaparotomy intraperitoneal injection. NSAIDs will obtund transduction by decreasing production of endogenous algogenic substances such as prostaglandins at the site of injury. Transmission can be abolished by local anesthetic blockade of peripheral nerves or nerve plexuses or by epidural or subarachnoid injection. Modulation can be augmented by subarachnoid or epidural injection of opioids, and/or α_2 -adrenergic agonists. Perception can be obtunded with general anesthetics or by systemic administration of opioids and α_2 -agonists either alone or in combination with tranquilizer-sedatives.¹⁰⁷

Balanced or multimodal analgesia results from the administration of analgesic drugs in combination and at multiple sites to in-

duce analgesia by altering more than one part of the nociceptive process. Multimodal analgesia relies on the additive or synergistic effects of two or more analgesic drugs working through different mechanisms of action. When multimodal analgesia is used, doses of individual drugs can be reduced, thereby decreasing the potential for any one drug to induce adverse side effects. Thus, transduction could be reduced by NSAIDs, transmission decreased by epidural local anesthetics, and modulation increased by epidural or intrathecal opioids and/or α_2 -agonists. Balanced analgesic techniques appear to offer several advantages in the management of postoperative pain. When used preemptively, this approach prevents nociceptive-induced neuroplasmic changes within the spinal cord (windup), prevents development of tachyphylaxis, and suppresses the neuroendocrine response to pain and injury more effectively than when single-drug regimens are used, and shortens convalescence through improved tissue healing and mobility. Preemptive analgesia refers to the application of balanced analgesic techniques prior to exposing patients to noxious stimuli (surgical trespass). By so doing, the spinal cord is not exposed to the barrage of afferent nociceptive impulses that induce the neuroplasmic changes leading to central hypersensitivity. This concept has gained acceptance as the most effective means of controlling postoperative pain.^{55,108,109}

Analgesic Drugs

Analgesics consist of those classes of drugs whose primary effect is to suppress pain or induce analgesia (Table 3.2). Although actions and effects of most other drugs differ little among mammalian species, there are marked differences in response to selected analgesics (e.g., opioids) that are independent of pharmacokinetics among species.^{110–112} The concentration of opioid receptors in the amygdala and frontal cortex of species that are depressed by opioids (e.g., dogs and primates) is nearly twice as great as in those species that become excited in response to opioids (e.g., horses and cats).¹¹³ In contrast, μ opioid receptor binding in the frontal cortex, left somatosensory cortex, colliculus, and granule cell layer of the cerebellum was higher in horses than in dogs, whereas κ opioid receptors were higher in the frontal cortex of dogs as compared with horses and higher in the cerebellum of horses as compared with dogs.¹¹⁴ Thus, the distribution of specific opioid receptors differs among species, which probably contributes to the clinical differences in mentation and efficacy when opioid analgesics are administered. Morphine doses of 100 to 170 $\mu\text{g}/\text{kg}$ did not increase the risk of perioperative problems in horses undergoing general anesthesia and surgery as compared with horses that did not receive morphine.¹¹⁵ Perhaps, by simply decreasing the dose, excitement can be avoided in those species prone to bizarre reactions. Excitement may result indirectly from increased release of norepinephrine and dopamine.¹¹² This may explain the mechanism whereby dopaminergic and noradrenergic blocking drugs such as phenothiazine and butyrophenone tranquilizers suppress clinical evidence of opioid-induced excitement. Xylazine and detomidine (α_2 -agonists) are effective in preventing opioid-induced excitement in horses and ruminants. Because analgesia and excitement

Table 3.2. Classes of analgesic drugs commonly used in animals.

Classification	Examples
Opioids	Morphine, hydromorphone, fentanyl, meperidine, methadone oxymorphone, pentazocine, butorphanol, nalbuphine, and buprenorphine
Salicylates	Aspirin and salicylate
Para-aminophenol derivatives	Acetanilid, acetaminophen, and phenacetin
Nonopioid and nonsalicylate	Phenylbutazone, dipyrrone, meclofenamic acid, flunixin, carprofen, ketoprofen, etodolac, meloxicam, tepoxaline, deracoxib, firocoxib, and piroxicam
Local anesthetic agents	Procaine, lidocaine, mepivacaine, tetracaine, and bupivacaine
α_2 -Adrenergic agonists	Xylazine, detomidine, medetomidine, and romifidine

are mediated by different receptors (i.e., μ receptors for analgesia and phencyclidine for excitement), they can occur concurrently and are not mutually exclusive.

Opioid analgesics induce CNS depression accompanied by miosis, hypothermia, bradycardia, and respiratory depression in primates, dogs, rats, and rabbits. In horses, cats, ruminants, and swine, stimulation can be characterized by mydriasis, panting, tachycardia, hyperkinesis, and sweating.^{111,112} Opioid-induced excitatory effects can occur in any species, but are uncommon when opioids are administered to animals in pain or are administered in combination with sedative/tranquilizing agents. Systemic effects of opioids include release of arginine vasopressin (antidiuretic hormone), prolactin, and somatotropin; inhibition of the release of luteinizing hormone; increased vagal tone; release of histamine and attendant hypotension; decreased motility and increased tone of the gastrointestinal tract; spasm of the biliary and pancreatic ducts; spasm of ureteral-smooth muscle and increased bladder tone; and decreased uterine tone.

Opioids raise the pain threshold or decrease the perception of pain by acting at receptors in the dorsal horn of the spinal cord and mesolimbic system (i.e., brain stem–nucleus raphe magnus and locus caeruleus), midbrain PAG, and several thalamic and hypothalamic nuclei. In the dorsal horn, opioids induce postsynaptic inhibition of nociceptive projection neurons (T cells). In addition, there is some evidence that opioids may act presynaptically to inhibit release of substance P from primary afferents. Centrally, at the level of the mesencephalon and medulla, opioids activate the descending endogenous antinociceptive system that modulates nociception in the dorsal horn via release of serotonin and perhaps norepinephrine. Opioids act at the limbic system to alter the emotional component of the pain response, thus making it more tolerable. The presence of opiate receptors in peripheral tissues has increased interest in using small doses of opioids for their peripheral effects. The density of opioid-binding sites in articular and periarticular tissues has been shown to be significantly increased 12 h after the induction of inflammation in the radiocarpal joints of dogs.¹¹⁶ Immunohistochemical analysis and radioligand binding have demonstrated the presence of opioid receptors in the synovial membranes of horses.¹¹⁷ These studies support the clinical practice of administering intra-articular opioids (morphine) for postoperative analgesia following arthroscopic surgery. The role of peripheral opioid receptors in pain re-

lief is intriguing because opioid receptors have traditionally been thought of as exerting their analgesic effects within the CNS. For example, morphine (5 mg) infiltrated into the donor bone graft site from the ileum for spinal fusion surgery significantly reduced the incidence of chronic pain at the donor site in people 1 year after surgery.¹¹⁸ The reason why locally infiltrated morphine at the graft site exerted a significantly better analgesic effect as the same dose of morphine administered intramuscularly is not clear, but points to the ubiquitous role that opioid receptors play in both the peripheral and central nervous systems. Opioid growth factor and its specific receptors are present in the corneas of dogs, cats, and horses.¹¹⁹ Although opioids have been theorized to inhibit corneal healing, the topical application of 1% morphine sulfate solution in dogs in one study provided analgesia without interfering with wound healing.¹²⁰

Successful use of opioids requires appropriate selection of the drug and dose for the given species to avoid undesirable side effects. Opioids must be used with caution in animals that have impaired pulmonary function because they depress the respiratory and cough centers, decrease secretions, and may induce bronchospasm secondary to histamine release. In species that can freely vomit, nausea and vomiting may occur. Repeated doses can cause constipation, ileus, and urinary retention. Mice and rats rapidly develop tolerance to and physical dependence on opioid agonists.^{121–123} Morphine decreases the number and phagocytic function of macrophages and polymorphonuclear leukocytes in mice and may alter their immune function. These side effects are typically managed successfully in clinical patients; thus, opioids are the analgesic drugs of choice for the treatment of all forms (mild to severe) of acute pain.

Whereas opioids induce analgesia by interfering with nociceptive neural transmission centrally, the nonopioid, nonsteroidal, anti-inflammatory analgesics (NSAIDs) act primarily in the periphery to decrease production of algogenic substances, primarily prostanooids, which facilitate generation and conduction of impulses that give rise to pain. When tissues are damaged, mediators are synthesized or released that activate nociceptors and primary afferent neurons, leading to the sensation of pain. When administered prior to tissue damage, the nonopioid analgesics induce analgesia by suppressing inflammation and the production and elaboration of kinins and prostaglandins. There is, however, evidence that NSAIDs may also act in the CNS. These drugs are

effective primarily against pain of low to moderate intensity associated with inflammation.¹²⁴ They are generally regarded as being useful for treating chronic pain of somatic or integumental origin, but of little use for visceral pain. An exception is flunixin, which appears to blunt visceral pain effectively in horses.¹²⁵ The efficacy of NSAIDs has been investigated for acute postoperative pain. In dogs, the preemptive (preoperative) administration of carprofen has been shown to induce superior postoperative analgesia with less sedation than pethidine (meperidine) after orthopedic surgery.¹²⁶ Similarly, carprofen has been shown to induce profound analgesia as effective as that induced by papaveretum, but with quicker anesthetic recovery and less postrecovery sedation.¹²⁷ In horses, administration of carprofen, flunixin, and phenylbutazone at the end of surgery were equally effective at inducing postoperative analgesia, with flunixin providing the longest action and phenylbutazone the shortest.¹²⁸ In rats undergoing midline laparotomy, buprenorphine or carprofen administration results in greater food and water consumption and less weight loss than occur in rats receiving saline.¹²⁹ The optimal timing of NSAID administration must be tailored to the individual patient in order to minimize side effects. In people, NSAIDs have been shown to exert a limited preemptive effect; however, the analgesic effects must be balanced against side effects, such as bleeding and impaired renal function.⁷⁴ Carprofen and meloxicam administered to healthy dogs prior to anesthesia had no adverse effects on renal function.^{130–132} These studies used young, healthy dogs with normal renal function, and the degree of hypotension was moderate. Thus, caution should be used when considering the timing of NSAID administration to clinical patients, particularly in older patients that may have subclinical renal compromise. Although NSAIDs are an integral part of many multimodal analgesic protocols, it is often safer to administer the NSAIDs postoperatively to avoid the concurrent potentially detrimental renal effects of NSAIDs and hypotension.

The pharmacokinetics of NSAIDs varies widely among species. Following oral administration, wide species variations in plasma concentration result in part from the size of the gastrointestinal tract and gastric emptying time, which affect the rate of absorption and the rate of metabolism and elimination.¹³³ Toxicity of the NSAIDs also varies widely among species and drugs and deserves some consideration.¹²⁵ The most common toxic side effects include gastric and intestinal ulceration, with secondary anemia and hypoproteinemia. Impaired platelet function and delayed parturition have been reported. Nephropathy can occur in patients with hypovolemia, congestive heart failure, or other cardiovascular impairment (anesthesia) caused by inhibition of renal prostaglandin function in the face of increased norepinephrine and angiotensin II. Chronic or repeated use has been associated with chronic interstitial nephritis and renal papillary necrosis. Phenylbutazone and dipyron have been associated with blood dyscrasias.

α_2 -Adrenergic agonists (e.g., xylazine, detomidine, medetomidine, dexmedetomidine, and romifidine) are generally regarded as sedative-hypnotics and are most commonly administered to induce sedation.^{134,135} They possess some analgesic action, as well. Xylazine has been shown to be a more potent analgesic

agent in horses for the relief of both visceral and somatic pain than opioids and NSAIDs.^{136,137} α_2 -Agonists exert their sedative effects through stimulation of α_2 -adrenoceptors in the brain, decreasing norepinephrine release. Sedation results from decreased activity of ascending neural projections to the cerebral cortex and limbic system.^{121,122} Analgesia appears to be the result of both cerebral and spinal effects, possibly in part mediated by serotonin and the descending endogenous analgesia system.¹²³ α_2 -Adrenergic and opioid receptors appear to interact in ways that are not fully understood.^{123,134,138} Administration of α_2 -agonists (i.e., clonidine) has been shown to relieve symptoms of withdrawal in opioid-dependent people.^{139–142} They have also been used to “rescue” opioid-induced analgesia that has waned following chronic administration. The combination of an opioid and an α_2 -agonist enhances and prolongs analgesia in dogs and cats, and these combinations have been used for some years in horses.^{141–145}

Although xylazine is the most commonly used sedative-analgesic in veterinary medicine, its comparative pharmacokinetics have not been studied extensively.¹³⁵ When administered intravenously, xylazine has a rapid onset and brief action. There is a wide variation in species sensitivity and response to xylazine. Detomidine is more potent and longer acting than xylazine. Medetomidine use in small animal practice has been reviewed.¹⁴⁶ Medetomidine is the most potent and selective α_2 -agonist in veterinary practice to date. In addition to having profound sedative and analgesic activity, α_2 -agonists induce cardiovascular and metabolic responses also related to their peripheral adrenergic effects. Following their administration, arterial blood pressure increases and then decreases; cardiac output decreases.¹⁴⁷ Medetomidine (1 to 20 $\mu\text{g}/\text{kg}$ intravenously) reduces cardiac index significantly in dogs, although the reduction is generally less with the use of lower doses (1 and 2 $\mu\text{g}/\text{kg}$).¹⁴⁸ Insulin release is inhibited, resulting in hyperglycemia.^{149–151} Urinary output is increased as a result of decreased arginine vasopressin release and decreased water reabsorption by nephrons.^{149,152–154} Analgesia can be induced by neural blockade of the nociceptive nerves or tracts by local infiltration, by regional nerve blocks, or by epidural or intrathecal injection of local anesthetic agents. Analgesia so induced is complete in the area blocked. Intercostal nerve blockade and intrapleural local anesthetic administration have been advocated to relieve pain following thoracotomy and presumably produce better alveolar ventilation postoperatively than when opioid-induced analgesia is present.^{155,156} Digital nerve blocks or distal limb ring blocks with lidocaine and bupivacaine are an excellent means to control postoperative pain from declaw procedures in cats. Nonpharmacological methods of pain relief (rehabilitation therapy) can be used to good effect. These include immobilization and support with casts, splints, or bandages; appropriate use of hot or cold packs; and physical therapy such as massage and stretching.¹⁵⁷

When pain is severe and acute, opioids are the most effective analgesics under most circumstances. These drugs do, however, have relatively short half-lives and thus require supplemental dosing. Most will provide analgesia within 30 min of administration. Duration of action varies but is usually on the order of 2

to 4 h. Surgically induced pain may require the use of opioids for 1 to 2 days postoperatively. Intra-articular morphine administration following joint surgery has been shown to relieve pain effectively for many hours postoperatively.¹⁵⁸ The NSAIDs generally are not sufficient by themselves to relieve severe postoperative pain. The NSAIDs can be used in combination with opioids postoperatively to good effect because these 2 classes of agents have differing mechanisms and sites of action. Further, NSAIDs can be continued when opioids are no longer necessary. Generally, NSAIDs provide good analgesia where pain is induced by inflammation or is chronic and of integumentary or musculoskeletal origin and are typically administered at 12- to 24-h intervals.

Although the foregoing discussion has focused on the use of analgesics to control pain in conscious patients, one must not ignore their use in patients that are chemically restrained. Animals are frequently anesthetized for diagnostic and manipulative procedures that are otherwise difficult or not possible in conscious patients. Where pain is not present or caused by the procedure (e.g., radiology), only muscle relaxation and hypnosis or sedation are required for patient management. However, when the procedure is painful or invasive, the protocol should be chosen to ensure that analgesia is sufficient to prevent the patient from perceiving pain. The phencyclidine derivatives ketamine and tiletamine induce a dissociative cataleptoid state, somatic analgesia, and altered consciousness. The patient is immobilized but not relaxed or fully unconscious, and analgesia is incomplete. The dis-

sociative state is poorly understood, but it is believed that somatic analgesia results from the interruption or dissociation of ascending nociceptive input as painful stimuli traverse the thalamocortical system. The dissociative agents are excellent for chemical restraint and immobilization, but should be supplemented with an analgesic for invasive procedures and particularly those involving visceral manipulation. Several studies have assessed and documented the analgesic efficacy of epidurally administered ketamine; however, the safety of epidural ketamine has not been fully established.^{159,160} Ketamine has long been known to induce analgesia for superficial pain (e.g., skin incisions) but not deep pain. Ketamine has been used to help prevent sensitization (windup) of the nociceptive pathways in the spinal cord. Ketamine blocks the effects of glutamate, an excitatory neurotransmitter, at the NMDA receptor. Stimulation of the NMDA receptor has been theorized to be a key component in sensitizing nociceptive pathways after surgery or trauma. The exact role that ketamine may play in preventing exaggerated pain states is not known at this time; however, ketamine might be doing more good than any of us realized.¹⁶¹⁻¹⁶⁷

Recommended doses and dose intervals (where available) for selected analgesics used in common domestic species are listed in Tables 3.3 through 3.6. As with any therapeutic regimen, the response should be monitored, and where pain has not been adequately relieved, additional therapy should be considered. Extrapolation of data from one species to another should be avoided where specific information for pain therapy is available.

Table 3.3. Doses of analgesics for use in dogs.

Drug	Dose (mg/kg)	Route	Frequency/Duration
Opioid agonists			
Fentanyl ^a	0.001 to 0.002	IV	0.25 to 0.5 h
	0.001 to 0.006 ^b	CRI (mg/kg/h)	Duration of infusion + ~0.5 h
	0.01 to 0.04 ^c	CRI (mg/kg/h)	Duration of infusion + 0.5 to 1.0 h
Hydromorphone	0.02 to 0.1	IV, IM, SC	1 to 4 h
Methadone	0.1 to 1.0	IV, IM, SC	1 to 4 h
Oxymorphone	0.02 to 0.1	IV, IM, SC	1 to 4 h
Morphine ^a	0.05 to 1.0	IV, IM, SC	1 to 4 h
	0.1 to 0.3 mg/kg/h	CRI	Duration of infusion + 0.5 to 1.0 h
Preservative-free morphine	0.1 to 0.2	Epidural	6 to 24 h
Partial opioid agonist			
Buprenorphine	0.005 to 0.02	IV, IM	4 to 8 h
Opioid agonist-antagonist			
Butorphanol	0.1 to 0.5	IV, IM, SC	0.25 to 2.0 h
α_2-Agonists^e			
Medetomidine	0.01 to 0.04	IM	0.5 to 2.0 h
	(Postop: low dose) 0.001 to 0.002	IV	0.5 to 1.0 h
Xylazine	0.1 to 0.5	IM, SC	0.5 to 2.0 h
	(Postop: low dose) 0.1 to 0.2	IV	0.5 to 1.0 h

(continued)

Table 3.3. Doses of analgesics for use in dogs (*continued*).

Drug	Dose (mg/kg)	Route	Frequency/Duration
Local anesthetics			
Bupivacaine	1.5 to 3.0	Local blocks	2 to 6 h
		Intrapleural	
	1.0 to 1.5	Epidural	4 to 6 h
Lidocaine	0.1 to 0.5 ^f	Epidural	4 to 6 h
	1 to 2	Local blocks	1 to 2 h
		Prior to bupivacaine	
NMDA receptor antagonist			
Ketamine	0.25 to 0.5	IV	Loading dose
	0.01 to 0.02 mg/kg/h	CRI	Duration unknown
NSAIDs^g			
Carprofen	2.2	SC, IM, PO	12 h
	4.4	SC, IM, PO	24 h
Deracoxib	3 to 4	PO (max. 7 days)	24 h
	1 to 2	PO	24 h
Firocoxib	5	PO	24 h
Ketoprofen	1 to 2	SC	24 h
Meloxicam	0.2	IV, SC, PO (once)	24 h
	0.1	IV, SC, PO	24 h

BID, twice a day; CRI, constant-rate infusion; IM, intramuscularly; IV, intravenously; NMDA, *N*-methyl-D-aspartate; NSAIDs, nonsteroidal anti-inflammatory drugs; PO, per os (orally); SC, subcutaneously; SID, once a day.

^aFentanyl doses may be increased incrementally above the recommended dose, provided the patient is monitored for respiratory depression and bradycardia.

^bHigh doses of fentanyl are associated with bradycardia and hypoventilation, and usually decrease anesthetic gas requirements.

^cMust be administered slowly to avoid side effects, such as hypotension and excitement.

^dThese doses have been compiled from many sources and reflect doses used by the authors. The wide variability of recommended doses appears related to the variety and severity of stimuli used to establish the individual drug's analgesic activity in a given species. Doses are intended as guidelines only. Clinical judgment must be exercised to provide effective analgesia in a given situation.

^ePostsurgical doses and duration of effect have not been clearly established. Use cautiously to avoid profound cardiac depressant effects.

^fBupivacaine dose when combined with preservative-free morphine at 0.1 mg/kg.

^gDo not use in the presence of hypovolemia, hypotension, renal disease, gastrointestinal bleeding, or coagulopathies.

Table 3.4. Doses of analgesics for use in cats.

Drug	Dose (mg/kg)	Route	Comments
Opioids			
Butorphanol	0.1 to 0.4	IV, IM	Short acting (less than 90 min). Increasing the dose does not provide more intense or longer periods of analgesia.
Buprenorphine	0.01 to 0.02	IV, IM, transmucosal	
Fentanyl	0.005 to 0.01	IV	May take up to 12 h to reach effective plasma concentration.
Hydromorphone	25 µg/h patch	Transdermal	Uptake affected by body temperature.
	0.05 to 0.1	IV, IM	SC route associated with vomiting. Doses of 0.1 mg/kg and higher can produce hyperthermia.
Meperidine	5 to 10	IM	Must not be given IV.
Morphine	0.2 to 0.5 mg/kg	IV, IM	May be less effective in cats compared with other species because of a lack of active metabolites.
Oxymorphone	0.05 to 0.01	IV, IM	
NSAIDs			
Carprofen	1 to 4	SC	Do not use in hypotensive or hypovolemic patients. Not licensed for cats in the United States. Should not be repeated.
Ketoprofen	1 to 2	SC	Not licensed for cats in the United States.
Meloxicam ^a	0.2 or 0.1	SC, IV, PO	Can be repeated with care (1 to 5 days at 1 mg/kg). One dose. Dose depends on degree of pain (e.g., orthopedic vs. soft tissue).
	0.1		Repeat once daily for 3 days.
	0.025 mg/kg (0.1 mg/cat) lean weight		Alternate day or twice weekly.
Local anesthetics			
Lidocaine	2 to 4	Local anesthetic blocks	Duration of action 1 to 2 h. Constant-rate infusions not recommended in cats because of cardiovascular depression.
Bupivacaine	2	Local anesthetic blocks	Duration of action 4 to 5 h.
α₂-Agonists			
Medetomidine	0.005 to 0.02	IV, IM, SC	Use with great care in cats with cardiovascular disease.
	0.01	Epidural	Low doses combined with an opioid offer good sedation and analgesia.
Other			
Ketamine	2	IV	No published data about cats on the efficacy of low-dose constant-rate infusions.

IM, intramuscularly; IV, intravenously; PO, per os (orally); SC, subcutaneously.

^aThe only licensed NSAID for cats in the USA. The oral formulation is off-label; however, this has been used in cats with *careful* attention to dose delivered.

Table 3.5. Doses of analgesics for use in horses^a, 168

Drug	Dose (mg/kg)	Route	Frequency/Duration
NSAIDs			
Phenylbutazone	2.2 to 4.4	IV, PO	SID-BID
Flunixin	1.1	IV, IM, PO	SID-BID
Ketoprofen	2.2	IV, IM	SID-BID
Carprofen	0.7	IV, PO	SID-BID
Opioids			
Butorphanol	0.01 to 0.02	IV	q 2 to 4 h
Morphine	0.02 to 0.1	IV	q 2 to 4 h
	0.1 to 0.2	Epidural	q 12 to 24 h
Preservative-free morphine (1 mg/mL)	5 to 10 mL	Intra-articular	Once
Fentanyl	0.001 to 0.002	IV	q 0.25 to 0.5 h
	0.001 mg/kg/h	CRI	
Fentanyl transdermal patch	1 to 3 patches per horse (10 mg or 100 µg/h patches)	72 h	
Local anesthetics			
Lidocaine	1 to 2	Infiltration	1 to 2 h
Lidocaine CRI	2	IV (loading dose administered over 20 min)	
	30 to 50 µg/kg/min	CRI	
Lidocaine patch	Undetermined at this time	Transdermal	
Bupivacaine	1 to 2	Infiltration	6 to 8 h
α₂-Agonists			
Xylazine	1.0 to 2.2	IM	0.5 to 2.0 h
	0.3 to 1.0	IV	0.5 h
	25-mg total dose	Epidural—added to morphine	
Detomidine	0.005 to 0.01	IV	1 to 2 h
	0.01 to 0.02	IV, IM	1 to 2 h
	0.03 to 0.06	Epidural	2 to 3 h
	0.01	Epidural—added to morphine	

BID, twice a day; CRI, constant-rate infusion; IM, intramuscularly; IV, intravenously; PO, per os (orally); SC, subcutaneously; SID, once a day.

^aThese doses have been compiled from many sources and reflect doses used by the authors. The wide variability of recommended doses appears related to the variety and severity of stimuli used to establish the individual drug's analgesic activity in a given species. Doses are intended as guidelines only. Clinical judgment must be exercised to provide effective analgesia in a given situation.

Table 3.6. Doses of analgesics for use in ruminants and swine^{a, 169}

Drug	Dose (mg/kg)	Route	Frequency	Species
NSAIDs				
Aspirin	50 to 100	PO	q 12 h	Cattle
	50 to 100	PO	q 12 h	Sheep/goat
	10	PO	q 4 h	Swine
Phenylbutazone	Not recommended			Cattle
	5	IV, PO	Daily	Sheep, llama
	4	IV, PO	Daily	Swine
Flunixin	1.1	IV	q 12 h	Cattle, llama
	2.2	IV	q 12 h	Sheep
Ketoprofen	1 to 3.3	IV, IM	Daily	Ruminants/llama
Opioids				
Butorphanol	0.044 to 0.07	IV	q 4 h	Cattle
	0.05 to 0.2	IV, IM	q 4 h	Camelid
	0.1 to 0.5	IV, IM, SC	q 4 h	Sheep
	0.1 to 0.2	IV, IM, SC	q 4 h	Goats
Buprenorphine	0.005 to 0.01	IV, IM, SC	q 12 h	Sheep, goats
Morphine	0.05 to 0.5	IV, IM, SC	q 4 to 6 h	Ruminants/camelids
	0.1	Epidural	q 12 h	Ruminants/camelids
	0.2	IV, IM	q 4 to 6 h	Swine
Fentanyl Patch	0.002 to 0.004	IV	q 0.25 to 0.5 h	Ruminants
	0.002 (equivalent to 15 mg/70-kg sheep)	Transdermal	q 72 h	Sheep
Local anesthetics				
Lidocaine	Do not exceed 10 mL (2% lidocaine)			Adult sheep/goats
	Do not exceed 1 mL (2% lidocaine)			Dehorning young kids
	4 to 5 mL (2%)	Epidural		Cattle
	1 to 2 mL (2%)	Epidural		Sheep
Bupivacaine	1 to 2 mg/kg	Infiltrations		Ruminants/camelids
α₂-Agonists				
Xylazine	0.1	IM	As needed	Cattle
	0.05 to 0.1	IM	As needed	Sheep
	1	IM	As needed	Swine
Detomidine	0.01	IV	As needed	Cattle

IM, intramuscularly; IV, intravenously; PO, per os (orally); SC, subcutaneously.

^aThese doses have been compiled from many sources and reflect doses used by the authors. The wide variability of recommended doses appears related to the variety and severity of stimuli used to establish the individual drug's analgesic activity in a given species. Doses are intended as guidelines only. Clinical judgment must be exercised to provide effective analgesia in a given situation.

Introduction

A fundamental understanding and appreciation of the role of the cardiovascular system and circulatory dynamics are paramount for safe anesthetic practice. The uptake, distribution, and elimination of anesthetic drugs depend on blood flow. The importance of the cardiovascular system to patient well-being and the diverse effects of drugs used in the practice of anesthesia on hemodynamics emphasize the need to have a working knowledge of hemodynamics to monitor patient status adequately. The cardiovascular system, which is composed of the heart, blood vessels, lymph vessels, and blood, is designed to supply a continuous flow of oxygen and nutrients to all tissues of the body. Oxygen

and nutrient supply and waste removal are facilitated by major exchange organs, including the lungs, where blood becomes oxygenated and carbon dioxide is removed; the gastrointestinal system, where nutrients are absorbed and solid and liquid wastes are eliminated; and the kidneys, where additional by-products of metabolism are excreted. More specifically, the principal function of the heart is to pump blood, of the vasculature to carry blood to and from the heart and facilitate exchange processes in the peripheral tissues, and of the blood to function as the transport medium, or solvent, for all the body homeostatic and exchange processes.

Oxygenated blood returning from the lungs enters the left ventricle via the left atrium and mitral valve, and is ejected into the aorta, which, through an elaborate array of major arteries, distributes blood to all the tissues of the body. The end branches of these major arteries—the arterioles—differentially regulate blood flow and give rise to a vascular bed of small vessels—the capillaries—where oxygen and nutrients are exchanged for the by-products of cellular metabolism. The capillaries, in turn, recombine to form venules and veins that return blood to the right atrium, right ventricle, and lungs (Fig. 4.1). Circulation of blood depends on a functional heart, normal blood vessels, and adequate blood volume, and serves to maintain a constant internal environment for all living cells.

This chapter reviews the physiology of the cardiovascular system. A stepwise approach is taken that describes the structure and function of the heart, blood vessels, lymphatic system, and blood. This is followed by a discussion of the neural, humoral, and local control mechanisms that regulate cardiovascular function. Methods for assessing cardiovascular function are briefly reviewed, followed by a general discussion of diseases of the cardiovascular system.

Functional Anatomy of the Heart and Circulation

Heart

The structure of the cardiovascular system is well suited for its function: the delivery of oxygen and nutrients to peripheral tissues and removal of the by-products of cellular metabolism. The heart, as one key component of the cardiovascular system, functions to pump blood throughout the body. The heart is composed of four chambers: two thin-walled atria separated by an interatrial septum, and two thick-walled ventricles separated by an interventricular septum. The boundaries of the various chambers

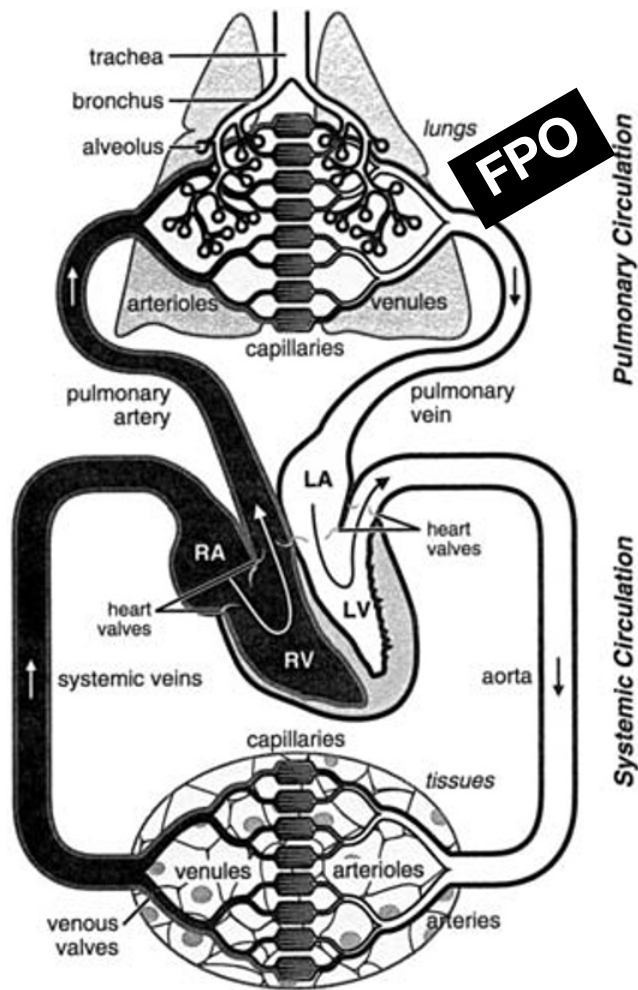

Fig. 4.1. The cardiovascular system is comprised of the heart, blood, and two parallel circulations (pulmonary and systemic). *Pulmonary circulation:* The pulmonary artery carries blood from the right ventricle (RV) to the lungs, where carbon dioxide is eliminated and oxygen is taken up. Oxygenated blood returns to the left atrium (LA) via the pulmonary veins. *Systemic circulation:* Blood is pumped by the left ventricle (LV) into the aorta, which distributes blood to the peripheral tissues. Oxygen and nutrients are exchanged for carbon dioxide and other by-products of tissue metabolism in capillary beds, after which the blood is returned to the right atrium (RA) through the venules and large systemic veins. Modified from Shepherd and Vanhoutte,¹⁰² p. 3.

are easily defined by the great veins (cranial and caudal vena cava), which return blood to the right atrium; the smaller pulmonary veins, which return oxygenated blood from the lung to the left atrium; the coronary sulcus, which demarcates the atria from the ventricles; and the anterior and posterior interventricular (longitudinal) sulci, which separate the right and left ventricles (Fig. 4.2A).

The paraconal branch of the left main coronary artery, frequently referred to as the *left anterior descending coronary artery* in humans, provides the blood supply to the ventricular septum and left ventricular free wall. The subsinuosal coronary artery,

most frequently an extension of the left circumflex coronary artery (the other major branch of the left main coronary artery), but occasionally can branch off of the right coronary artery, provides the blood supply to the posterior left ventricle. The right coronary artery provides the blood supply to the right ventricular free wall and the posterior wall of the left ventricle (Fig. 4.2B). The left coronary artery is generally dominant in dogs and the right coronary artery is dominant in cats and horses. The atria receive blood returning from the systemic circulation (right atrium) and pulmonary circulation (left atrium), and to a limited degree act as storage chambers. The ventricles, the major pumping chambers of the heart, are separated from the atria by the tricuspid valve on the right side and the mitral valve on the left side. The ventricles receive blood from their respective atria and eject it across semilunar valves (the pulmonic valve between the right ventricle and pulmonary artery and the aortic valve between the left ventricle and aorta) into the pulmonary circulation (right ventricle) and systemic circulation (left ventricle). Once the process of cardiac contraction is initiated, almost simultaneous contraction of the atria is followed by nearly synchronous contraction of the ventricles, which results in pressure differences between the atria, ventricles, and pulmonary and systemic circulations. Cardiac contraction produces differential pressure changes that are responsible for atrioventricular and semilunar valve opening and closing and the production of heart sounds (S_1 , S_2 , S_3 , and S_4). Chordae tendineae originating from papillary muscles located on the inner wall of the ventricular chambers are attached to the free edges of the atrioventricular valve leaflets and help to maintain valve competence and prevent regurgitation of blood into the atrium during ventricular contraction. Alteration in heart chamber geometry (e.g., stretch or hypertrophy) produced by changes in blood volume, deformation (pericardial tamponade), or disease can have profound effects on myocardial function, as do the effects produced by neurohumoral, metabolic, and pharmacological perturbations.

Blood Vessels

The principal role of blood vessels and the vascular network is to carry blood to and from oxygen-exchange and nutrient-exchange sites: the capillaries.¹ The large and small vessels of the pulmonary and systemic circulations facilitate the delivery of blood to the exchange sites in the pulmonary and systemic capillary beds and return blood to the heart. The aorta and other large arteries compose the high-pressure portion of the systemic circulation and are relatively stiff compared to veins, possessing a high proportion of elastic tissue in comparison to smooth muscle and fibrous tissues. This structural difference enables the aorta to stretch following ventricular contraction and the ejection of blood. The potential (stored) energy in the stretched aorta following cardiac contraction is returned as kinetic (motion) energy and blood flow during ventricular relaxation. The highly elastic architecture of the aorta facilitates the continuous, albeit nonuniform, flow of blood to peripheral tissues throughout the cardiac cycle (contraction-relaxation-rest) and has been termed the *Windkessel effect*. The Windkessel effect is believed to be responsible for as much as 50% of peripheral blood flow in most species during normal heart rates. Tachyarrhythmias and vascu-

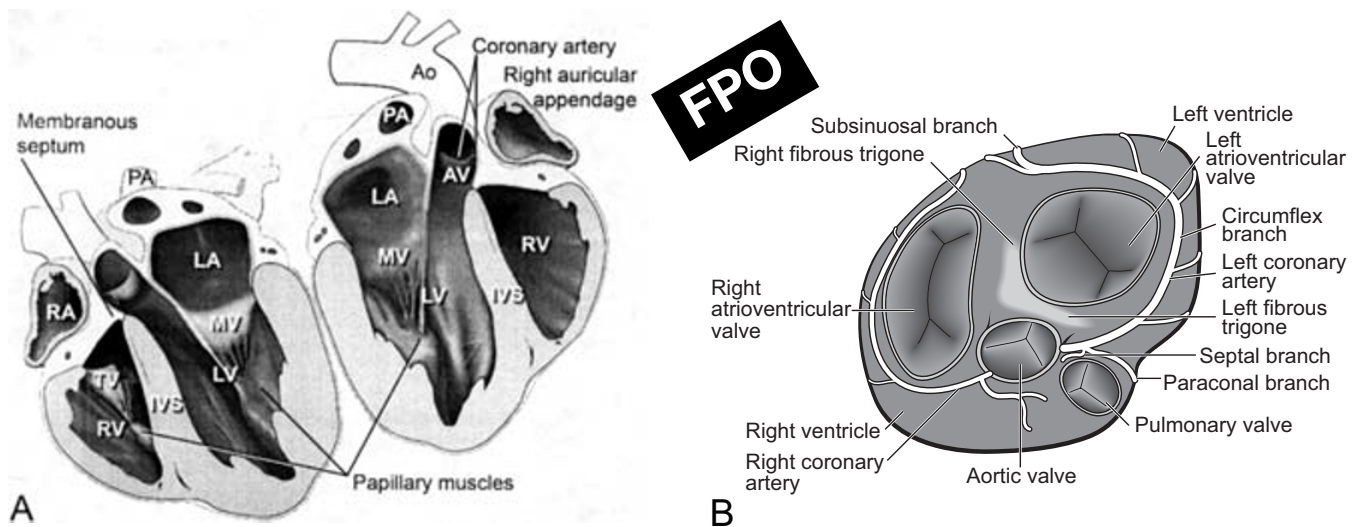

Fig. 4.2. **A:** The heart is a pump comprised of two thin-walled and two thick-walled chambers and a highly reactive and diffuse vascular network (coronary circulation). The thin-walled right atrium (RA) and left atrium (LA) are separated from each other by a membranous septum (between the right and left atria). The interventricular septum (IVS) lies between the right and left ventricles. The tricuspid valve (TV) and mitral valve (MV) lie between the RA and RV and the LA and LV, respectively. The pulmonary and aortic (AV) valves separate the RV and LV from the pulmonary artery (PA) and aorta (Ao), respectively. **B:** A fibrous trigone located at the center of the heart provides the scaffolding to which the heart valves, atria, and ventricles are attached. The right and left coronary arteries emerge from the base of the aorta and with the paraconal arteries to supply blood to all the chambers of the heart including the heart valves.

lar diseases (stiff nonelastic vessels) hamper the Windkessel effect and produce distinctive changes in the arterial pressure waveform. More distal larger arteries contain greater percentages of smooth muscle compared to elastic tissue and act as conduits for the transfer of blood under high pressure to tissues. The most distal small arteries, terminal arterioles, and arteriovenous anastomoses contain a predominance of smooth muscle, are highly innervated, and function as resistors that regulate the distribution of blood flow, aid in the regulation of systemic blood pressure, and modulate tissue perfusion pressure. The capillaries are the functional exchange sites for oxygen, nutrients, electrolytes, cellular waste products, and other substances. These vessels are generally no more than one or two cell layers thick and comprise that portion of the vasculature with by far the largest surface area. Capillaries are of three different types: continuous (lung and muscle), fenestrated (kidney and intestine), and discontinuous (liver, spleen, and bone marrow). All capillaries are highly porous and are found in varying numbers in different tissue beds, depending on tissue metabolism and the importance of fluid exchange. Postcapillary venules are composed of an endothelial lining and fibrous tissue and function to collect blood from capillaries. Some venules act as postcapillary sphincters, and all venules merge into small veins. Small and larger veins contain increasing amounts of fibrous tissue in addition to smooth muscle and elastic tissue, although their walls are much thinner than comparably sized arteries. Many veins contain valves that act in conjunction with external compression (contracting muscles and pressure differences in the abdominal and thoracic cavities) to facilitate the return flow of blood to the right atrium. The venous

system also acts as a major blood reservoir. Indeed, 60% to 70% of the blood volume may be stored in the systemic venous vasculature during resting conditions (Fig. 4.3).

Two additional structural components that are important during normal circulatory function are arteriovenous anastomoses and the lymphatic system. Arteriovenous anastomoses, as the name implies, bypass capillary beds. They possess smooth muscle cells throughout their entire length and are located in most, if not all, tissue beds. Most arteriovenous anastomoses are believed to be extremely important in regulating blood flow to highly vascular tissue beds (skin, feet, and hoofs). Their role in maintaining normal homeostasis, however, is speculative other than for thermoregulation.

The peripheral lymphatic system is not anatomically part of the blood circulatory system. Nevertheless, it is integrally involved in maintaining normal circulatory dynamics, especially interstitial fluid volume (approximately 10% of the capillary filtrate). Lymphatic capillaries collect interstitial fluid—lymph—which is eventually returned to the cranial vena cava and right atrium after passing through a series of lymph vessels, lymph nodes, and the thoracic duct. Lymph vessels have smooth muscle within their walls and contain valves similar to those in veins. Contraction of skeletal muscle (lymphatic pump) and lymph vessel smooth muscle, in conjunction with lymphatic valves, are responsible for lymph flow.

Blood

Blood is the fluid (approximately 60% plasma and 40% cells) responsible for carrying oxygen, nutrients, and other bloodborne

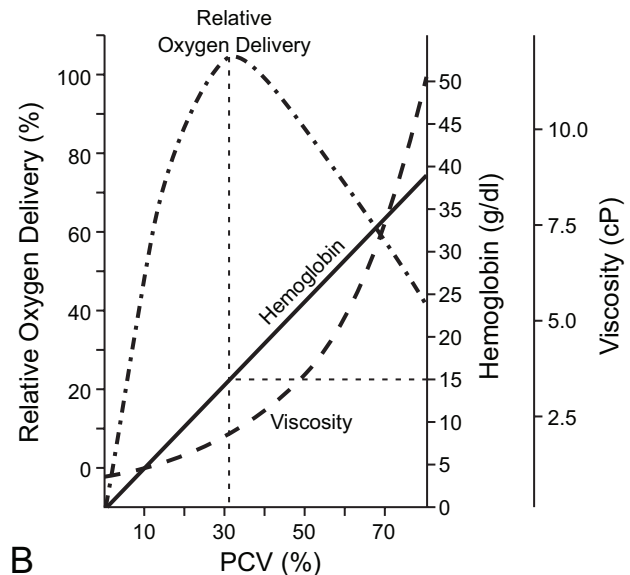

Fig. 4.3. Blood is unevenly distributed throughout the circulatory system. The largest portion of the blood volume is contained within the systemic veins. Relatively small changes in venous capacity can alter the heart's filling pressure dramatically, causing predictable changes in cardiac output (Q), peripheral vascular resistance (R), and arterial blood pressure (P). Decreases in filling pressure, for example, decrease Q and P and increase R . Modified from Shepherd and Vanhoutte,¹⁰² p. 11.

substances to all the tissues of the body and for delivering carbon dioxide, the by-products of cellular metabolism, and foreign substances (e.g., anesthetic drugs) to the appropriate organs of elimination. This suspension of red and white blood cells and platelets in plasma is also responsible for maintaining a normal cellular environment (homeostasis), prevention of hemorrhage (clotting), and defense against foreign substances (immunity).² The most essential function of blood is to deliver oxygen to tissues. Oxygen is relatively insoluble in plasma (0.003 mL per 100 mL per 1 mm Hg partial pressure of oxygen [PO_2]; approximately 0.3 mL per 100 mL at $PO_2 = 100$ mm Hg). The erythrocytes (red blood cells [RBCs]) transport much larger amounts of oxygen than can be carried in solution, and the actual amount that can be carried depends on the amount of hemoglobin (Hb) in the erythrocytes. The balance between oxygen delivery by whole blood and oxygen partial pressure in the tissues and cells has evolved to incorporate a diverse group of regulatory processes designed to accommodate the encapsulation of Hb within RBCs. Hemoglobin exists as a tetramer (molecular weight, 64 kDa) consisting of two α and two β polypeptide chains. Each polypeptide chain contains heme and a central iron molecule that can bind oxygen.³ The affinity of Hb for oxygen depends on the partial pressure of carbon dioxide (PCO_2), pH, body temperature, the intraerythrocyte concentration of 2,3-diphosphoglycerate and the chemical structure of Hb (Fig. 4.4A).³ Heme must be in the reduced or ferrous state (Fe^{2+}) to bind oxygen. Methemoglobin is

A

B

Fig. 4.4. A: The oxyhemoglobin-dissociation curve illustrates the relationship between the blood partial pressure of oxygen (PO_2) and the saturation of hemoglobin (Hb) with oxygen (O_2). Note that this curve is right shifted (Hb has less affinity for O_2) by acidosis (\downarrow pH \uparrow carbon dioxide [CO_2]), increases in body temperature, and the enzyme 2,3-diphosphoglycerate (2,3-DPG). This effect helps to unload O_2 from Hb in metabolizing tissues and increases Hb affinity for O_2 in the lungs. The total arterial oxygen content (CaO_2) is determined by the total blood Hb concentration, its percent saturation ($\%SaO_2$), and the arterial oxygen partial pressure. **B:** The hemoglobin (Hb) concentration and the blood viscosity (μ) determine oxygen delivery to tissues. There is an "ideal" Hb or packed cell volume (PCV; $3 \times Hb = PCV$) at which oxygen delivery to tissues is optimized. cP, centipoise.

formed when the iron is oxidized to the ferric state (Fe^{3+}), and this form of Hb cannot bind oxygen. Hemoglobin is maintained in the Fe^{2+} state inside the RBC by reduced nicotinic-adenine dinucleotide (NADH)—methemoglobin reductase. Carboxyhe-

moglobin, sulfhemoglobin, and cyanmethemoglobin are other Hbs that are not capable of reversible associations with oxygen. Once the amount of deoxygenated Hb (unsaturated Hb) exceeds 5 g/100 mL in arterial blood, the blood changes from red to blue (cyanosis). Some of the carbon dioxide produced by metabolizing tissues binds to deoxygenated Hb and is eliminated by the lungs during the Hb oxygenation process prior to the blood returning to the systemic circulation and the cycle repeating itself.

Encapsulation of Hb within RBCs has important biological consequences, including the rate of its saturation with oxygen, its intravascular half-life, prevention of renal toxicity, and maintenance of colloid osmotic pressure. The PO_2 at which Hb is half-saturated with oxygen is termed the P_{50} . The P_{50} varies among species (23 to 32 mm Hg), and free Hb (lysed RBCs and blood substitutes) has a lower P_{50} than does blood (Fig. 4.4A). The high intracellular concentration of 2,3-diphosphoglycerate compared to plasma facilitates the release of oxygen from Hb and helps maintain a physiologically relevant P_{50} (26 to 28 mm Hg). Once free in the plasma (hemolysis), Hb dissociates into $\alpha\beta$ dimers, which initially bind to haptoglobin and are removed by the liver. Depletion of haptoglobin leads to clearance of free Hb dimers by the kidneys. Renal clearance of large quantities of Hb dimers can result in their precipitation in the proximal tubules, leading to renal tubular damage and renal failure.⁴ Free Hb also increases the colloid osmotic pressure of whole blood.

Blood is a nonhomogeneous suspension of particles (non-Newtonian fluid). Therefore, the concentration of RBCs, RBC interactions, and fluid characteristics of whole blood determine its fluidity, flow resistance, velocity, and local shear stress, which modifies cardiac output, cardiac work, blood flow distribution, and oxygen delivery to tissues. Oxygen delivery to tissues plays a very important role in determining microcirculatory autoregulatory responses, with increases in PO_2 causing vasoconstriction and vice versa. Changes in packed cell volume (PCV) require appropriate shifts in the viscosity (μ) of whole blood in order to optimize oxygen delivery to tissues. Small decreases impact PCV, and blood μ (hemodilution) generally increases blood flow velocity and decreases diffusional oxygen exit from the arterioles, thereby augmenting oxygen delivery to tissues (Fig. 4.4B). Intentional hemodilution (e.g., crystalloid or colloid administration) to improve oxygen delivery, however, is limited by the “transfusion trigger” (about 6 to 8 g/dL). When the Hb concentration decreases below this range, the decreased amount of oxygen carried by Hb may cause tissue hypoxia. Fortunately, increases in plasma μ induce vasodilatation, thereby helping to preserve capillary perfusion and functional capillary density, suggesting that the transfusion trigger is also a viscosity trigger and that both PCV and μ must be considered together when selecting fluid therapy.

Maintaining adequate tissue oxygenation depends on oxygen uptake by the lungs, oxygen delivery (DO_2) to and oxygen extraction (OE) by tissues, and oxygen use by the metabolic machinery within cells. The factors that determine the supply of oxygen to tissues are Hb concentration, the affinity of Hb for oxygen (P_{50}), the saturation of Hb with oxygen (SaO_2), the arterial oxygen partial pressure (PaO_2), the cardiac output (CO), and

the tissue oxygen consumption (VO_2). The Fick, or oxygen consumption, equation ($VO_2 = CO [CaO_2 - CvO_2]$) contains all the essential components of this relationship. The Fick equation can be used to derive oxygen delivery ($DO_2 = CO \times CaO_2$), oxygen extraction ($OE = CaO_2 - CvO_2$), and the oxygen extraction ratio ($OER = CaO_2 - CvO_2 / CaO_2$), noting that all of the equations contain the term CaO_2 and are therefore mathematically coupled. Arterial blood oxygen content (CaO_2) is calculated by $CaO_2 = Hb \times 1.35 \times SaO_2 + PaO_2 \times 0.003$. Arterial blood (Hb = 15 g/dL; PCV = 45%), for example, contains approximately 20 to 21 mL of oxygen/dL of blood when the $SaO_2 = 100\%$ and the $PaO_2 = 100$ mm Hg (room air). The venous blood oxygen content (CvO_2) is generally 14 to 15 mL/dL yielding an OER of 0.2 to 0.3 (20% to 30%). Decreased hemoglobin concentrations (parasitism, hemorrhage, and hemodilution) cause oxygen extraction to increase to maintain the requisite oxygen delivery required by metabolizing tissues. The critical DO_2 and OER are approximately 5.0 mL/kg/min and 0.6 (60%) in normal healthy dogs, suggesting that most dogs and other mammals have significant reserve. An increase in arterial blood lactate concentration is the cardinal sign of inadequate oxygen delivery to metabolizing tissues and suggests that oxygen consumption has become delivery dependent or that some defect in tissue oxygen extraction or use has developed.

Hemorheology

Hemorheology is the study of blood flow in the vascular system.^{5,6}

Pressure, Resistance, and Flow

In electric circuits, current flow (I) is determined by the electromotive force or voltage (E) and the resistance to current flow (R) according to Ohm’s law:

$$I = E/R$$

The flow of fluids (Q) through nondistensible tubes depends on pressure (P) and the resistance to flow (R). Therefore, and in the most general terms,

$$Q = P/R$$

The resistance to blood flow is determined by blood viscosity (η) and the geometric factors of blood vessels (radius and length). The steady, nonpulsatile, laminar flow of Newtonian fluids (homogenous fluids in which viscosity does not change with flow velocity or vascular geometry), like water, saline, and, under physiological conditions, plasma, can be described by the Poiseuille-Hagen law, which states

$$Q = (P_1 - P_2) r^4 \pi / 8L\eta; R = 8L\eta / r^4 \pi$$

where $P_1 - P_2$ is the pressure difference, r^4 is the radius to the fourth power, L is the length of the tube, η is the viscosity of the fluid, and $\pi/8$ is a constant of proportionality.⁷ The maintenance of laminar flow is a fundamental assumption of the resistance offered to steady-state fluid flow in the Poiseuille-Hagen equation. This law, although frequently used for assessing blood flow in

the vascular system, is descriptive only and must be kept in perspective when considering the real-life situation, because blood is not a homogenous fluid and blood flow is not steady, but pulsatile, and is not always laminar. These differences from the idealized steady laminar flow of Newtonian fluids through nondistensible tubes of constant radius have important consequences on the quantity of blood flow to peripheral tissue beds, oxygen delivery, and the distribution of blood flow between tissue beds.

The relationship between vessel (or chamber when describing the heart)-distending pressure, vessel diameter, vessel wall thickness, and vessel wall tension is described by Laplace's law:

$$P = 2Th/r \text{ or } T = Pr/2h$$

where T is wall tension, P is developed pressure, r is the internal radius, and h is the wall thickness. This relationship is extremely important because it relates pressure and vessel dimension to changes in developed tension, which is known to be an important determinant of ventricular-vascular coupling (afterload), myocardial work, and myocardial oxygen consumption.⁸

Viscosity

Since blood is a non-Newtonian fluid that is delivered through progressively narrowing blood vessels in a pulsatile nonlaminar or even turbulent manner, how can blood flow be accurately characterized? More specifically, how can the resistance (R) to blood flow be thought of in functional terms? First, the major factors influencing blood flow resistance (R_p) are blood viscosity (η) and impedance (Z), which collectively can be considered vascular hindrance:^{9,10}

$$R_p = \eta \times Z$$

It should be noted that the term R_p is not the same as R in Ohm's law or the equivalent thereof in the Poiseuille-Hagen equation ($8L\eta/r^4\pi$), but represents the resistance to blood flow in a pulsatile (R_p ; p = pulsatile) or oscillatory non-steady-state or, simply stated, more physiological system. The resistance (R) term in the two previous examples is more correctly thought of in terms of a nonpulsatile, nonoscillatory, and nonphysiological system.

The viscosity term (η), although of lesser importance than Z in determining R_p , depends on RBC concentration or hematocrit, RBC aggregability and deformability, plasma viscosity, temperature, and blood flow conditions.⁶ The rheological term that characterizes blood flow conditions is shear rate, which is a function of blood flow velocity and vascular geometry. The viscosity of blood is shear rate dependent. Viscosity decreases as shear rate increases according to this equation:

$$\eta = \text{shear stress (dynes/cm}^2\text{)}/\text{shear rate (s}^{-1}\text{)}$$

where shear stress is the force applied during pulsatile blood flow between theoretic layers of blood in the blood vessel. It is interesting that shear rate gradually increases and η decreases as large arteries become smaller, and is greatest in the capillaries regardless of low flow rates and then decreases in venules and large veins. This phenomenon, known as the *Fahraeus-Lindquist effect*, is attributed to "plasma skimming" and RBC deformability; that is, viscosity in capillaries is low because RBCs may only be

able to pass through capillaries single file, permitting the development of a cell-free layer of plasma next to the capillary wall that, in conjunction with RBC folding, increases the cell-free component of blood compared to the situation in larger blood vessels.⁹ The smaller the vessel, the greater is the effect. Under normal circumstances, the most important variable in determining η is the hematocrit.

The optimum hematocrit for transporting the most oxygen per unit time to tissues varies among species (e.g., human, 47%; dog, 46%; cow, 32%; horse, 42%; and camel, 27%) because of differences in anatomy and circulatory dynamics. Dogs and horses also can contract their spleen, providing additional RBCs (raising the hematocrit) and oxygen-carrying capacity during times of stress or exercise. High hematocrits (polycythemia), low blood flow conditions (shock), increased RBC aggregability, rouleaux formation (sepsis), and hyperproteinemia (dehydration) can all cause η to increase, resulting in a decrease in oxygen delivery to tissues (Fig. 4.5). Hematocrits greater than 65% lead to sludging of blood in capillaries and venules and dramatically increase the work of pumping blood. Hemodilution (fluid administration) is often beneficial in treating these conditions and has been used during anesthesia to reduce RBC loss and improve oxygen delivery during low blood flow states.^{11,12} Indeed, the optimum hematocrit for dogs subjected to hemorrhagic shock and an arterial blood pressure of 50 mm Hg is 20% to 25% (Fig. 4.5).⁹ The advent and clinical use of hemoglobin-based oxygen-carrying solutions derived from human, bovine, or synthetic sources have provided an alternative method for oxygen delivery to tissues. Their development has markedly increased our understanding of oxygen uptake, delivery, and use and ushered in new ideas regarding the mechanisms responsible for the distribution of blood flow and the control of the microcirculation.

Impedance

The impedance (Z) term, the second key factor in determining blood flow in pulsatile systems, is a measure of the opposition to flow presented by pulsatile blood flow in an elastic vascular system.¹⁰ Quantitatively, impedance is the relationship between pulsatile pressure and pulsatile flow in arteries:

$$Z_L = P_1 - P_2/Q \text{ (} Z_L = R_p + R \text{)}$$

where Z_L represents longitudinal impedance, which is the sum of the pulsatile (R_p) and steady nonpulsatile resistive (R) components of longitudinal arterial resistance. Under normal (non-stressed) conditions, the steady nonpulsatile resistive component represents 90% of the total impedance to blood flow while the pulsatile component comprises 10%. This fact ($R = 90\%$ of Z_L) is the principal reason so many investigators and clinicians calculate vascular resistance from Ohm's law. The components of Z_L may change considerably, however, in diseased animals or during pharmacological manipulation, with R_p becoming much more important.

Impedance is determined by the various frequency components that comprise the arterial pressure and flow waveforms, is measured by applying a Fourier or harmonic analysis to these waveforms, and is expressed as a ratio or modulus and phase

Fig. 4.5. The effects of changes in hematocrit (% Hct) on an index of oxygen transport (Hct/η). The arrow marked *N* represents a relatively normal Hct. The arrow marked *D* represents a patient with anemia or hemodilution. The dashed line represents the normal situation when Hct is the only variable. The solid line represents the response to changes in Hct when plasma viscosity (η) is increased, red cell aggregation (aggreg.) is increased, red cell deformability (deform.) is decreased, or blood flow rate is decreased. Modified from Lasala et al.,⁶ p. 210.

(Fig. 4.6). A positive phase value indicates that flow harmonics lag behind pressure harmonics, and vice versa, the key point being that impedance is a frequency-dependent, not time-dependent, index. Input impedance (Z_i), the ratio of pressure and flow at an arterial site that is considered to be the input to the vascular tree (e.g., the aortic root), depends on local arterial properties (e.g., elastance or compliance), the properties of all the vessels beyond the point of measurement down to the points where pulsations and pulse-wave reflections from narrowing arteries (particularly arterioles) and vessel bifurcations disappear. Impedance to blood flow, therefore, is viewed as having a resistive (steady state) component due primarily to the arterioles and a reactive (pulsatile) component due to vessel wall properties (compliance, elastance, and pulse-wave reflection). Low systolic arterial pressure enables more complete ventricular ejection, maintains low myocardial oxygen demands, and provides little stimulus for hypertrophy. High diastolic pressure ensures adequate coronary blood flow and myocardial perfusion because the majority of myocardial blood flow occurs during ventricular relaxation. Increases in arterial stiffness increase pulse-pressure amplitude and systolic pressure, and decrease diastolic pressure. Poorly timed wave reflections generally increase diastolic pressure (increase Z). The totality of these effects increases myocardial work, oxygen consumption, and energy requirements, and decreases myocardial perfusion. Ideally, the best match between the heart's pumping activity and the vascular response to the ejection of blood (ventricular-vascular coupling) is obtained

Fig. 4.6. The impedance modulus and phase of a hypothetical aortic impedance spectra. The impedance modulus decreases from 0 Hz (*R*, peripheral vascular resistance) to a low value that oscillates around a characteristic value (Z_0) because of pulse-wave reflections (*RF*). Negative phase values indicate that flow harmonics lead pressure harmonics and vice versa.

when myocardial work is kept as low as possible (low systolic pressure) while adequate perfusion of the heart and peripheral tissues (high diastolic pressure) is maintained.^{13–15} Within perfusing limits, a reduction in mean arterial pressure (a characteristic of most anesthetic drugs) improves arterial distensibility, delays pressure-wave reflections, and causes a smaller reduction in diastolic pressure than does hypovolemia. Anesthesia and anesthetic drugs also produce variable effects on hematocrit, RBC deformability, and plasma protein concentrations, leading to alterations in η , which, when combined with changes in Z , may favorably affect ventricular-vascular coupling, providing hypotension (mean, less than 50 to 60 mm Hg) does not occur.^{9,16,17}

Turbulence

Pulsatile blood flow may be laminar with a longitudinal velocity that takes the form of a parabola or may be irregular or turbulent (Fig. 4.7). More pressure, myocardial release of energy, and work are required to pump blood when the flow is turbulent. The po-

Fig. 4.7. Velocity profiles for laminar and turbulent blood flow. Note that during turbulent blood flow vortices develop and that both axial and mean velocities are lower than during laminar flow. V_{max} , maximum velocity.

tential for turbulence to develop in blood vessels can be predicted by a dimensionless number called the Reynolds number (RN):¹⁸

$$RN = \rho Dv/\eta$$

where ρ is fluid density, D is vessel diameter, and v is the mean blood flow velocity. The blood viscosity (η) is inversely proportional to the Reynolds number and is an important determinant of turbulent blood flow. Turbulence usually produces periodic wave fluctuations and vibrations of the surrounding tissue structures, leading to murmurs and, with time, vascular dilation caused by weakening of the supporting elements of the vessel wall. Chronic or acute hemodilution (fluid therapy) reduces hematocrit; therefore, η , leading to an increase in Reynolds number and the production of “functional” cardiac murmurs. Furthermore, flow restriction caused by congenital disease (aortic or pulmonic stenosis) or blood vessel narrowing leads to an increase in the velocity of blood flow as predicted by the continuity equation which states that blood flowing through different areas of a continuous intact vascular system must be equal; therefore, blood flow through a narrowing or narrowed orifice must increase. The flow downstream from the obstruction or narrowing is usually turbulent with multiple velocities and directions. Cardiac diseases (pulmonic and aortic stenosis) and vascular diseases (thrombophlebitis) that narrow valve openings or blood vessels increase v and are important causes of murmurs. Blood flow velocity measurements can be assessed clinically by Doppler echocardiography and the Bernoulli equation, $\Delta P = 4v^2$, with the assumption that velocity distal to the obstruction is significantly greater than the velocity proximal to the obstruction and therefore may be ignored.

The Heart

The purpose of the heart is to pump blood in quantities sufficient to meet the body’s metabolic and exercise demands. To achieve this function requires a highly integrated series of electric, mechanical, and metabolic events that culminate in repetitive contraction and relaxation of the myocardium.

Electrophysiology

Normal cardiac electric activity is essential for normal cardiac contractile function (excitation-contraction coupling). Indeed, myocardial contraction is preceded by, and will not occur without, electric activation, although normal or near-normal electric activity is possible without myocardial contraction (electric-mechanical uncoupling; electric-mechanical dissociation). The cardiac cell membrane (sarcolemma) is a highly specialized lipid bilayer that contains protein-associated channels, pumps, enzymes, and exchangers in an architecturally sophisticated, yet fluid (reorganizable and movable), medium. Most drugs and many anesthetic drugs produce important direct and indirect effects on the cell membrane and intracellular organelles, ultimately altering cardiac excitation-contraction coupling.

The molecular composition and fluidity of cardiac membranes determine their ion transport and membrane-associated electric properties. The unequal distribution of different ions, especially sodium, potassium, and chloride, is responsible for the development of the resting membrane potential of cardiac cells as predicted by the Nernst equation or, more accurately, the Goldman-Hodgkin-Katz constant-field equation.^{19–21}

Nernst equation:

$$E = (RT/ZF) \ln(K_i/K_o)$$

$$-61 = 2.303 RT/F$$

$$E = -61 \text{ mV}/Z \log (C_i/C_o)$$

where

E = electromotive force

C_i and C_o = ion concentration inside (*i*) and outside (*o*) the cell membrane

Z = valence

R = gas constant

T = absolute temperature

F = Faraday constant

2.303 = conversion of ln to log 10

mV = millivolts at 37°C

Goldman-Hodgkin-Katz equation:

$$E_m = -61 \text{ mV} \log \frac{[K]_i + (P_{Na}/P_K) [Na]_i}{[K]_o + (P_{Na}/P_K) [Na]_o}$$

where

E_m = resting membrane potential

P_{Na}/P_K ratio = relative permeability of membrane Na to K, normally 0.04 in myocardial cells

The transmembrane electric potential generated by cardiac cells is the result of transmembrane ion fluxes (active properties) through “gated” membrane pores or channels (Table 4.1).²¹ Ion channels are characterized by their ionic selectivity, conductance, gating characteristics, and density. The channel-gating mechanisms control ion passage and are composed of both activation

Table 4.1. Currents associated with the cardiac action potential

Current	Abbreviation	Qualities
Fast inward sodium current	I_{Na}	Responsible for upstroke of action potential; abolished by tetrodotoxin; inhibited by class I antiarrhythmic agents
Slow inward calcium current	I_{Ca} and I_{si}	Important for plateau phase of cardiac action potential; involved in excitation-contraction coupling; increased by β stimulation; inhibited by calcium antagonist
Subtype T	$I_{Ca(t)}$	Transient calcium current, opening at low voltages (–60 to –50 mV); may be important in sinus node depolarization
Subtype L	$I_{Ca(l)}$	Long-duration calcium current; inhibited by calcium antagonists
Background potassium current (inward rectifier)	I_{K1} or I_{Kir}	Helps to maintain resting membrane potential
Voltage-gated delayed rectifier potassium currents	I_K (includes K_r and K_s)	Time-dependent outward potassium current; activated by depolarization (fully active at +10 mV) and deactivated by repolarization; voltage gated; responsible for repolarization in nodal cells and contributes to spontaneous depolarization; divided into I_{Kr} (r = rapid) and I_{Ks} (s = slow)
Early transient outward potassium current	I_{to}	Transient outward early potassium current, previously called <i>chloride current</i> ; prominent in epicardial ventricular cells, Purkinje fibers, and atrial cells; causes phase 1; may also shorten action-potential duration
Other currents		
Diastolic pacemaker current in sinoatrial node and Purkinje fibers	I_f or I_h	Produces automaticity in sinoatrial node and Purkinje fibers
Sodium-calcium exchange current	$I_{NA/CA}$	Contributes to late phase of cardiac action potential
Chloride current	I_{Cl}	Activated by cAMP; shortens action-potential duration during adrenergic stimulation
Ligand-operated G-dependent K currents		
Acetylcholine sensitive	I_{KACH}	Activated by acetylcholine muscarinic receptors in nodal, Purkinje, and atrial cells; not in ventricles; time independent; when current switched on in nodal cells, spontaneous depolarization is delayed
Adenosine sensitive	I_{KADO}	Probably same as I_{KACH} ; adenosine stimulates time-independent background potassium current
Adenosine triphosphate (ATP) regulated	I_{KATP}	Lack of ATP activates (e.g., ischemia); inhibited by sulfonureas, activated by K-channel activators (pinacidil)

cAMP, cyclic adenosine monophosphate.

Modified from Opie.¹⁰⁶

Fig. 4.8. Cardiac transmembrane potential changes associated with fast-response and slow-response action potentials. Note that slow-response action potentials originate from a less negative resting membrane potential and have a much slower rate of rise (phase 0). During the supernormal period, a subthreshold stimulus can elicit a normal action potential. See the text for an explanation of the action-potential phases 1 through 4. ERP, effective refractory period; and RRP, relative refractory period.

and inactivation gates, which are voltage and frequently time dependent. The functional configuration of the gates determines channel state: activated or open, inactivated or closed, and resting (capable of being activated). The directional movement (inward or outward) of the various ions ultimately depends on channel state and the electrochemical driving force (equilibrium potential minus membrane potential) for each ion. The electrochemical driving force, as illustrated by the Nernst equation, is composed of an electric force and a concentration gradient. It should be noted that in the presence of many anesthetic drugs, particularly local anesthetics (lidocaine or mepivacaine), and inhalation anesthetics (halothane, isoflurane, or sevoflurane), these same channels may demonstrate use-dependent block.^{22,23} Use-dependent block is the phenomenon exhibited by cardiac cells wherein, in the presence of a drug, increases in stimulation rate (e.g., heart rate) produce a more pronounced drug effect on the electrophysiological properties of the heart than during slower rates of stimulation.

Excitability, or the ability of the cardiac cell membrane to generate an electric potential (action potential), is a fundamental intrinsic property of cardiac cells.¹⁹ The action potential of cardiac muscle varies considerably from that of nerves and skeletal muscle. The cardiac action potential arises from a more negative membrane potential (90 vs. 65 mV), is greater in magnitude (130 vs. 80 mV), and is much longer in duration (150 to 300 vs. 1 ms). Five characteristic phases of the cardiac action potential are discernible in most cardiac cells: Phase 0, or the phase of rapid depolarization, is caused by the rapid and relatively large influx of sodium ions (fast inward current) into the cell; phase 1, the early phase of repolarization, is caused by the transient outward movement of potassium ions; phase 2, the plateau phase, is attributed to the continued, but decreased, entry of sodium ions and a large, but slow, influx of calcium ions (slow inward current) into cells; phase 3 is the phase of repolarization during which the membrane potential returns to its resting value because of potassium efflux (outward current) from the cell; and phase 4 is a resting phase in atrial and ventricular muscle cells prior to the initiation

of the next action potential (Fig. 4.8 and Table 4.2). The magnitude and rate of sodium influx into cardiac cells determine the magnitude and rate of change in membrane potential (dV/dt) during phase 0 of the cardiac action potential. The greater the dV/dt , the more rapid are the transmission and conduction of the cardiac impulse through cardiac tissue.²⁰ Cardiac cells that normally possess a more negative membrane potential (atrial and ventricular muscle cells, and Purkinje cells) demonstrate greater excitability and a more rapid conduction velocity than those with less negative membrane potentials (sinoatrial and atrioventricular nodes, and diseased myocardium).²³ Calcium entry into cardiac cells during phase 2 triggers intracellular calcium release, which is important for normal cellular contraction and, with potassium, determines action-potential duration in atrial and ventricular myocytes. Since calcium enters the cell slowly and at a less negative membrane potential, cardiac cells with a reduced resting membrane potential (sinoatrial and atrioventricular nodes) demonstrate a considerably decreased dV/dt and slow conduction velocity compared to atrial and ventricular muscle and Purkinje cells.²⁰ Potassium efflux from cardiac cells is controlled by a variety of mechanisms, including concentration differences across the membrane and the changing permeability (diffusional) characteristics of the cell membrane to potassium (Table 4.1). Collectively, the channels responsible for phase 3 repolarization are also the major determinants of cardiac action-potential duration, cardiac cell refractoriness, and the duration of the supernormal period (Fig. 4.8). The duration of the cardiac action potential has important clinical implications relative to the amount of calcium entry and the potential for arrhythmia development.²² Longer cardiac action potentials permit more calcium entry into the cell and prolong cellular refractoriness. Arrhythmias develop if there are large disparities or inhomogeneities in the action-potential duration and refractoriness of adjacent cardiac cells because of reentry of electric impulses and reexcitation of the heart (see the Cardiac Arrhythmias section).²⁴ Reentry is one mechanism whereby the ultra-short-acting barbiturates and inhalation anesthetics are known to produce cardiac arrhythmias.

Table 4.2. Major ion fluxes during the cardiac action potential

Name	Ion	Movement	Current	Phase of Action Potential
I_{Na}	Na^+	In	Inward	0 Depolarization
I_{to}	K^+	Out	Outward	1 (early repolarization)
I_{Cl}	Cl^-	In	Outward	1 Early repolarization
I_{Ca}	Ca^{2+}	In	Inward	2 Plateau
I_{K1}	K^+	Out	Outward	2 Plateau
I_k	K^+	Out	Outward	3 Repolarization
I_f	Na^+	In	Inward	4 Depolarization in automatic cells

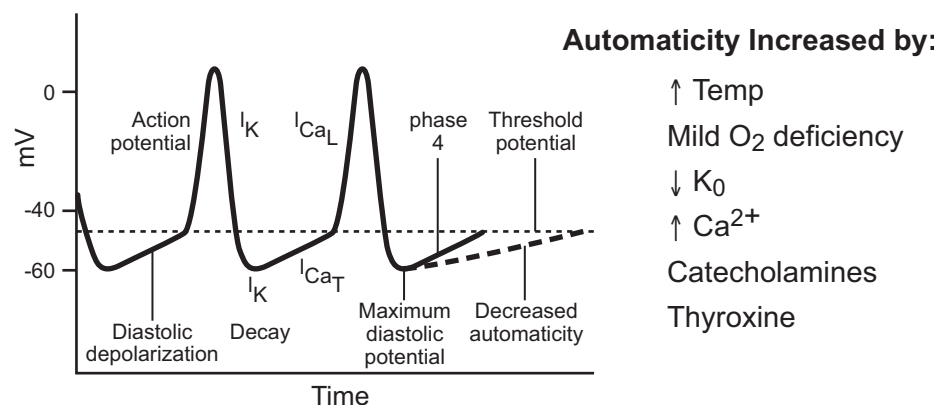

Open I_{K1} channels in resting cells are the major contributors to the equilibrium responsible for the Nernst potential during phase 4 (resting potential). Modified from Katz.¹⁰⁷

Phase 4 diastolic depolarization (pacemaker potential) occurs in the sinoatrial and atrioventricular nodes and atrial and ventricular (Purkinje network) specialized tissues.^{20,21} Diastolic depolarization imparts the unique property of automaticity to the heart. The resting membrane potential depolarizes toward a threshold potential in tissues with this property, which when reached triggers the development of an action potential. The ionic processes responsible for phase 4 or diastolic depolarization vary between the various specialized tissues of the heart primarily because of differences in their resting or maximum diastolic potential and cell type (e.g., sinoatrial node vs. atrioventricular node vs. Purkinje cell). Cells in the sinoatrial and atrial ventricular nodes have comparatively less negative maximum diastolic potentials (-65 mV) than do Purkinje cells and depend on the entry of calcium ion (slow inward current) and a progressive decrease in membrane permeability to potassium efflux for their automaticity (Fig. 4.9). Automatic cells in atrial specialized pathways and the ventricular Purkinje network have a more negative maximum diastolic potential (-90 mV) and depend on a hyperpolarizing-induced “funny” inward current, termed I_f , carried mainly by sodium ions and a decrease in potassium efflux for their automaticity (Table 4.1). Because potassium ions normally leave cardiac cells in order to restore or maintain the resting membrane potential, any decrease in potassium efflux facili-

tates depolarization. The principal mechanisms responsible for altering automaticity are changes in the threshold potential, the rate of phase 4 depolarization, and the maximum diastolic potential following repolarization. The cardiac tissue with the most rapid rate of phase 4 depolarization (normally the sinoatrial node) is termed the *pacemaker* and determines the heart rate. The cardiac pacemaker normally depresses the automaticity of slower or subsidiary pacemakers (overdrive suppression), preventing more than one pacemaker from controlling heart rate. In mechanical terms, overdrive suppression in subsidiary pacemakers is due to activation of the sodium ion–potassium ion (Na^+K^+) pump, leading to membrane hyperpolarization and a longer time to reach threshold.^{20,22} Subsidiary pacemakers are most suppressed at fast heart rates because the Na^+K^+ pump is more active at faster rates, resulting in a more negative maximum diastolic potential. Automaticity is also influenced by local factors, including temperature, pH, and blood gases (PO_2 and PCO_2), extracellular potassium concentration, catecholamines, and various hormones (Fig. 4.9).

The algebraic sum of all the action potentials produced by each cardiac cell following activation by the sinoatrial node is responsible for the body surface electrocardiogram (ECG [Fig. 4.10]). Initiation of an electric impulse in the sinoatrial node is followed by rapid electric transmission of the impulse through

Fig. 4.9. The transmembrane potential of cardiac tissue within the sinoatrial node (pacemaker tissue) is characterized by a less negative maximum diastolic potential, which depolarizes toward threshold (phase 4 diastolic depolarization), a slow phase 0 caused primarily by activation of, and a relatively rapid repolarization due to, I_K . The rate of phase 4 diastolic depolarization (automaticity) can be increased by increases in heart rate, temperature, calcium, catecholamines, and thyroxine and decreases in oxygen tension and extracellular potassium concentration.

Fig. 4.10. The transmembrane potential (action potential) recorded from all the tissues of the heart (specialized tissue and muscle) summate to produce the P-QRS-T complex of the electrocardiogram (ECG) recorded at the body surface. AV, atrioventricular node; brs, branches; int, interval; LA, left atrium; LV, left ventricle; m, muscle; RA, right atrium; RV, right ventricle; SA, sinoatrial node; and seg, segment.

the atria, giving rise to the P wave. Repolarization of the atria gives rise to the Ta wave, which is most obvious in large animals (horses and cattle), where the total atrial tissue mass is substantial enough to generate enough electromotive force to be electrocardiographically recognizable. Repolarization of the atria in smaller species (dogs and cats) and depolarization of the sinoatrial and atrioventricular nodes do not generate a large enough electric potential to be recorded at the body surface except in cases of sinus tachycardia. Repolarization of the atria or Ta waves can be observed in dogs and cats with increased heart rates. Once the wave of depolarization reaches the atrioventricular node, conduction is slowed because of the atrioventricular node's low resting membrane potential (approximately -60 mV) and the relatively depressed rate of phase 0 (decremental conduction). Increased parasympathetic tone can produce marked slowing of atrioventricular nodal conduction, leading to first-degree, second-degree, and, rarely, third-degree heart block. Many drugs used in anesthesia, including opioids, α_2 -adrenergic agonists, and occasionally acepromazine, increase parasympathetic tone, causing heart block and bradyarrhythmias (see the Cardiac Arrhythmias section). The use of antimuscarinic drugs atropine and glycopyrrolate is generally effective therapy in these situations unless the block is caused by structural disease (e.g., inflammation, fibrosis, or calcification).

Under normal conditions, conduction of the electric impulse through the atrioventricular node produces the PR or PQ interval of the ECG and provides time for the atria to contract prior to activation and contraction of the ventricles. This delay is functionally important, particularly at faster heart rates, because it enables atrial contraction to contribute to ventricular filling. It is worth remembering that cells of the atrioventricular node are ex-

tremely dependent on calcium ion for the generation of an action potential and conduction of the electric impulse. Thus, cells of the atrioventricular node are extremely sensitive to drugs that block transsarcolemmal calcium flux, like large doses of anesthetics (inhalant and injectable anesthetics) and the so-called calcium antagonists verapamil and diltiazem. These and other drugs and cardiac disease can produce atrioventricular block and post-repolarization refractoriness that are not responsive to anticholinergic drugs. Post-repolarization refractoriness is the phenomenon wherein cardiac cells remain refractory to electric activation after complete repolarization.^{22,24} This phenomenon is most likely to produce atrioventricular block as the rate of atrial depolarization is increased. Increases in parasympathetic tone, therefore, particularly in the presence of drugs or disease (ischemia) that interfere with conduction of the electric impulse through the atrioventricular node, can lead to ECG evidence of first-degree (prolonged PR interval), second-degree (blocked P wave), or third-degree (dissociation of P and QRS complex) atrioventricular block.

Once the electric impulse has traversed the atrioventricular node, it is rapidly transmitted to the ventricular muscle by specialized muscle cells commonly referred to as *Purkinje fibers*. Bundles of Purkinje cells—the right and left bundle branches—transmit the electric impulses to the ventricular septum and the right and left ventricular free walls, respectively, via the moderator band in the right ventricle and the left anterior and posterior divisions of the left bundle branch in the left ventricle. Purkinje cells and the so-called M or midmyocardial cells located at the terminal ends of the ventricular bundle branches and in the middle of the ventricular walls, respectively, have the longest action potential and therefore serve as physiological “gates” preventing the reentry and recycling of electric impulses in the ventricular

myocardium.²⁰ The relatively long duration of M cell action potential is believed to be, in part, responsible for the development of U waves in the ECG. Purkinje fibers conduct the electric impulse at relatively rapid speeds (3 to 5 m/s) based on their size and electric properties (Fig. 4.10). Their distribution accounts for differences in the pattern of the ECG (ventricular depolarization) among species. Purkinje fibers have much longer action potentials and refractory periods than do ventricular muscle cells, which normally prevents reentry of the electric impulse and reactivation of the ventricles (see the Cardiac Arrhythmias section).

It is important to remember that—although the transmission of the electric impulse has, by analogy, been compared to dropping a pebble in water, leading to a concentric wave front, or, in the case of the heart, a concentric wave of depolarization—the conduction of the electric impulse in the heart ultimately depends on uniform (isotropic) cell-to-cell resistive and capacitive (passive) membrane properties that are largely determined by low-resistance gap or nexus junctions between cells and the spatial variation in myocardial cell refractoriness.^{25–27} The configuration and magnitude of the T wave vary considerably among species and are influenced by changes in heart rate, blood temperature, and the extracellular potassium concentration. Hyperkalemia, for example, produces an increase in membrane conductance to potassium. This shortens repolarization and produces T waves that are of large magnitude, generally spiked or pointed, and of short duration (short QT interval).

The interval beginning immediately after the S wave of the QRS complex (J point) and preceding the T wave is referred to as the *ST* or *ST segment* and is important clinically. Elevation or depression of the ST segment (± 0.2 mV or greater) from the isoelectric line is usually an indication of myocardial hypoxia or ischemia, low cardiac output, anemia, pericarditis, or cardiac contusion, and suggests the potential for arrhythmia development. Rarely, U waves can be distinguished immediately following the completion of the T wave and are believed to represent repolarization of M cells and possible Purkinje cells.²⁰ Like Ta waves, U waves are more frequently observed in larger species (horses and cattle) during electrolyte imbalances (hypokalemia or hypocalcemia) or drug therapy (quinidine or digitalis) (Fig. 4.10).

In summary, the cardiac cell membrane possesses both active (ion movement) and passive (resistive and capacitive) properties that determine the heart's excitability, automaticity, rhythmicity, refractoriness, and ability to conduct an electric impulse. Anesthetic drugs, via their effects on both the active properties (e.g., lidocaine, a sodium-channel blocker; barbiturates and inhalants suppress calcium currents) and passive properties (e.g., volatile inhalant anesthetics change membrane fluidity and depress gap junctions) of the heart, can produce significant alterations in cardiac excitability and conduction of the electric impulse, ultimately predisposing patients to cardiac arrhythmias and mechanical contraction abnormalities.^{28–33}

Excitation-Contraction Coupling

Excitation-contraction coupling refers to the process wherein electric activation of the heart is transformed to muscle contraction. The process begins with the cardiac action potential and de-

polarization, and ends with the interaction of the contractile proteins in the individual sarcomeres. The normal extracellular calcium-ion concentration is 10^{-3} M compared to an intracellular calcium-ion concentration of 10^{-7} M. The electric activation of the sarcolemma and transverse tubule (T tubule) membranes by the cardiac action potential causes an influx of a small quantity of calcium ions during phase 2 of the cardiac action potential, triggering the release of a much greater quantity of calcium (calcium-induced calcium release) from calsequestrin-bound calcium sources in the sarcoplasmic reticulum. Calcium-induced calcium release raises the intracellular calcium concentration from 10^{-7} to 10^{-5} M and causes cellular contraction (Fig. 4.11). The importance of calcium influx during phase 2 of the action potential in the contractile process of cardiac muscle compared to other muscles (skeletal and smooth) cannot be overemphasized, because cardiac contraction is more dependent on and responds instantaneously to changes in the extracellular calcium concentration. Most calcium ions entering the cardiac cell do so through voltage-dependent calcium channels, although some calcium ions enter via the calcium-sodium exchange reaction.³⁴ Calcium channels are located throughout the T-tubule system, which penetrates deep into the cell interior. The T tubules abut large terminal cisternae, which are the terminal portion of a diffuse intracellular longitudinal tubular system: the sarcoplasmic reticulum. Voltage-dependent calcium channels are of two types (Table 4.1): a slow, long-lasting (L type) channel that is opened by complete cellular depolarization, and a fast but transient (T type) channel that is activated earlier than L-type channels and at more negative potentials (Fig. 4.9). The exact mechanism whereby the calcium channels (both L type and T type) of the T tubules communicate with the calcium-release channels of the sarcoplasmic reticulum remains unresolved. It is generally accepted that the majority of calcium entering the cardiac cell during each action potential does so through the L-type channel, also termed the *dihydropyridine* (DHP) *receptor* because of its sensitivity to specific types of calcium antagonists (verapamil, diltiazem, and nifedipine-like compounds).³⁵ Whether or not the amount of calcium passing through the DHP receptor (L-type channel) is essential for initiating the series of events leading to cellular contraction, however, remains controversial, since it is known that the rate of change of intracellular calcium concentration is the most effective activator of intracellular calcium release from the sarcoplasmic reticulum. This latter observation suggests that the rapid T-type channels may be important in the excitation-contraction process. T-type channels activate at more negative potentials than L-type channels and are insensitive to sodium-channel blockers (e.g., lidocaine or tetrodotoxin) and calcium-antagonist drugs.³⁴ Taken together, these observations suggest that T-type channels account for the early phase of calcium-channel opening and may be important in initiating intracellular calcium release and electric depolarization of less polarized tissues, such as the sinoatrial and atrioventricular nodes.^{21,22} The L-type (DHP receptor) channels are more prevalent in atrial and ventricular muscle cells than are T-type channels, open at less negative potentials, and may account for the latter phases of calcium-channel opening.³⁴ Both channels, however, are physio-

Fig. 4.11. Calcium can enter the cardiac cell during the cardiac action potential (slow response), via a calcium channel or in exchange for intracellular sodium. Increases in intracellular calcium trigger the release of calcium from the sarcoplasmic reticulum (SR) by a process termed *calcium-induced calcium release*. Increases in intracellular calcium (10^{-7} to 10^{-5} M) in the vicinity of the contractile proteins cause the myosin heads to flex, resulting in sarcomere shortening. The use of adenosine triphosphate (ATP) and formation of adenosine diphosphate and inorganic phosphate, in combination with reuptake of calcium by the SR, cause the myosin head to relax. Phospholamban modulates the pump responsible for the reuptake of calcium into the SR.

logically linked via specialized proteins termed *feet*, which are bridging or spanning proteins connecting them to the calcium-release mechanism in the sarcoplasmic reticulum. The foot proteins are a part of a high molecular weight protein complex in the sarcoplasmic reticulum, termed the *ryanodine receptor* because of its affinity for the insecticide ryanodine.³⁵ Low concentrations of ryanodine enhance calcium release, whereas large concentrations inhibit calcium release from the sarcoplasmic reticulum.

To summarize, the large extracellular (10^{-3} M) to intracellular (10^{-7} M) calcium-ion gradient facilitates the transsarcolemmal flux of calcium ions through calcium channels (T type and primarily L type) during the depolarization. The L-type channel can be blocked by DHP drugs and is therefore called a *DHP receptor*. The increase in intracellular calcium triggers the release of calcium from specialized calcium channels (ryanodine receptors in the sarcoplasmic reticulum), causing an increase in intracellular calcium-ion concentration (10^{-5} M), which causes myocardial cellular contraction.

Contraction and Relaxation

Contraction

Cardiac myocytes are composed of contractile units termed *sarcomeres*, which contain thick (myosin) and thin (actin) contractile proteins, regulatory proteins (troponin and tropomyosin), and various structural proteins. The thick myosin filaments are composed of approximately 300 molecules, each ending in a bilobed head. Half (150) of the myosin bilobed heads are located at each end of the sarcomere and project from the thick filament toward the thin filaments (crossbridges). The thin filaments are attached at one end to structural proteins (Z line) that separate each sar-

comere. Each thin filament contains two helical strands of actin intertwined with tropomyosin, which has periodic troponin complexes (Fig. 4.12). Increases in intracellular calcium initiated during phase 2 of the cardiac action potential and amplified by subsequent calcium-induced calcium release serve as the catalyst for actin-myosin interaction and sarcomere shortening. More specifically, calcium ions bind to the regulatory protein troponin C (C for calcium), which removes the inhibitory function of troponin I (I for inhibitor) on the chemical interaction between actin and myosin. Transformation of chemical energy into sarcomere shortening and mechanical work centers on adenosine triphosphate (ATP) hydrolysis by myosin ATPase. Hydrolysis of ATP to adenosine diphosphate (ADP) with the release of inorganic phosphate (P_i) produces a strong attachment between actin and myosin and a conformational change in the bilobed myosin head that causes the head to flex and the actin filaments to move centrally, resulting in sarcomere shortening and/or tension (Fig. 4.12). Increases in intracellular calcium facilitate this chemical process by increasing myosin ATPase activity. Therefore, by combining with troponin C and increasing intracellular myosin ATPase activity, calcium serves as the principal factor in determining the rate at which crossbridges attach and detach. The rate of crossbridge interaction is the basis for the force-velocity relationship in isolated tissue experiments studying cardiac muscle contractile activity (Fig. 4.13). The rate of crossbridge attachment determines the velocity of sarcomere shortening and has been termed *cardiac contractility*. Furthermore, by increasing the number of interacting crossbridges, intracellular calcium increases the maximum force attainable. Clinically, the rate of pressure change (dp/dt) and the rate of force development

Fig. 4.12. A cardiac muscle fiber contains an overlapping array of thin (actin) and thick (myosin) contractile proteins that produces various bands (A, H, I, and Z) within each sarcomere when viewed microscopically. Note that both the transverse tubule (T tubule) and longitudinal tubule systems facilitate the presence of relatively large amounts of extracellular calcium (10^{-3} M) in the vicinity of the contractile proteins (**top**). Membrane depolarization initiates calcium entry into the cardiac cell, contractile protein interaction, and sarcomere shortening (**left**). More specifically, the binding of calcium with troponin C (Tn-C) removes the inhibitory function of troponin I (Tn-I) on actin-myosin interaction. Troponin t (Tn-t) links the troponin complex to tropomyosin (**right**).

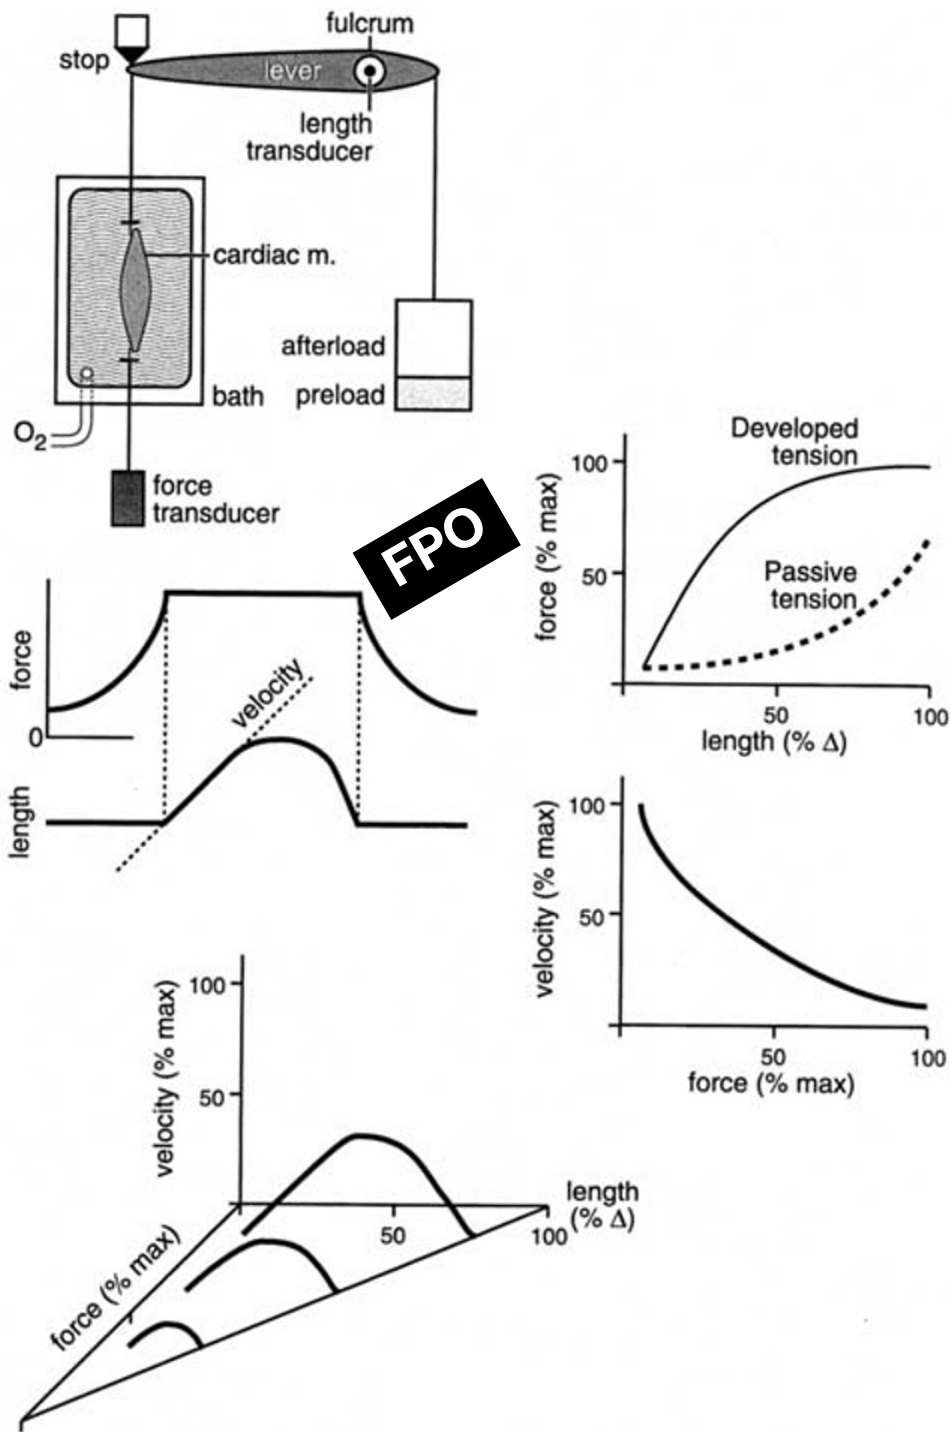

Fig. 4.13. The relationship between force development, velocity of muscle fiber shortening, and muscle length in an isolated cardiac muscle experiment. Within physiological limits, force and velocity increase as muscle length increases (Frank-Starling effect), and velocity decreases as developed force increases. Isolated muscle experiments are used to determine the direct effects of drugs upon cardiac mechanics without neurohumoral influences. Although preload is frequently equated to ventricular filling pressure and afterload is clinically thought of in terms of arterial blood pressure, the transfer of experimental data obtained from isolated muscle experiments to intact animals must be done knowledgeably and cautiously.

(dF/dt) in intact animals have been used as indirect, albeit crude, measures of cardiac contractility.^{36,37}

Optimal sarcomere length for actin-myosin interaction is approximately 2.2 microns. Lengths shorter or greater than this were once thought to decrease the force of cardiac contraction by theoretically decreasing the number of available myosin heads for interaction with actin.³⁶ The concept of optimal sarcomere length relative to the velocity of sarcomere shortening serves as the explanation for the *Frank-Starling law of the heart*, which

predicts an increase in contractile force when sarcomeres are stretched (increased ventricular volume) to their optimal length (Fig. 4.13). It is unlikely, however, that this explanation is totally correct, since sarcomeres rarely change in length (or only minimally so) when loaded, even during dilated forms of heart failure.³⁵ The more accepted and probable explanation for Starling's law of the heart is that sarcomere loading increases troponin-C affinity for calcium, leading to increased activation of the myofilament and sarcomere shortening without increases in sarcomere

length or additional increases in intracellular calcium.³⁷ Many intravenous anesthetic drugs (e.g., barbiturates, ketamine, and propofol), and in particular the inhalation anesthetics, are known to decrease cardiac contractility by decreasing calcium influx through L-type channels, decreasing calcium release from the sarcoplasmic reticulum and decreasing troponin-C sensitivity to calcium.^{38–46} This has led to the relatively routine use of positive inotropes (e.g., dopamine and dobutamine) to support cardiac contractile force and vascular tone in high-risk patients in order to increase cardiac output and arterial blood pressure.

Relaxation

Decreased interaction between actin and myosin filaments signals the beginning of the actin-myosin uncoupling process and myocardial relaxation, and is directly related to a decrease in intracellular calcium-ion concentration. Three principal mechanisms are important in reducing intracellular calcium-ion concentration and the subsequent decrease in cardiac contractile force. The depolarization-triggered increases in intracellular calcium increase the activity of the calcium regulatory protein calmodulin. Calmodulin serves as an intracellular calcium sensor and, when activated (calmodulin-calcium complex), stimulates the active extrusion of calcium by pumps in the sarcolemma, increases the activity of a phospholamban-modulated calcium pump (increasing calcium uptake by the sarcoplasmic reticulum), and enhances the activity of the sodium-calcium exchanger.³⁷ Notably, halothane (and other inhalants), ischemia, catecholamines, and acidosis interfere with the reuptake of calcium by the sarcoplasmic reticulum, thereby interfering with the relaxation process and ultimately leading to intracellular calcium depletion.^{43,44} The calmodulin-calcium complex also inhibits the release of calcium from the sarcoplasmic reticulum. Mitochondrial uptake of calcium ion only minimally buffers increases in intracellular calcium concentration (Fig. 4.11). From this series of events, it is clear that increases in intracellular calcium first enhance (through the calcium-induced calcium-release mechanism) and then decrease (through the formation of the calmodulin-calcium complex and related mechanisms) the concentration of intracellular calcium, leading to cyclic sarcomere shortening and lengthening and ultimately myocardial contraction (systole), relaxation, and rest (diastole) before the next electric event triggers the mechanical process to repeat itself (Fig. 4.11).

The Cardiac Cycle and Pressure-Volume Loop

Historically, the cardiac cycle has been used as a diagrammatic attempt to describe the electric (ECG), mechanical (pressure, volume, and flow), and acoustic (heart sound) events associated with cardiac contraction and relaxation as a function of time (Fig. 4.14A). Just as important (but not as descriptive) as the time-varying cardiac cycle is the time-independent representation of the cardiac cycle: the ventricular pressure-volume loop (Fig. 4.14B). The advantage of the pressure-volume loop compared to the cardiac cycle is its ability to be used to assess load-independent indices of ventricular systolic and diastolic performance, ventricular vascular interaction (coupling), and myocardial energetics. Changes in the pressure-volume loop can also be used

to illustrate and quantitate the determinants of changes in cardiac function: preload, afterload, and cardiac contractility.^{5,7,15,36} The various qualitative components of the cardiac cycle and pressure-volume loop are essentially identical for both the right and left ventricles, although the sequence of electric activation and the pressure changes is different.

Because electric activity precedes mechanical activity, the P wave of the surface ECG is a reasonable starting point to begin a description of the cardiac cycle (Fig. 4.14A). Electric activation of the atria produces the P wave of the ECG and causes almost simultaneous contraction of the atria. Atrial contraction increases intra-atrial pressure, producing the “a” wave of the atrial pressure curve. The atria (both right and left) normally function as blood reservoirs and conduits for blood transfer and, upon contraction, prime the ventricles by contributing approximately 10% to 30% (more at faster heart rates) of the blood volume that fills the ventricles. The atrial contribution to ventricular filling is frequently referred to as the *atrial kick*. The atrial kick brings the atrioventricular valves into relatively close apposition prior to ventricular contraction and is responsible for the fourth heart sound (S_4). Ventricular contraction is signaled by the R wave of the ECG and begins after a variable delay (PR interval) during which the electric impulse traverses the atrioventricular node and Purkinje network. Once the ventricular pressure increases to a value greater than that in the atrium, the atrioventricular valves close, actually bulging into their respective atria and giving rise to the “c” wave of the atrial pressure curve. The atrioventricular valves are prevented from completely prolapsing into the atrial chambers by chordae tendineae. The sudden development of tension in the contracting myocardium and tensing of the chordae tendineae coincident with atrioventricular valve closure are responsible for the first heart sound (S_1). The rapid increase in ventricular pressure while both the atrioventricular (mitral and tricuspid) and semilunar (aortic and pulmonic) valves are closed is termed *isovolumic contraction* because the volume of the ventricle remains constant (Fig. 4.14A and B). Once ventricular pressure exceeds that in the aorta or pulmonary artery, the semilunar valves open and ejection begins (Fig. 4.14A). The ejection phase of the cardiac cycle is characterized by a slowing of the increase in ventricular pressure after the semilunar valves open and an abrupt decrease in ventricular volume. These changes coincide with a large increase in aortic flow velocity and a decrease in the venous pressure curve as the atrioventricular valves are drawn toward the apex of the heart. Ventricular pressure exceeds aortic pressure during the first one-third of ventricular ejection (rapid ejection period), reaches equilibrium with aortic pressure, and thereafter, because of the onset of ventricular relaxation, declines more rapidly than aortic pressure. Blood continues to be ejected from the ventricle until the semilunar valves close. Closure of the semilunar valves marks the end of ventricular systole (by most definitions) and is associated with the development of the second heart sound (S_2). The second heart sound is composed of both aortic (A_2) and pulmonic (P_2) components and is frequently split (10 to 15 ms) during slow heart rates and in larger species (horses and cattle).⁴⁷ Rarely is the volume of blood ejected (stroke volume [SV]) by the normal

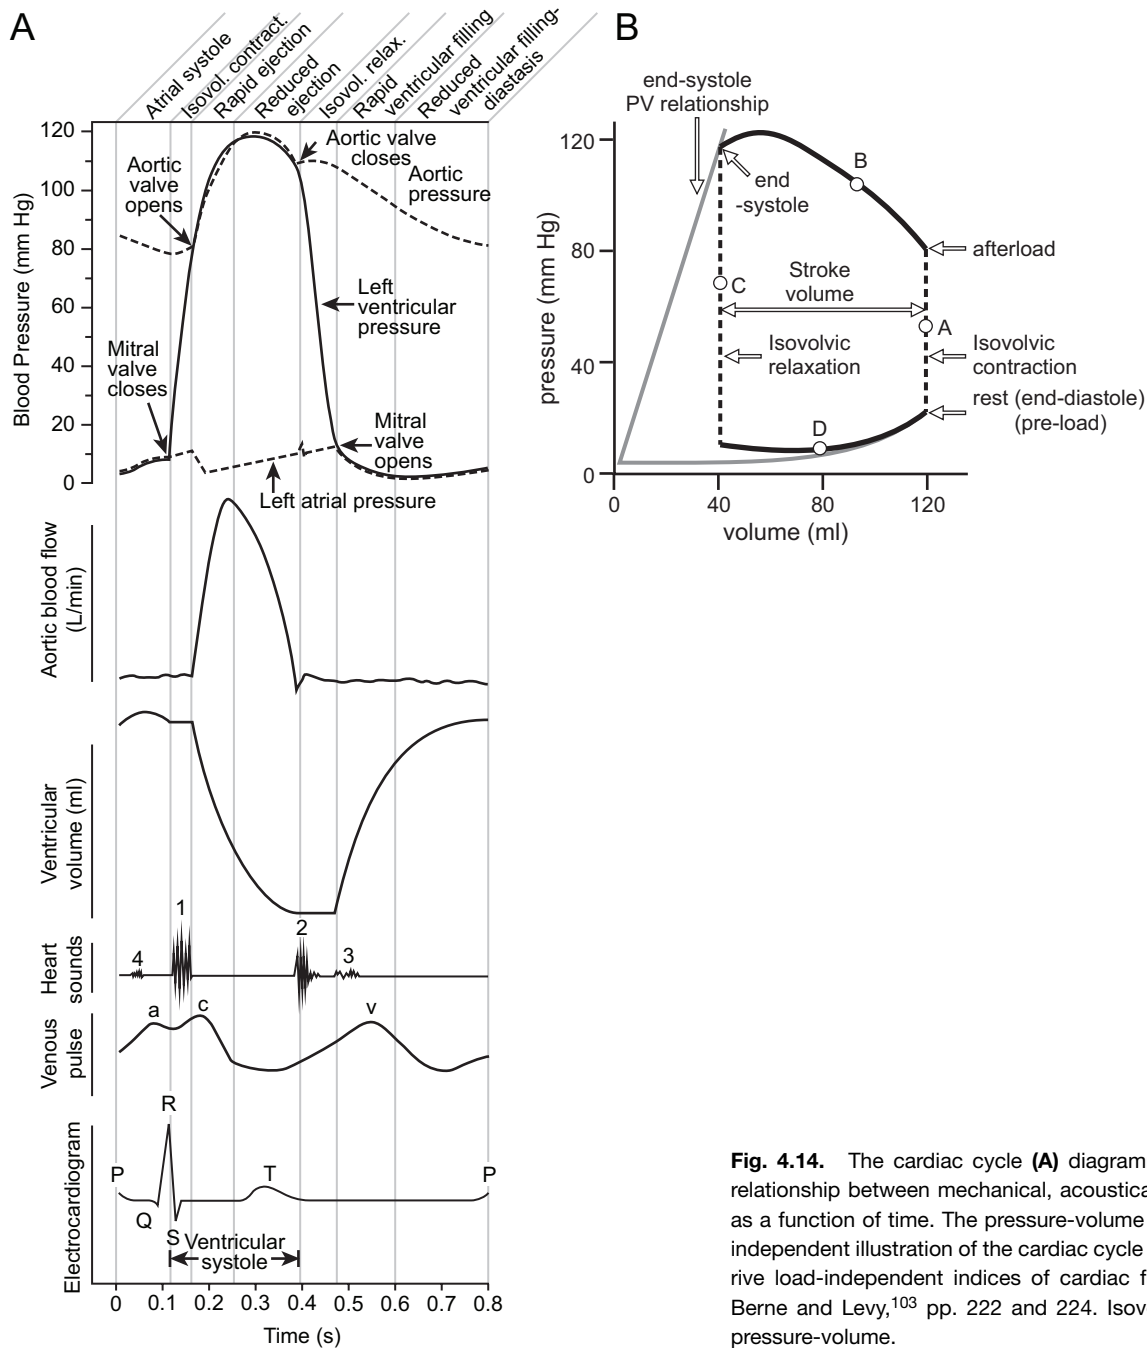

Fig. 4.14. The cardiac cycle (**A**) diagrammatically illustrates the relationship between mechanical, acoustical, and electrical events as a function of time. The pressure-volume (PV) loop (**B**) is a time-independent illustration of the cardiac cycle that can be used to derive load-independent indices of cardiac function. Modified from Berne and Levy,¹⁰³ pp. 222 and 224. Isovolumic, isovolumic; and PV, pressure-volume.

ventricle greater than 55% to 60% (ejection fraction [EF]) of its total volume.

The period between closure of the semilunar valves and opening of the atrioventricular valves is termed *isovolumic relaxation* and marks the beginning of ventricular relaxation (Fig. 4.14A and B). Isovolumic relaxation is characterized by a rapid decrease in ventricular pressure and no change in ventricular volume, and coincides with the V wave of the atrial pressure curve (Fig. 4.14A). Once ventricular pressure falls below atrial pressure, the atrioventricular valves open, initiating the phase of rapid ventricular filling (possibly facilitated by ventricular suction) and

producing the third heart sound (S_3). The third heart sound is believed to be caused by vibrations when the ventricular walls reach their elastic limit during ventricular filling, and gives rise to the characteristic ventricular gallop in dogs and cats with dilated forms of cardiac disease and increases in left atrial pressure.⁴⁸ Ventricular filling proceeds more gradually after the initial rapid filling phase, whereas ventricular pressure and volume increase nonlinearly during late diastole (Fig. 4.14B). The slope of the pressure-volume curve (dP/dV) during ventricular filling is an index of ventricular stiffness, and its inverse (dV/dP) is used to

assess ventricular compliance.⁴⁹ The slow middiastolic ventricular-filling phase continues as blood returns to the atria from the systemic and pulmonary circulations until the cardiac cycle is reinitiated by the next electric impulse.⁵⁰

Determinants of Performance and Output

The cardiac cycle and pressure-volume loop provide a picture of the temporal hemodynamic events that occur during cardiac contraction and relaxation. Clinically, M-mode echocardiography and color-flow Doppler echocardiography are used to assess ventricular function. These techniques provide a dynamic temporal representation of cardiac function and, when coupled with hemodynamic computer software analysis systems, a pictorial and quantitative assessment of cardiac performance (Fig. 4.15A to C). The oxygen requirements of tissues are met by the continuous adjustment of cardiac output (CO), which is the product of heart rate (HR) and stroke volume (SV):

$$\text{CO} = \text{HR} \times \text{SV}$$

Decreases in ventricular filling time and vascular autoregulatory effects limit cardiac output at faster heart rates.⁷ Normal left ventricular ejection velocity is between 1.0 and 1.5 m/s. Many injectable anesthetics (barbiturates and propofol) and inhalant anesthetics (halothane, isoflurane, and sevoflurane) decrease ejection velocity and cardiac output. Stroke volume is the amount of blood ejected from the ventricle during contraction and therefore represents the difference between the end-diastolic and end-systolic ventricular volumes ($\text{SV} = \text{EDV} - \text{ESV}$ [Fig. 4.14B]). Traditionally, stroke volume has been considered to be primarily determined by one intrinsic property, cardiac contractility, and two vascular coupling factors, preload and afterload.¹⁵ The refinement and development of more descriptive methods for the assessment of cardiac function, however, have led to the consideration of relaxation (lusitropic) effects on stroke volume.^{50,51} Lusitropic (compliance = $1/\text{stiffness}$) properties are those that are responsible for ventricular chamber stiffness (dP/dV) or its inverse, compliance (dV/dP). Finally, ventricular wall motion abnormalities caused by ischemia, cardiac arrhythmias, myocardial inflammation, and space-occupying lesions (tumors or pericardial effusion) may influence stroke volume. It should be remembered that changes in preload, afterload, or myocardial contractile (inotropic) and relaxant (lusitropic) properties can influence one another and therefore influence stroke volume. These factors in turn are all influenced by heart rate, leading to a complex interplay of variables that collectively determine cardiac output (Fig. 4.16).^{5,7,8}

The terms *preload* and *afterload*, described earlier in this section as two determinants of cardiac output, originated from isolated muscle experiments in which preload represented the original load, length, or stretch placed on the muscle prior to its stimulation and contraction, and afterload represented the force or tension developed before the ventricle ejects. Isolated cardiac muscle studies continue to be essential for understanding and describing cardiac muscle physiology, metabolism, and muscle responses to various perturbations (hypoxia, ischemia, and drugs), and are usually presented as three-dimensional plots of force, ve-

locity, and length (Fig. 4.13). Cardiac function in intact animals is unlike isolated cardiac muscle, however, because ventricular performance is determined by intrinsic and vascular coupling factors and modulated by neurohumoral influences, the autonomic nervous system, pericardial and intrathoracic constraints, ventricular-vascular interaction, and atrial contraction.^{13,52,53} Regardless, the terms *preload* and *afterload* remain popular jargon when describing ventricular performance in intact animals.

Preload

Preload in intact animals is usually explained in terms of the Frank-Starling relationship or as heterometric autoregulation: increases in myocardial fiber length (ventricular volume) (Figs. 4.16 and 4.17) increase the force of cardiac contraction and cardiac output.^{8,15} Whether or not individual sarcomeres actually increase in length (stretch) with increases in ventricular volume is controversial (see the Contraction and Relaxation section); more likely, the myofilaments develop an increased sensitivity to calcium, resulting in an increase in contractile force.³⁵ Regardless of individual sarcomere length changes, the Frank-Starling relationship serves as an important compensatory mechanism for maintaining stroke volume when ventricular contractility and afterload are acutely changed. Because of the difficulty in accurately determining ventricular volume in the clinical setting, ventricular diameter, ventricular end-diastolic pressure, pulmonary capillary wedge pressure, and occasionally mean atrial pressure are used as estimates of preload.⁵⁰ The substitution of pressure for volume, although common, must be done with the understanding that there are many instances (open-chest procedures and stiff or noncompliant hearts) when pressure does not accurately represent changes in ventricular volume and therefore is not an accurate index of preload.

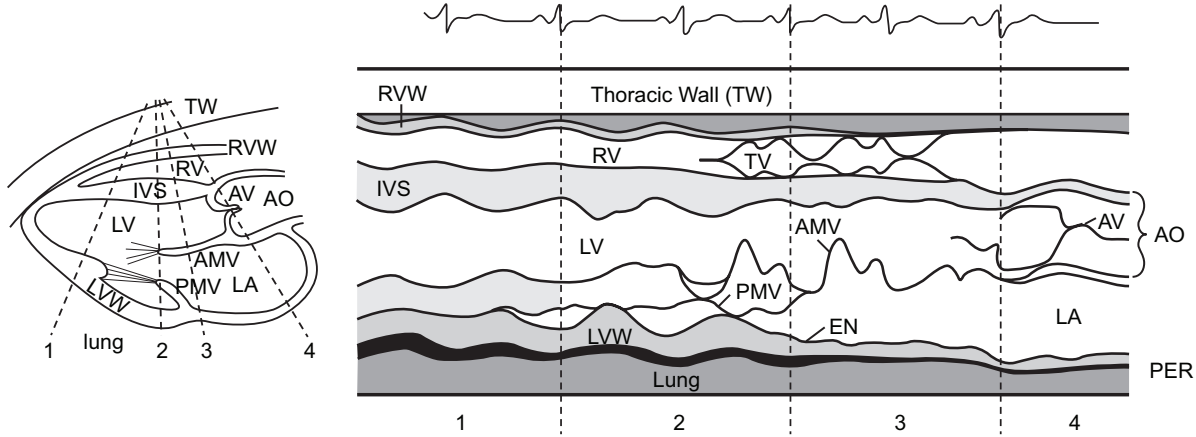

Afterload

The term *afterload* is used throughout the basic and clinical cardiology literature to describe the force opposing ventricular ejection.^{7,15} One major reason for the great interest in this physiological determinant of cardiac function is its inverse relationship with stroke volume and its direct correlation with myocardial oxygen consumption (Fig. 4.16).^{15,54} Although conceptually straightforward, clinical descriptions and use of the term *afterload* have suffered from an incomplete understanding of what the term actually represents. Afterload in isolated tissues is the force generated *after* the preload in order for the muscle to shorten. The total load in isolated muscle experiments is therefore represented by the preload plus the afterload. In contrast to isolated muscle, afterload in intact animals changes continuously throughout ventricular ejection and is more accurately described by the tension (stress) developed in the left ventricular wall during ejection or as the arterial input impedance (Z_i).⁵⁵ Ventricular wall stress or tension has traditionally been estimated from the Laplace relationship:

$$\text{tension } (T) = Pr/2h$$

It is noteworthy that using this assessment of ventricular afterload assumes a spherical ventricular geometry. A much more ac-

curate, yet technically more difficult, method for assessing after-load in intact animals is to measure ventricular-vascular coupling.⁵⁵ Arterial input impedance is an expression of the arterial system's response to pulsatile blood flow and is a function of arterial pressure, arterial wall elasticity, vessel dimensions down to

the point where pulsations are attenuated, and blood viscosity (see the section on Hemorrhology: Impedance). As such, arterial input impedance incorporates time-varying resistance components (pressure and flow) and reactance components (intrinsic vessel wall characteristics). The measurement of arterial input

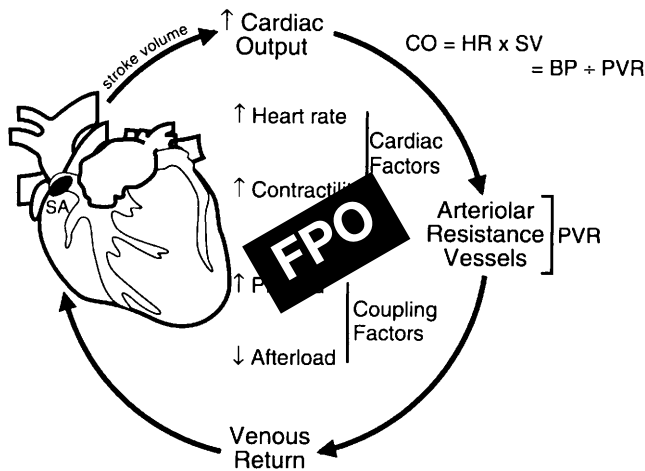

Fig. 4.16. Cardiac output is equal to heart rate (HR) times stroke volume (SV), or arterial blood pressure (BP) divided by peripheral vascular resistance (PVR). Increases in heart rate, cardiac contractility, and preload, and decreases in afterload can all increase cardiac output. Preload and afterload are considered to be coupling factors because they depend on vascular resistance, capacitance, and compliance.

impedance requires the simultaneous and instantaneous measurement of aortic root pressure and flow.^{10,55} Both waveforms are subjected to a Fourier transformation from which a series of sine waves and frequencies are derived. The amplitude ratios of the pressure-flow components at each frequency are calculated and plotted versus frequency as impedance moduli. Any phase shift between pressure and flow (pressure leading flow or vice versa) occurring during the ejection phase is also plotted at each frequency (Fig. 4.6). From this relationship, the characteristic impedance (Z_0) can be determined by averaging the impedance moduli at high frequencies. The characteristic impedance is the pressure-flow relationship when pressure and flow waves are not influenced by wave reflection (it approximates input impedance during maximal vasodilation). Characteristic impedance is approximately 5% of the total arterial resistance and is generally an exquisitely sensitive indicator of vessel wall elasticity or compliance. The impedance modulus at zero frequency (nonpulsatile flow) is equivalent to vascular resistance (R) and is usually described as total peripheral resistance (TPR) or systemic vascular resistance (SVR). The SVR can be calculated (with appropriate values) by

$$SVR = 80 \times \frac{(MAP - CVP)}{CO}$$

where MAP is mean arterial pressure, CVP is central venous pressure, CO is cardiac output, and 80 is a conversion factor used to change measurements in L/min and mm Hg to $\text{dynes} \cdot \text{s} \cdot \text{cm}^{-5}$. Although much less accurate than the determination of impedance moduli, particularly when assessing the effects of progressive cardiac disease or drugs that change both cardiac and vascular properties simultaneously, the measurement of SVR is

Fig. 4.17. Cardiac output increases as preload increases (Frank-Starling effect). The steepness of the Frank-Starling curve is also affected by changes in cardiac contractility and afterload.

used clinically as a measure of afterload and vascular tone because it is technically simple to obtain and intuitively easier to understand.

Inotropy

Cardiac contractility (inotropy) is the intrinsic ability of the heart to generate force and, as such, relates directly to physicochemical processes and the availability of intracellular calcium (see the section on Excitation-Contraction Coupling).^{35,36} The term *homeometric autoregulation* is frequently applied to those factors other than muscle fiber length that influence the force of cardiac contraction.⁷ Contractility is generally described in isolated muscle preparations by shifts of the force, velocity-length relationship (Fig. 4.13), or in intact animals by shifts in the ventricular function curve (e.g., shifts in the Frank-Starling relationship [Fig. 4.17]). A decrease in cardiac contractility is a key factor in heart failure in patients with cardiac disease or following the administration of potent negative inotropic drugs (e.g., anesthetics).^{43,44,56–59}

Ideal indices of cardiac contractility should be independent of changes in heart rate, preload, afterload, and cardiac size—in other words, be load independent. Many indices of contractility have evolved in an attempt to develop a truly load-independent measure of cardiac contractile activity. These indices vary considerably in their load dependency, sensitivity, and specificity as measures of cardiac contractility, and generally fall into one of four broad categories: (1) isovolumic contraction phase indices, (2) ejection phase indices, (3) pressure-volume relationship indices, and (4) stress-strain relationship indices (Table 4.3).^{49,59,60} Although many approaches for assessing cardiac contractility are

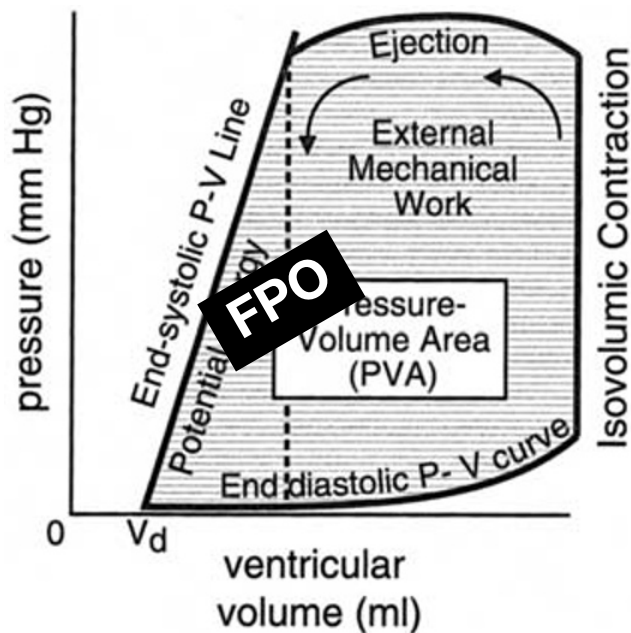

Fig. 4.18. The ventricular pressure-volume (P-V) loop and the end-systolic P-V line can be used to determine the pressure-volume area (PVA). The area within the pressure-volume loop (within the dotted lines) represents the external work done by the heart and is proportional to myocardial oxygen consumption. The triangular area between the end-systolic P-V line and isovolumic relaxation represents the end-systolic potential energy and is proportional to the oxygen consumed for basal metabolism.

useful experimentally and clinically, only the isovolumic phase indices (because of their ease of measurement), the pressure-volume relationship indices (because of their load independence), and the ejection phase index (preload recruitable stroke work) have gained acceptance.⁵⁹ Additionally, the measurement of the pressure-volume relationship can be used to assess myocardial energetics.^{15,49} This is because the amount of oxygen consumed by the heart for mechanical work is proportional to the area within the pressure-volume loop, while the oxygen consumed for basal metabolism is proportional to the area enclosed by the end-systolic pressure-volume relationship, the diastolic pressure-volume curve, and the isovolumic relaxation phase of the pressure-volume loop (Fig. 4.18).

Lusitropy

A description of the relaxation phases following cardiac contraction is often omitted from textbooks of cardiovascular physiology, but is fundamentally important to an understanding of cardiac performance.⁵⁰ Two reasons for the lack of attention are the inability to agree on a definition of when diastole begins and disagreement over acceptable indices for the assessment of the various phases of diastole. The most popular and clinically relevant definition of diastole states that relaxation begins with the closure of the aortic valve, which is heralded by the second heart sound (S_2 [Fig. 4.14A]).^{50,51} Diastole is thereafter divided into four phases: (1) isovolumic relaxation, (2) early rapid ventricular

are of special interest because of their importance in determining ventricular compliance or stiffness. A partial list of methods used to quantitatively describe relaxation includes pressure, volume-derived, and interval indices (Table 4.3). All of these indices provide useful information, but must be carefully applied in order to properly analyze the appropriate phase of relaxation. Indices of isovolumetric relaxation (rate of ventricular pressure decline $[-dp/dt]$ and the time constant for relaxation) are useful for measuring the active phase of relaxation and reflect the dissociation of actin-myosin linkages because of reuptake of cytoplasmic calcium by the sarcoplasmic reticulum (Fig. 4.11). These indices are particularly influenced by myocardial systolic function, ventricular loading conditions (preload and afterload), and heart rate. Indices of diastasis or slow ventricular filling (chamber stiffness, $-dp/dV$, and myocardial stiffness) are used to determine the passive properties of diastolic function and are principally influenced by viscoelastic properties, ventricular interaction, coronary blood flow, and pericardial restraint.

Regardless of the care in picking an index to evaluate cardiac systolic or diastolic performance, it is clear that even greater thought must be given to the factors (determinants of performance) that influence the index. Drugs used as preanesthetic medication or for intravenous or inhalation anesthesia can produce profound effects on indices of cardiac performance and are often much more complex in their actions than originally surmised (Table 4.4).^{50,56,61–63}

Ventricular-Vascular Coupling

The concept of ventricular-vascular coupling is not new, but is rarely discussed or adequately described by most textbooks.¹⁴ The principal reason for inadequate treatment is the historical

focus on pressure-derived measurements and the cardiac cycle, which stems from the relative ease with which pressure can be measured. Sphygmomanometry-based measurements and their derivations are undoubtedly important, but by themselves lead to an overly simplistic and often erroneous understanding of cardiovascular function. New technologies (M-mode and two-dimensional Doppler echocardiography) and theory have made it possible to expand our understanding of cardiac mechanical activity and begin to appreciate the relevance, dependence, and importance of both the venous and the arterial systems and their coupling to the heart (Fig. 4.15A to C).^{5,52} The clinical relevance of this understanding is increasingly apparent from the new and improved theories of cardiovascular disease (congenital or acquired), myocardial metabolic disturbances (ischemia and hypoxia), and the mechanisms of drug effects (anesthetics, etc.) on the cardiovascular system. Indeed, the clinical application of the principles of ventricular-vascular coupling has resulted in new and improved therapies for cardiovascular disease.^{13,16}

Ventricular-vascular coupling, as the name implies, concerns the interrelationship or coupling of the heart to the venous and arterial systems. Thus, loading conditions (preload and afterload) and vascular dynamics (resistive, reactance, and viscoelastic properties) ultimately influence ventricular performance and blood flow.^{14,49} Coronary blood flow and myocardial perfusion are also important components of ventricular-vascular coupling because normal function and the viability of the heart depend on adequate myocardial perfusion, which occurs almost exclusively during diastole.

Vascular Function Curve

The modern concept of ventricular-vascular coupling has been popularized by Guyton, who used the vascular function curve,

and more precisely the venous-return curve and cardiac (ventricular) function curve, to predict changes in cardiac output (Fig. 4.19A).⁵ Guyton's ventricular-vascular coupling diagrams emphasize that the important independent variables in the determination of cardiac output are the sums of vascular resistances and capacitances and cardiac contractility. The venous-return curve describes an inverse relationship between venous return and cardiac output. The horizontal (abscissa) intercept of the venous-return curve or the venous pressure at zero cardiac output is the mean circulatory filling pressure, which is a function of venous capacitance and the total blood volume and has been directly correlated with survival from hemorrhagic and septic shock. Variations in the venous-return curve can be produced by altering venous resistance, capacitance, or blood volume (Fig. 4.19B). Equilibrium of the venous-return-ventricular function curve is reached when venous return at a given pressure is matched by the ability of the ventricle, when distended to the same pressure, to pump the venous return. Thus, an increase in venous pressure increases cardiac output during the next cardiac cycle, as defined by the ventricular function curve. Increases in cardiac output in turn transfer blood from the venous to the arterial circulation, thus decreasing venous pressure. This process continues in progressively decreasing steps until a new equilibrium for cardiac output and venous return is reached, realizing that only one equilibrium point for cardiac output and venous return exists. Similar rationalizations can be used for other perturbations: changes in blood volume, arterial resistance, and cardiac contractility.^{8,52} It can be argued that this type of presentation of hemodynamics and cardiovascular function results in circular reasoning, since a change in cardiac output can be used to explain the change in venous return and vice versa. Indeed, since both venous return and cardiac output are equal to the flow around the circuit, the point that a given cardiac output is obtained is determined by a myriad of venous-return and ventricular function curves and their determinants (venous and arterial capacitance and resistance, blood volume, and cardiac contractility).^{5,7,8}

Ventricular-Arterial Coupling

More recent evaluations of ventricular-vascular coupling have focused on the left ventricular pressure-volume relationship and the ejection of blood into the ascending aorta (ventricular-arterial coupling) (Fig. 4.20A).¹³ This approach, first popularized and validated by Suga and Sunagawa in isolated and intact dog hearts, has been applied clinically using noninvasive (echocardiographic) techniques.^{15,49,53,64} The power of this approach stems from its clinical applicability and the ability to derive a multitude of important indices for assessing cardiovascular function in intact animals.⁴⁹

The inscription of the instantaneous pressure-volume loop enables the calculation of load-dependent and independent indices of cardiac contractility, myocardial oxygen requirements, and myocardial efficiency.¹⁵ For example, the ratio of ventricular pressure to ventricular volume (dP/dV) varies throughout the cardiac cycle (time-varying elastance) and inscription of the pressure-volume loop. Acute reductions in preload are used to produce progressively smaller pressure-volume loops and construct

a straight line by connecting all of the end-systolic points. This line is known as the *end-systolic pressure-volume relationship*, the slope of which is the end-systolic ventricular elastance (E_{es}), a load-independent index directly proportional to ventricular contractility (Figs. 4.18 and 4.20A). The mechanical work (stroke work [SW]) performed by the heart is proportional to the pressure-volume area (PVA), which is linearly related to myocardial oxygen consumption (MVO_2), and which, when plotted against the end-diastolic volume, derives another sensitive and load-independent index of cardiac contractility termed *preload recruitable stroke work* (PRSW). Mechanical efficiency (ME) of the heart is the ratio of SW to MVO_2 and is derived by dividing SW by PVA ($ME = SW/PVA$).

The ejection of blood into the ascending aorta is governed by the same resistive and reactive (viscoelastic) properties that govern venous return. These arterial loading properties (afterload) influence stroke volume.⁵⁵ The difference between the end-diastolic and end-systolic volumes of the pressure-volume relationship is stroke volume, which, when plotted versus end-systolic pressure (P_{es}) during decreases in stroke volume, renders a line, the slope of which is the effective arterial elastance (E_a). In practice, E_a is generally approximated by the ratio of P_{es} to stroke volume ($P_{es}/SV = E_a$). This parameter is particularly powerful because it incorporates the principal elements of vascular load (afterload), including peripheral resistance, total vascular compliance, characteristic impedance (see the section on Determinants of Cardiac Performance and Cardiac Output), and alterations induced by heart-rate changes. It is noteworthy that the purely resistive components of vascular load are adequately accounted for by determining the steady-state or nonpulsatile parameter, total peripheral resistance, which accounts for approximately 90% of vascular load under normal conditions. The pulsatile or dynamic component of vascular load generally accounts for approximately 10% of vascular load under normal conditions, adds to the resistive component, and becomes increasingly important during cardiovascular disease, changes in blood volume, or following the administration of drugs (e.g., anesthetics) that affect the cardiovascular system.^{49,57,58,60} Other methods for accurately analyzing arterial afterload have been described (see the section Determinants of Cardiac Performance and Cardiac Output).

Because both E_{es} and E_a have the measurement of P_{es} and ventricular volume in common, they can be plotted on a single graph to yield the "ideal" ventricular-arterial coupling point for any set of cardiovascular circumstances (Fig. 4.20B). Stated another way, if end-diastolic volume (preload), E_a , and E_{es} are known, stroke volume and therefore cardiac output ($CO = SV \times HR$) can be predicted. Furthermore, this analysis predicts that SW should be maximized when this relationship is equal to 1 ($E_{es} = E_a$) and that maximal mechanical efficiency (ME) is attained (when $E_a = E_{es}/2$, since $ME = SW/PVA = 1/(1 + E_a/E_{es}/2)$).

The ideal ventricular-arterial coupling point in intact animals occurs when mean arterial pressure is adequate for organ flow (approximately 60 to 70 mm Hg) and, as stated earlier, systolic pressure is low while diastolic pressure is high (small pressure pulse). Low systolic pressure facilitates maximal ventricular

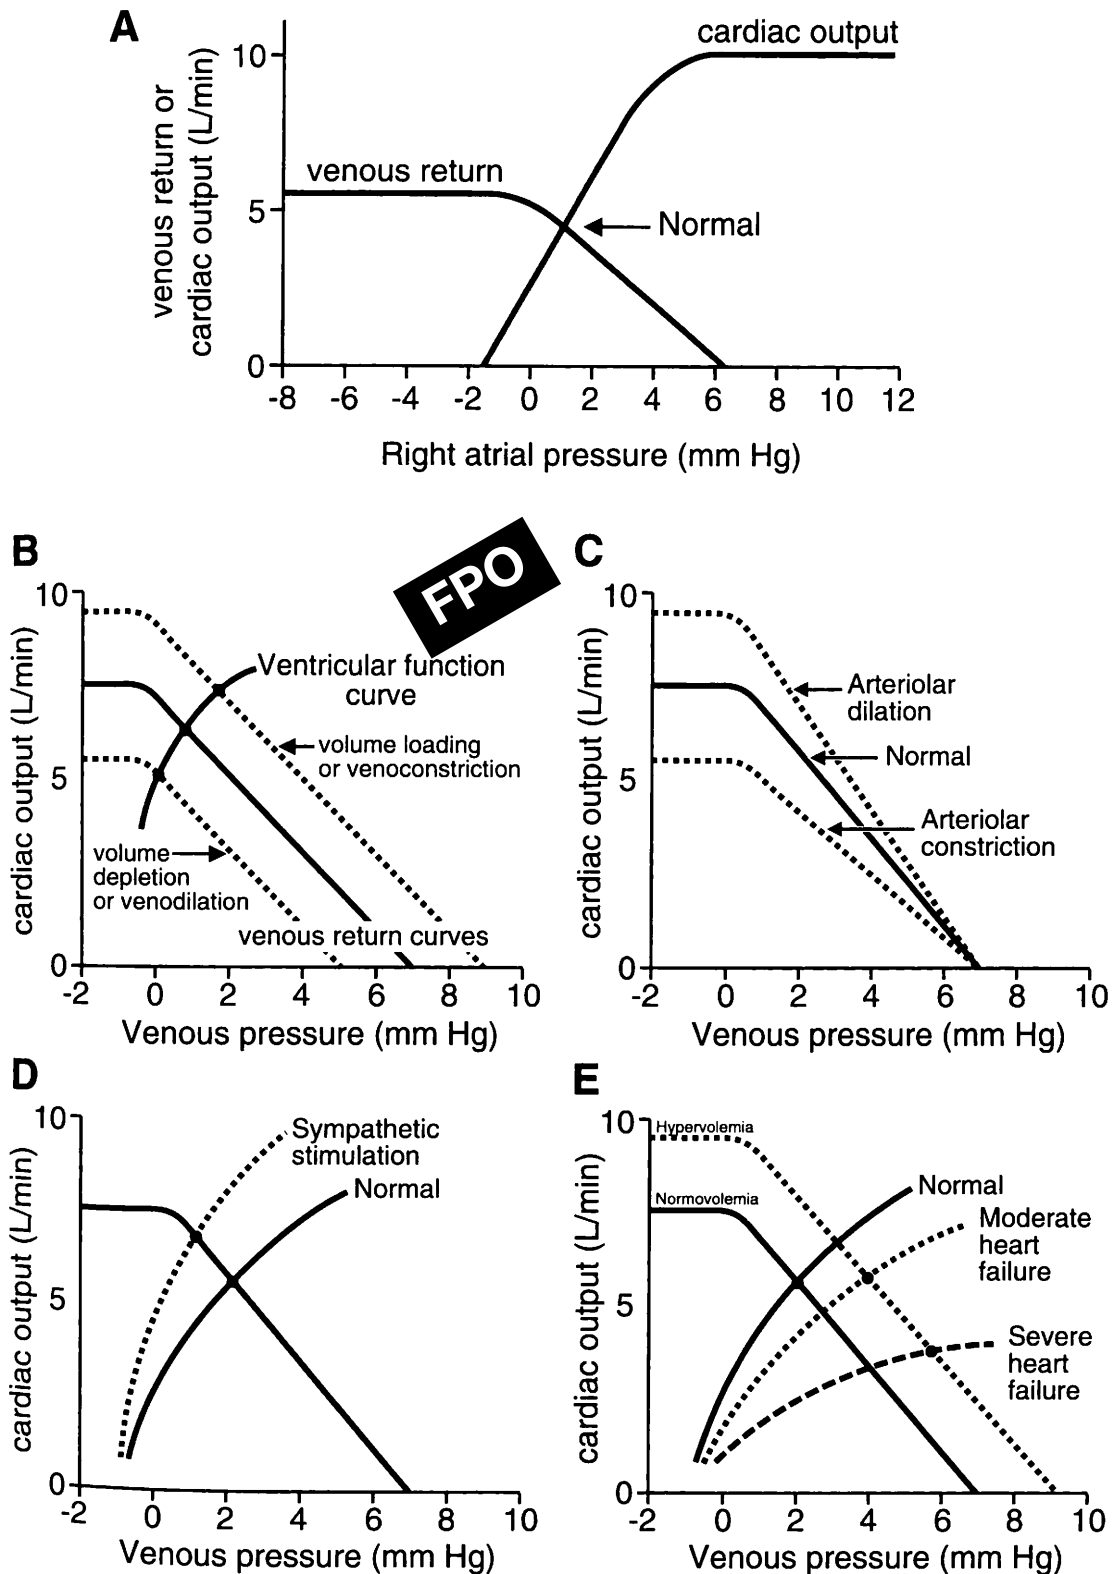

Fig. 4.19. Ventricular-vascular coupling curves. Venous return and cardiac output are determined by the opposing effects of right atrial pressure (**A**). For example, increases in right atrial pressure increase cardiac output, but decrease venous return. Alterations in blood volume (**B**), sympathetic tone (**C**), vascular tone (**D**), and cardiac function (**E**) produce predictable effects upon the coupling of venous return to cardiac output at a given venous pressure. Note that, during heart failure (**E**), cardiac output is preserved at the expense of increases in venous pressure. Modified from Berne and Levy.¹⁰³

Fig. 4.20. Ventricular-arterial coupling. The coupling of the ventricle with the arterial system (**A**) produces an equilibrium point (**A**, bottom) at which the ventricle functions. The shaded area in **B** represents the maximal stroke work during optimal coupling when the slopes of the arterial and ventricular relationships are the same. E_a , effective arterial elastance; EDV, end-diastolic volume; E_{es} , end-systolic elastance; LVV, left ventricular volume; P_{es} , end-systolic pressure; SV, stroke volume; and T, time. Modified from Sunagawa et al.¹⁰⁴

ejection and low oxygen demands by the myocardium, whereas high diastolic pressure ensures adequate coronary perfusion. Ideal ventricular arterial interaction is impaired by anything that decreases cardiac contractility (decreased E_{es}) or increases arterial stiffness (increased E_a). Increases in arterial stiffness increase pulse amplitude, increasing systolic pressure and thereby decreasing stroke volume for a given cardiac contractility while increasing MVO_2 . Diastolic pressure usually falls, thereby reducing coronary blood flow and myocardial perfusion. Furthermore, alterations in the timing of pulse-wave reflection, principally initiated by increases in arteriolar tone, could augment systolic pressure and reduce diastolic pressure, exacerbating the situation.^{10,55,65}

Cardiac Metabolism

The maintenance of normal cardiac activity depends on the metabolic pathways by which ATP is generated. Even a superficial description of these pathways is far beyond the scope and purpose of this chapter and is more appropriately described in texts specifically designed to discuss this subject.⁵⁴ Suffice it to say

that the heart generates ATP by two primary methods: glycolysis and oxidative phosphorylation. These processes are continually modified by the energy requirements of the cell and by neural and hormonal inputs. The ATP produced supplies energy for cardiac contraction, relaxation, and related activities (Fig. 4.21).

The Vascular System

The purpose of the vascular system (arteries, capillaries, and veins) is to transport and facilitate the exchange of a wide range of nutrients and waste products. Originating from the heart, the circulatory system consists of two separate circulations connected in series (Fig. 4.1). The pulmonary circulation receives the majority of its blood supply from the right ventricle, perfuses the lung, and empties into the left atrium. The systemic circulation receives its blood supply from the left ventricle, perfuses most of the body's organs and tissues, and empties into the right atrium. More specifically, the systemic circulation (like the pulmonary) undergoes repeated division into smaller and smaller parallel vascular beds that terminate in the arterioles (the smallest arteries), which further subdivide to form the capillary bed.⁷

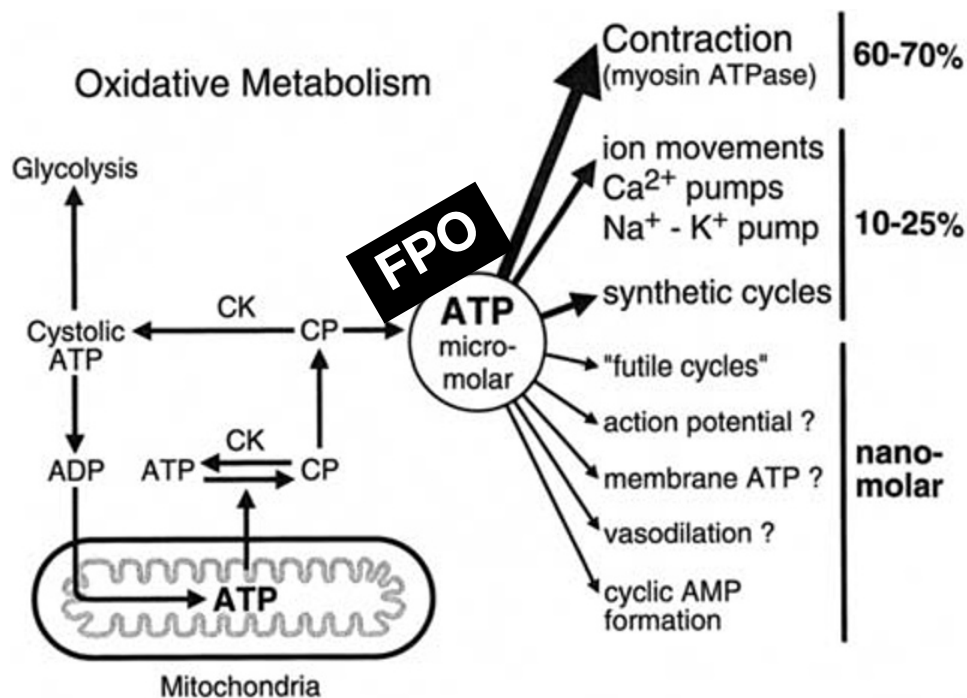

Fig. 4.21. Oxidative metabolism produces adenosine triphosphate (ATP), which supplies energy for cardiac contraction and other cellular activities. Note that over 60% of the ATP generated by oxidative metabolism is used for contraction. ADP, adenosine diphosphate; AMP, adenosine monophosphate; CK, creatine kinase; and CP, creatine phosphokinase.

During repeated division, the overall cross-sectional area of the circulation increases dramatically, reaching a maximum in the capillaries (Fig. 4.22).^{1,66}

Structurally, all blood vessels contain an endothelial layer (tunica intima) on their inner surface that provides a smooth surface and prevents clotting. All but capillaries also contain varying proportions of elastic fibers, smooth muscle, and collagen (Fig. 4.23). These three tissue types comprise the tunica media, which is composed mostly of smooth muscle and elastic connective tissue, and the tunica externa (adventitia), which contains fibrous collagen fibers. The proportion of elastic connective tissue to smooth muscle determines the vessel's principal function (i.e., conduit, resistive, or capacitive). The amount of smooth muscle also determines the vessel's resting tone, myogenic basal tone (spontaneous contractions), and the amount of stress relaxation (delayed capacitance), and reverse stress relaxation exhibited by the vessel. Stress relaxation is characterized as a rapid initial increase in resting tone caused by an increase in vascular volume that declines gradually during the next several minutes. Pressure decreases because of smooth muscle myofilament rearrangement. Reverse stress relaxation is the reverse of this process.

Smooth Muscle Contraction

Vascular smooth muscle is considerably different from cardiac muscle, both structurally and functionally.³⁷ Vascular smooth muscle cells are small, 5 to 10 μm in diameter, and spindle shaped. They do not contain regular sarcomeric units or Z bands, or possess the same key regulatory proteins (absence of troponin

C and troponin N) as cardiac cells. Functionally, depolarization is not essential for initiation of muscle contraction in vascular smooth muscle. The contraction process is slow and tonic, is prolonged, and intracellular increases in cyclic adenosine monophosphate (cAMP) cause vascular smooth muscle cells and vessels to dilate, not contract. One thing that is similar between cardiac and vascular smooth muscle cells is that they both depend on increases in intracellular calcium for contraction.

A multitude of pathways are available by which vascular smooth muscle cells can increase intracellular calcium-ion concentration and contract, including calcium influx through voltage (slow calcium channels) and receptor-operated ion channels, calcium release from the sarcoplasmic reticulum by calcium (calcium-induced calcium release) or some other activator (inositol triphosphate [IP_3]), and reversal of the sodium-calcium exchange mechanism. Regardless of the mechanism responsible, increases in intracellular calcium serve as the second messenger for smooth muscle actin-myosin interaction. Once intracellular calcium concentration increases beyond a critical threshold, calcium ions combine with the ubiquitous calcium-binding protein calmodulin, forming a calcium-calmodulin complex, which in turn binds to myosin light-chain kinase and activates ATP-dependent phosphorylation of myosin, causing actin-myosin interaction (Fig. 4.24). The formation of the actin-myosin cross-bridge in vascular smooth muscle (in contrast to cardiac muscle) produces a sustained tonic type of contraction. The slow-cycling or noncycling crossbridges formed in vascular smooth muscle are called *latchbridges*. Relaxation occurs when myosin light-

Fig. 4.22. The relationship between blood pressure, blood flow velocity, and cross-sectional area of the cardiovascular system. Note that, as blood approaches the capillaries, blood pressure and blood flow velocity decrease and cross-sectional area increases. *v*, average velocity. Modified from Witzleb,⁶⁸ p. 408.

chain kinase is dephosphorylated by the enzyme myosin light-chain phosphatase. The regulation of myosin light-chain phosphatase is poorly understood, but is probably affected by many drugs used to produce chemical restraint and anesthesia.^{37,67} Other mechanisms that facilitate relaxation of vascular smooth muscle center around decreases in intracellular calcium concentration due to reuptake of calcium ion by the sarcoplasmic reticulum, exchange of intracellular calcium for extracellular sodium, stimulation of the calcium-ATPase calcium pump, and termination of calcium influx into the cell (Fig. 4.24). Increases in intracellular cAMP and cyclic guanosine monophosphate produce vasodilatory, not contractile, effects in vascular smooth muscle. Cyclic AMP inhibits myosin light-chain phosphorylation. The effects of cyclic guanosine monophosphate are incompletely un-

derstood, but it may produce an effect similar to cAMP or accelerate the ejection of calcium ions from vascular smooth muscle cells. Finally, vascular smooth muscle contraction can occur without an initial influx of extracellular calcium or the release of intracellular calcium.³⁷ α -Adrenoreceptor stimulation, for example, can act through a G protein to form diacylglycerol (DAG) and IP₃. IP₃ causes the release of calcium from the sarcoplasmic reticulum, initiating the contraction process. DAG can also activate a protein kinase, which may phosphorylate myosin light-chain kinase to initiate tonic contractions.

Vessel Types

From a purely functional standpoint, vessels can be categorized as primarily elastic Windkessel types or conduits (large arteries),

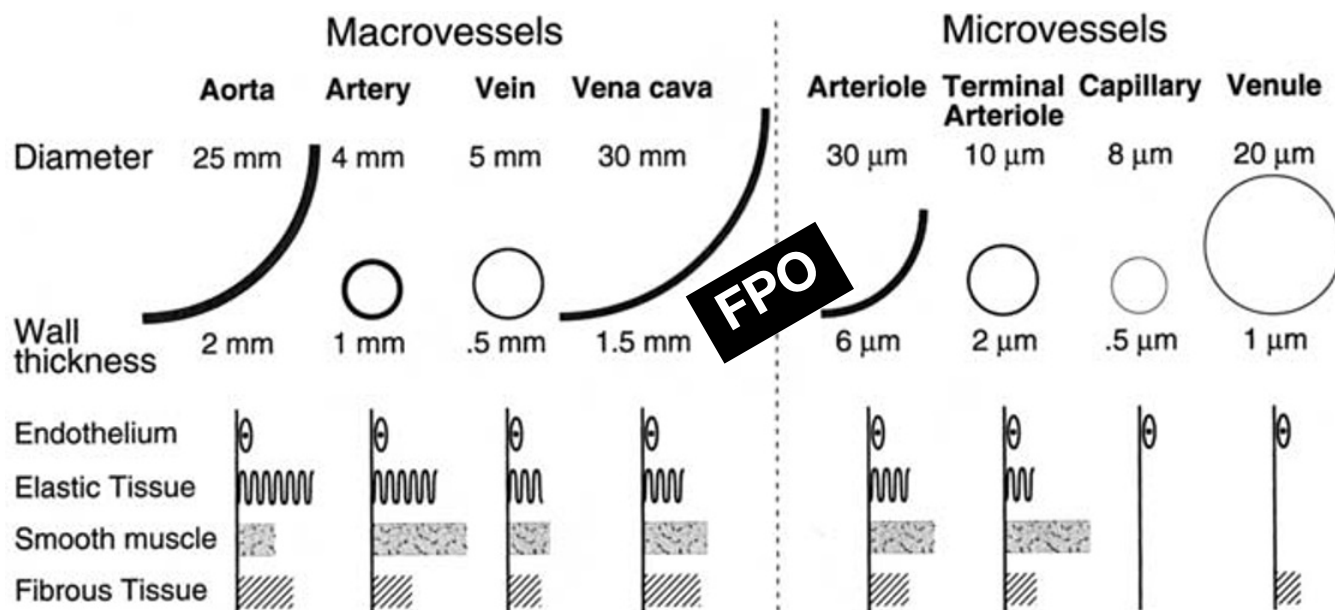

Fig. 4.23. The relative amounts of the various components (elastic, smooth muscle, and fibrous tissue) of macrovessels and microvessels are illustrated. Note the differences with changes in vessel diameter and between arteries and veins. Modified from Berne and Levy,¹⁰³ p. 195.

resistance vessels (small arteries), sphincter vessels (arterioles), exchange vessels (capillaries), capacitance vessels (venules and veins), and shunt vessels (arteriovenous anastomoses).^{1,68}

Large Arteries

Large arteries near the heart and throughout the extremities are highly elastic tubes that serve as conduits through which blood is transported to the periphery. The elasticity of large arteries opposes the stretching effect that the blood pressure produces following ventricular contraction. The initial stretching of the aorta produced by ventricular ejection, for example, is opposed by the elastic tissue in the vessel walls, which returns the aorta and large arteries to their original dimension (Fig. 4.23). As was previously mentioned, this squeezing phenomena of large arteries is termed the *Windkessel effect* and helps to convert the discontinuous (cyclic or phasic) flow of arterial blood associated with ventricular pumping into a continuous, although somewhat nonuniform, flow to the peripheral arteries. The degree to which the larger arteries can be stretched depends on the ratio of elastic to collagen fibers. Systemic arteries are in general six to ten times less distensible than systemic veins. The pulmonary artery, by contrast, is about half as distensible as systemic or pulmonary veins (Fig. 4.25).⁶⁹

Blood pressure in arteries (arterial pulse pressure and blood pressure), whether measured directly or indirectly, is frequently assessed during anesthesia. Arterial blood pressure measurement in particular is one of the fastest and most informative means of assessing cardiovascular function and, when done correctly and frequently, provides an accurate indication of drug effects, surgical events, and hemodynamic trends. The most important vascular determinant of arterial blood pressure is arteriolar tone, which can be modified by almost all drugs used to produce anesthesia.^{5,7,68} The factors that determine arterial blood pressure are

heart rate, stroke volume, vascular resistance, arterial compliance, and blood volume. Blood volume is one of the major variables affecting the *mean circulatory pressure*, which is defined as the equilibrium pressure of the circulation when blood flow is zero. The mean circulatory filling pressure is approximately 7 mm Hg when blood volume is normal (90 mL/kg). Increases in mean circulatory filling pressure augment ventricular filling and cardiac output. From the mechanical analogue of Ohm's law ($E = IR$), we know that $P = QR$. This formula predicts that if either cardiac output (Q) or peripheral vascular resistance (R) increase either individually or together, so will arterial blood pressure. Arterial blood pressure is a key component in determining perfusion pressure (upstream minus downstream pressure) and the adequacy of tissue blood flow. Perfusion pressures greater than 60 mm Hg are generally thought to be adequate for perfusion of tissues. Structures like the heart (coronary circulation), lung (pulmonary circulation), kidneys (renal circulation), and the fetus (fetal circulation) contain special circulations where changes in perfusion pressure can have immediate effects on organ function. In the coronary circulation, for example, if perfusion pressure (determined by the difference between arterial diastolic and ventricular end-diastolic pressures) decreases, subendocardial ischemia develops.⁷

Clinically, arterial blood pressure is generally measured as mean arterial pressure. When mean arterial blood pressure cannot be directly assessed, it is estimated by this formula:

$$P_m = P_d + 1/3 (P_s - P_d)$$

where P_m , P_s , and P_d are mean (m), systolic (s), and diastolic (d) blood pressures, respectively (Fig. 4.26).^{4,5} Both P_s and P_d can be measured indirectly using either Doppler or oscillometric techniques. Most drugs used to produce anesthesia decrease car-

Fig. 4.24. The excitation-contraction coupling process in vascular smooth muscle. Calcium enters cardiac cells through two types of voltage-dependent calcium channels (L and T) and several types of receptor-operated channels, which triggers the release of intracellular calcium (calcium-induced calcium release) from the sarcoplasmic reticulum (SR). Not shown is that some agonists act on smooth muscle membrane receptors to stimulate phosphatidylinositol turnover and the production of inositol triphosphate (IP₃) and diacylglycerol (DAG). IP₃ releases calcium from the SR and DAG activates protein kinase C, which stimulates the activity of the voltage-dependent slow calcium channels. Increases in intracellular calcium also interact with calmodulin to form a calcium-calmodulin complex stimulating myosin light-chain kinase, which together with intracellular calcium facilitates actin-myosin interaction. Contraction terminates when myosin light-chain phosphatase dephosphorylates the myosin light chain and intracellular calcium is reduced by sarcolemmal (SL) and SR reuptake, intracellular calcium–extracellular sodium exchange, and the turning off of the slow calcium channels.

diac output and peripheral vascular resistance. It should be remembered that if peripheral vascular resistance is elevated, the arterial blood pressure may be within normal limits, regardless of low blood flow to peripheral tissues. Several sedative and anesthetic drugs (α_2 -adrenergic agonists, ketamine, and low doses of thiobarbiturates) can increase peripheral vascular resistance (producing no change or increases in arterial blood pressure) while decreasing cardiac output (Table 4.4).

The arterial pulse pressure ($P_s - P_d$) and pulse-pressure waveform can provide valuable information regarding changes in vascular compliance and vessel tone. Generally, drugs (phenothiazines) or diseases (endotoxic shock) that produce marked arterial dilating effects increase vascular compliance, causing a rapid rise, short duration, and rapid fall in the arterial waveform while increasing the arterial pulse pressure. Situations that produce vasoconstriction decrease vascular compliance, producing a longer-duration pulse waveform and a slower fall in the systolic blood pressure to diastolic values.⁶⁸ The pulse pressure may con-

tain secondary and sometimes tertiary pressure waveforms, particularly if the measuring site is in a peripheral artery some distance from the heart.⁶⁵ Secondary and tertiary pulse waves are an indication of normal or elevated vascular tone in response to sympathetic nervous system stimulation or the vascular effects of drugs (e.g., ketamine, medetomidine, or catecholamines).

Resistance Vessels

These include the terminal (small) arteries, arterioles, and metarterioles, and to a much lesser extent the capillaries and venules. Under normal conditions, the arterioles provide over 50% of the total systemic vascular resistance, whereas large and small arteries account for 20%, capillaries 25%, and veins 5%. As indicated earlier, the Hagen-Poiseuille equation describes resistance as

$$R = 8 L \eta / \pi r^4$$

where L is length, η is blood viscosity, π is the constant 2.13, and r is the vessel radius. From this relationship, it should be clear

Fig. 4.25. Compliance (volume-pressure) curves for systemic arteries and veins and the lumped pulmonary vascular beds. Note that a small increase in volume causes a much larger increase in arterial pressure than venous pressure, suggesting a much lower compliance. Modified from Green,⁶⁹ pp. 66 and 67.

that as vessel radius decreases and vessel length and blood viscosity increase, vascular resistance increases.

Sphincter Vessels

Sphincter vessels represent a specific type of resistance vessel that is anatomically the absolute terminal portion of the precapillary arteriole. Functionally, sphincter vessels help to regulate the number of open capillaries and therefore the size of the capillary bed that is available for exchange processes. The relatively thick-walled muscular arterioles and sphincter vessels are influenced by a variety of neural, humoral, and local metabolic factors, and are the principal determinants for the regulation of both the volume and the distribution of blood flow to all tissues of the body (Table 4.5).

Arteriovenous Shunts

Arteriovenous anastomoses (AVAs) are a relatively poorly understood group of vessels that contain large amounts of vascular smooth muscle and function as pathways by which blood can bypass the capillaries and return to the venous circulation. These vessels can reduce or totally interrupt blood flow to capillaries.

AVAs are found in the greatest numbers in the skin and extremities (ears, feet, and hooves) of most species and were originally thought to be primarily involved in thermoregulation. More recently, their identification and verification in the intestinal wall, kidney, liver, and skeletal muscles have increased interest in their role as a separate blood flow regulatory mechanism for controlling nutrient blood flow to these tissues. The influence of anesthetic drugs on AVAs is poorly understood and largely unknown.^{68,70}

Capillaries

These are functionally the most important portion of the circulatory system, because they are the exchange units between the blood and interstitial fluid. They penetrate nearly every tissue of the body, their numbers per gram of tissue and ultrastructure being dependent on tissue metabolic rate and tissue function. Structurally, capillaries are one layer of endothelial cells surrounded by reticular fibers. There are three types of capillaries. Capillaries located in striated and smooth muscle, connective tissue, and the pulmonary circulation are uninterrupted or continuous, although they contain a large number of pores. Capillaries in the glomeruli of the kidney and in the intestine are fenestrated because of the high levels of metabolism and importance of active exchange of fluids. Capillaries in the liver, spleen, and bone marrow are discontinuous, containing intercellular gaps through which fluid and blood cells can easily pass.⁶⁸ Regardless of the type of capillary examined, the exchange of fluid, nutrients, and cellular waste products between blood and interstitial fluid is their primary function. Capillary exchange is governed by two primary processes: *diffusion* and *filtration*. Fick's law of *diffusion* describes solute exchange (J_s) as

$$J_s = DA/M_T \Delta C$$

where D is the diffusion coefficient, A is the capillary surface area, M_T is the membrane thickness, and ΔC is the concentration gradient or difference. The diffusion coefficient is determined by the diffusion medium and qualities characteristic of the diffusion particle such as molecular weight, ionic charge, and lipid solubility. Exchange by *filtration* is determined by four primary factors (P_c , P_i , π_c , and π_i) according to a dynamic equilibrium equation, first proposed by Starling and Landis and modified by Pappenheimer and Soto-Rivera, wherein

$$Q_c = K_f (P_c - P_i) + \sigma (\pi_c - \pi_i)$$

where Q_c is fluid flow across the capillary (positive for filtration, and negative for reabsorption), P_c and P_i are capillary and interstitial hydrostatic pressures, π_c and π_i are the plasma in the capillary and interstitial colloid osmotic pressures of proteins, K_f is the capillary filtration coefficient, and σ is the osmotic reflection coefficient for all plasma proteins (Fig. 4.27).^{71,72} The filtration coefficient (K) indicates the resistance of the capillary wall to fluid flow and is determined by the exchange surface area, the number and radius of capillary pores, the capillary wall thickness, and the viscosity of the filtering fluid. The osmotic reflection coefficient (σ) is an indicator of transvascular protein transport and is usually assumed to be 1, or close to 1, in normal

Fig. 4.26. Arterial blood pressure is determined by both physiological and physical factors. The mean arterial pressure (P_m) represents the area under the arterial pressure curve divided by the duration of the cardiac cycle and can be estimated by adding one-third the difference between the systolic arterial pressure (P_s) and diastolic arterial pressure (P_d) to P_d . P_s minus P_d is the pulse pressure. Modified from Berne and Levy,¹⁰³ p. 259.

animals, since most capillary beds are impermeable to colloids. Providing all factors can be measured, calculated, or estimated in Starling’s equation, net fluid flux across the capillary wall can be quantitated accurately.⁷¹ Under normal conditions, these factors are responsible for fluid filtration at the arterial end of the capillary and fluid reabsorption at the venous end of the capillary (Figs. 4.27 and 4.28). Lymph vessels carry excess fluid away. Increases in P_c (volume overload, venous obstruction, and heart failure) and K_f (histamine, cytokines, and kinins) or decreases in π_p (hypoproteinemia) cause excess fluid to accumulate in the interstitial space, resulting in edema. Excessive fluid accumulation in the lung, intestine, and liver (so-called overflow organs) can cause fluid collection in the alveoli, intestinal lumen, and peritoneal cavity.⁷² Decreases in P_c (hypotension and hypovolemia) and increases in π_p (hyperproteinemia and dehydration) induce a net reabsorption of fluid from the interstitial space and an increase in plasma volume. Anesthesia, anesthetic drugs, quantity and type of fluid administered, and the type of anesthetic techniques used can have important effects on the Starling forces.⁷² For example, most anesthetic drugs and anesthetic techniques decrease P_c , causing net fluid reabsorption from the interstitial space and hemodilution. If the anesthetic drug or technique produces significant cardiac depression, P_c may increase, resulting in edema (e.g., pulmonary edema). Finally, several drugs, including some opioids (e.g., morphine and meperidine), can cause histamine release, thereby increasing K_f , and interstitial fluid accumulation (Table 4.6).⁶⁸

Table 4.5. Distribution of cardiac output to peripheral tissues

Organ	% of Total
1. Heart	4
2. Brain	14
3. Kidneys	20
4. Gastrointestinal tract	22
5. Resting skeletal muscle	20
6. Skin	8
7. Other organs	12

Veins and Venules

The veins and venules comprise the final component of the vascular system and, although structurally similar to arteries, are relatively devoid of elastic tissue and possess comparatively less smooth muscle (Fig. 4.23). Veins in general have a greater radius and thinner walls than arteries and functionally serve to return blood to the heart and as capacitance (volume storage) vessels (Fig. 4.3). The relationship between vascular volume (V) and vascular transmural pressure (P) is termed *vascular compliance* ($C = \Delta V/\Delta P$), which is the inverse of elasticity and for the low-pressure veins is several orders of magnitude greater than most arteries (Fig. 4.25).⁶⁹ The lumped compliance of the pulmonary vascular bed is less than that of the systemic circulation, imply-

Starling's Law of the Capillary

Fig. 4.27. Starling's law of the capillary suggests that fluid (plasma) flux (exchange) across the capillary wall (J_v) and into the interstitium depends on transmural (capillary [c] – interstitial [i]) hydrostatic pressure ($P_c - P_i$), transmural protein colloid osmotic pressure (π ; $\pi_c - \pi_i$), the fluid filtration coefficient or porosity (κ_f), and the reflection coefficient for the movement of proteins (σ). Increases in P_c and κ_f and decreases in P_i , π_c , and σ increase J_v and vice versa.

Table 4.6. Causes of increased interstitial fluid volume and edema

Increased filtration pressure
Arteriolar dilation
Venule constriction
Increased venous pressure (heart failure, incompetent valves, venous obstruction, increased total extracellular fluid volume, effect of gravity, etc.)
Decreased osmotic pressure gradient across capillary
Decreased plasma protein level
Accumulation of osmotically active substances in interstitial space
Increased capillary permeability
Substance P
Histamine and related substances
Kinins, etc.
Inadequate lymph flow

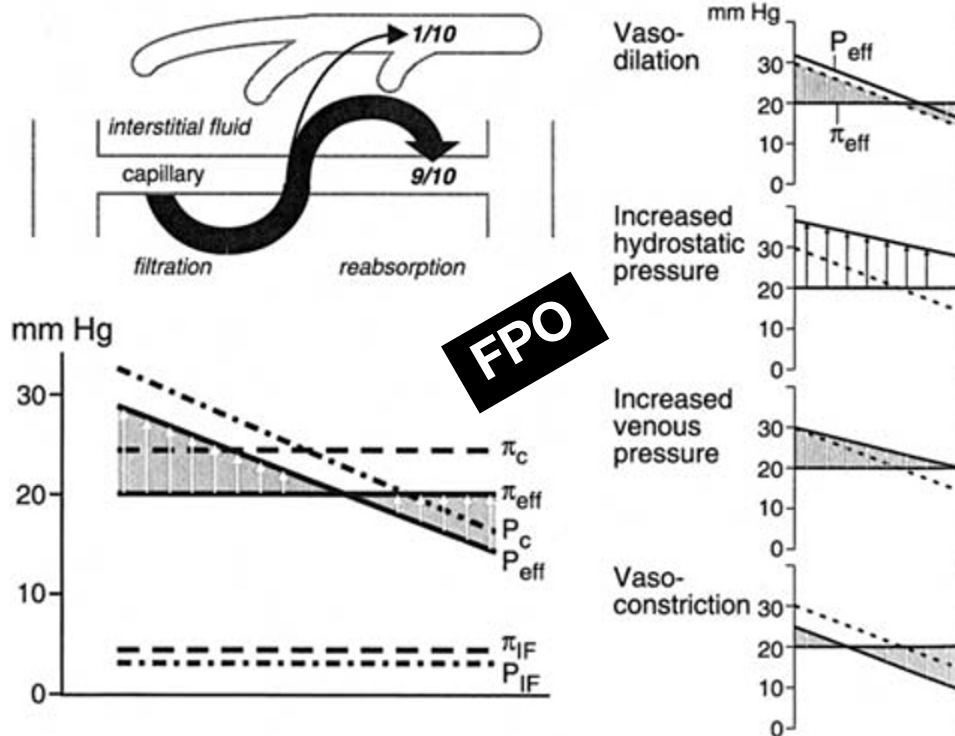

Fig. 4.28. Starling's law of the capillary suggests that fluid movement between the capillary and the interstitial space can be predicted by changes in capillary (P_c) and interstitial (P_i) hydrostatic pressures and capillary (π_c) and interstitial (π_i) colloid osmotic pressures. The algebraic sum of these pressures produces an effective transmural filtration pressure (P_{eff}) and effective colloid osmotic pressure (π_{eff}), which determine capillary filtration and reabsorption. Only about 10% of the plasma filtrate enters the lymphatic system under normal conditions. Filtration-reabsorption is shifted toward increased filtration during vasodilation and increased hydrostatic and venous pressure, and toward increased reabsorption during vasoconstriction. These diagrams assume the filtration coefficient and the osmotic reflection coefficient (see the text) are minimally affected. Modified from Witzleb,⁶⁸ pp. 419 and 420.

ing that the blood storage capability of the lungs compared to the systemic circulation, particularly the systemic small veins and venules, is small (Fig. 4.25). Venous return is facilitated by venous one-way valves, contraction of skeletal muscle (muscle pump), the negative intrathoracic pressure during breathing (respiratory pump), increases in intra-abdominal pressure (abdominal pump), and the suction effect of the heart during atrial relaxation, ventricular contraction, and rapid ventricular filling.⁶⁸ Hydrostatic pressure (gravity), increased intrathoracic pressure (intermittent positive-pressure ventilation [IPPV] and positive end-expiratory pressure [PEEP]), and venous occlusion or obstruction initially impair or inhibit venous return. The capacious venous vessels of the liver, splanchnic viscera, and skin (in many species), together with the sinusoids of the spleen, can be considered blood reservoirs, as are the pulmonary vessels, although to a much lesser extent.

Lymphatics

The lymphatic system constitutes a closed-ended, separate, yet parallel drainage system through which interstitial fluid (normally <10% of filtered fluid) is returned to the blood vascular system (Fig. 4.28).⁷² Lymphatic channels are thin-walled vessels (generally one cell layer thick) that contain one-way valves that facilitate the transfer of lymph (interstitial fluid) via lymph vessels of increasing size first to lymph nodes and eventually to the thoracic lymphatic duct and heart. Skeletal muscle contraction facilitates lymph flow (lymphatic pump) to the heart similar to its effect on venous blood flow.⁶⁸

Nervous, Humoral, and Local Control

The regulatory control of the cardiovascular system is integrated through the combined effects of the central and peripheral nervous systems, the influence of circulating (humoral) vasoactive substances, and local tissue mediators that modulate vascular tone.^{73–77} These regulatory processes maintain blood flow at an appropriate level while distributing blood flow to meet the needs of tissue beds that have the greatest demand.

Tissue blood flow is regulated by the integration of supraregional (central nervous system [CNS]), regional and local factors. Together these factors coordinate immediate and long-term adjustments in cardiac output, total peripheral vascular resistance, vascular capacitance, and blood volume. Higher brain centers, including the hypothalamus (pain and temperature) and cerebral cortex (emotions: vigilance and fear), facilitate or modify cardiovascular responses. Continuous adjustments in cardiovascular system function help to buffer significant changes in arterial blood pressure and intravascular volume and sustain oxygen and nutrient delivery to tissues (Table 4.7). The autonomic nervous system exerts a major influence on the regulation of cardiovascular function.⁷⁶ Peripheral receptors, including baroreceptors, mechanoreceptors, and chemoreceptors, respond to changes in blood pressure, volume, or gas tensions, respectively, and send information to the CNS through afferent nerves. These sensory signals are integrated, in “control centers” located in the hypothalamus, pons, and medulla, into re-

sponses carried by efferent sympathetic or parasympathetic nerves to the periphery (Fig. 4.29). The autonomic nervous system also modulates the release of various peptides providing a generalized humoral influence on cardiac contractile performance and vascular tone.⁶⁶ Minute-to-minute changes in blood flow are regulated by local control mechanisms, which are somewhat independent from nervous system input. Vasodilator substances, primarily the by-products of tissue metabolism, act on small vessels, producing vasodilation proportional to the amount of metabolite produced. In addition, the vascular endothelium is known to modulate both local and neural control mechanisms through the release of prostaglandins and endothelium-derived factors, such as nitric oxide. Anesthetic drugs can and do interfere with the sensory (input), neural integration (processing), and effector (output) mechanisms that control cardiovascular function.^{78–82} Decreases in arterial blood pressure from any cause (blood loss, bradycardia, or poor cardiac performance) are sensed by a variety of central and peripheral vascular baroreceptors, which are the most important short-term determinants of arterial blood pressure. Output from these receptors triggers readjustments in CNS autonomic output, which compensates for small changes in arterial blood pressure (Fig. 4.30). Local myogenic autoregulation also helps to protect the brain, heart, liver, mesentery, and skeletal muscle from small changes in blood pressure. If arterial blood pressure is reduced to a point that tissue blood flow is negatively affected, CNS centers are activated, leading to substantial increases in heart rate, cardiac contractility, and vascular tone. Epinephrine and norepinephrine are released from the adrenal gland, which, combined with increases in sympathetic tone and activation of the renin-angiotensin system, intensify vasoconstriction (Table 4.7). Blood flow is redistributed to the lungs, heart, and brain and away from the skin, skeletal muscle, and kidney and splanchnic viscera. Additionally, peripheral chemoreceptors sense changes in the blood oxygen tension (PO_2) and pH. The acute onset of hypoxemia or hypercarbia (acidemia) in conjunction with hypotension can induce peripheral vasoconstriction. If blood pressure is not restored, capillary hydrostatic pressure decreases, promoting the movement of fluid from the interstitial space into the capillaries, thus increasing intravascular volume. The intravascular shift of extravascular fluid can restore up to 50% of the intravascular volume in a relatively short period (hours). The constriction of the peripheral vasculature, centralization of blood volume, redistribution of the blood flow, and increase in cardiac output and arterial blood pressure are generally capable of restoring tissue perfusion, providing the episode of hypotension or blood loss does not exceed the body’s compensatory capabilities.

Normally, neural, humoral, local myogenic, and metabolic autoregulatory mechanisms combine to adjust vascular resistance and tissue blood flow continuously to meet tissue requirements. The partial pressure of oxygen is chief among the local factors regulating tissue blood flow. Decreases in the arterial partial pressure of oxygen (i.e., ischemia or hypoxemia) cause vasodilatation and vice versa. Similarly, sustained increases in the local concentration of carbon dioxide, hydrogen ions, potassium, lac-

Fig. 4.29. Nervous, humoral, and local (tissue) regulatory factors ensure that blood flow and pressure are maintained within physiological limits. Mechanoreceptors and chemoreceptors sense changes in wall tension (stretch) and pH and blood gases (arterial oxygen partial pressure [PaO_2] and partial pressure of carbon dioxide [PaCO_2]), respectively. Substances produced in peripheral tissues and released into the circulation by endocrine glands also modulate blood vessels and the distribution of blood flow. Nervous impulses generated by the heart, vasculature, and peripheral sensors are transmitted to and integrated in the brain stem, which alters sympathetic and parasympathetic tone in order to make appropriate adjustments. The release of norepinephrine (NE) by sympathetic nerves stimulates the heart and constricts blood vessels. The release of acetylcholine (Ach) by parasympathetic nerves depresses the heart. PCO_2 , partial pressure of carbon dioxide; PO_2 , partial pressure of oxygen; +, stimulatory; and -, inhibitory. Modified from Shepherd and Vanhoutte,¹⁰² p. 12.

tic acid, and/or adenosine induce arteriolar (the chief resistance vessels) vasodilatation. It is noteworthy that acid-base ($\text{pH} < 7.20$) and electrolyte disturbances ($\uparrow \text{K}^+$), relatively short periods (longer than 8 to 10 min) of hypoxemia ($\text{PaO}_2 < 40$ mm Hg) or ischemia ($< 25\%$ of normal blood flow), and prolonged or excessive exposure to drugs (most anesthetics) can blunt or abolish baroreceptor and chemoreceptor reflex activity and the vascular response to sympathetic stimulation, leading to a poor compensatory response and a delay in normal tissue blood flow.

Neural Control of Cardiovascular Function

Nervous system regulation of the cardiovascular system and blood volume depends on three components within the nervous system: afferent input, central integration and processing, and efferent output.^{76,83} Neural and hormonal factors, including osmoreceptors in the hypothalamus, antidiuretic hormone released by neurons in the supraoptic and paraventricular nuclei, aldosterone and renin produced by the kidney, and the release of atrial natriuretic peptide (ANP) by atrial receptors sensitive to stretch, are all integrally involved in maintaining plasma and therefore blood volume. The one mechanism above all others, however, that dominates the control of plasma and blood volume is the effect of blood volume on arterial blood pressure and the consequences of arterial blood pressure on the urinary excretion of sodium and water (Fig. 4.30A).⁴ Alterations in arterial blood pressure, therefore, can have profound effects on fluid exchange and blood volume (natriuresis and pressure diuresis). The interplay of these mechanisms ultimately controls hemodynamics, blood volume, extracellular fluid volume, and renal excretion of salt and water (Fig. 4.30B).

Afferent Input

Afferent input to the CNS is received from peripheral sensors that respond to acute changes in blood pressure, blood volume,

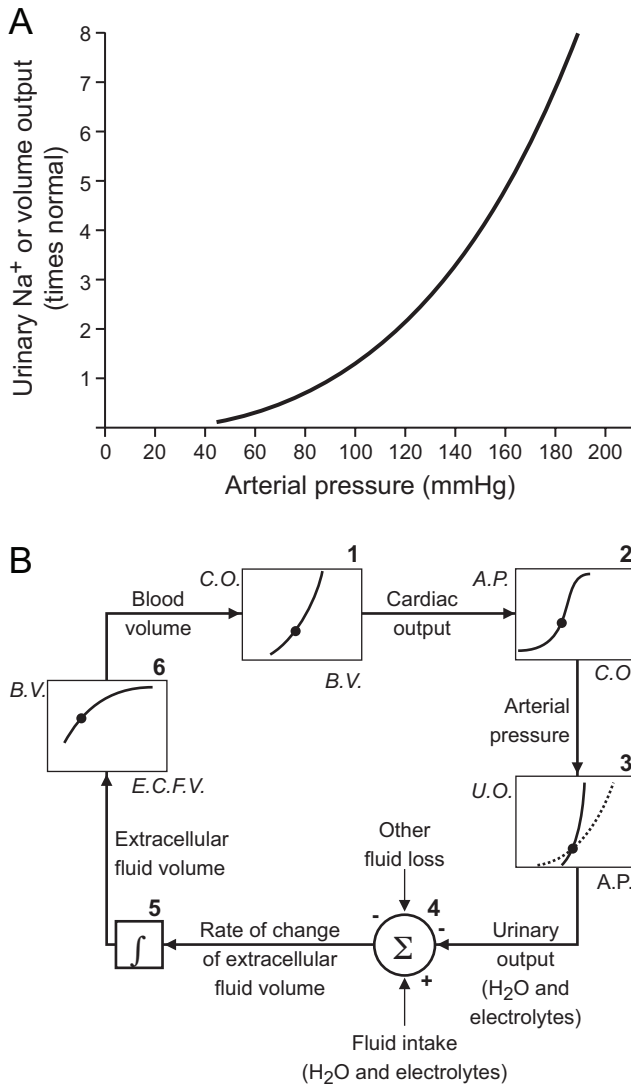

Fig. 4.30. The effect of arterial blood pressure on the urinary excretion of Na⁺ and urine volume (**A**), and a scheme for a basic feedback mechanism that controls blood volume and extracellular fluid volume (**B**). A.P., arterial blood pressure; B.V., blood volume; C.O., cardiac output; E.C.F.V., extracellular fluid volume; and U.O., urine output. Modified from Guyton,¹⁰⁵ 321.

and tissue metabolism. These peripheral sensors are the first step in a reflex arc in which the effector organs are the heart and vasculature. The reflex arc generally operates as a negative-feedback system designed to maintain a variable blood pressure at a fixed value, or *set point*.⁸³

Arterial baroreceptors are stretch receptors (mechanoreceptors) located in the carotid sinus and aortic arch that respond to increases in arterial blood pressure by incremental increases in the firing rate of sensory fibers, which are carried by the glossopharyngeal and vagus nerves.⁷⁶ These impulses travel to the nucleus tractus solitarius within the CNS, are processed, and initiate an effector response that returns blood pressure to its normal range (Fig. 4.29). This response is accomplished by parasympa-

Table 4.7. Factors that regulate arterial blood pressure and tissue perfusion

<i>Immediate (short term)</i>	
1. Autonomic nervous system (sympathetic and parasympathetic)	Regulates heart rate and vessel tone and capacity
2. Vascular baroreceptor or pressoreceptor reflexes (stretch receptors)	Regulate heart rate and vessel tone and capacity
3. Cardiac stretch receptors	Regulate heart rate and vessel tone and capacity
4. Chemoreceptor reflexes (sense changes in oxygen and carbon dioxide (hydrogen ions))	Regulate heart rate and vessel tone
5. Bloodborne (humoral) responses (epinephrine and norepinephrine)	Regulate heart rate, vessel tone, and cardiac contractility
6. Local factors	Arteriolar oxygen partial pressure
	Decreased oxygen produces vasodilatation and vice versa
	Local metabolites
	Increased production of carbon dioxide, hydrogen ions, and lactate
	Myogenic autoregulation
	Adjusts vessel tone to changes in blood pressure
<i>Intermediate</i>	
1. Transcapillary fluid shifts (Starling's law of the capillary)	Regulate fluid filtration and reabsorption
2. Hormonal responses (renin and angiotensin)	Regulate vessel tone and salt and water retention
<i>Long term</i>	
1. Oral fluid consumption	Regulates net fluid intake
2. Renal control system (vasopressin [ADH], aldosterone, and atrial natriuretic peptide)	Regulates total body water and renal fluid output

thetic activation, which decreases heart rate and inhibition of sympathetic vasoconstrictor output to arterioles and veins. Baroreceptors become inoperative at an arterial blood pressure below 60 mm Hg, but the frequency of nerve impulses increases progressively as pressure rises above 60 mm Hg, reaching a maximum at approximately 180 mm Hg.^{4,83} Most baroreceptors have a set point of approximately 100 mm Hg. However, if arterial blood pressure changes to a new value and remains static, the baroreceptors can “reset” to this new set point within 24 to 48 h. This is why baroreceptors are only effective for short-term control of blood pressure. Most, if not all, anesthetic drugs interfere with baroreceptor responsiveness. Inhalation anesthetics in particular depress normal baroreflex responsiveness and diminish sympathetic output from the CNS. The degree of baroreceptor depression depends on both the depth of anesthesia and the patient's physical status.^{84,85}

Cardiac mechanoreceptors are located in the right and left atria and ventricles and help to minimize changes in systemic blood pressure in response to changes in blood volume. These cardiac stretch receptors differ from the baroreceptors in that the stretch receptors respond to comparatively small changes in stretch or pressure as do pressure receptors within the pulmonary circulation. The atria contain two types of receptors located at the venoatrial junctions.⁸³ Atrial *A* receptors react primarily to changes in heart rate, whereas *B* receptors respond to short-term changes in atrial volume. An increase in atrial volume activates both the *A* and *B* atrial mechanoreceptors, sending impulses to the medulla via vagal afferents. Depending on the prevailing heart rate and arterial blood pressure, heart rate may increase (Bainbridge reflex) or decrease (baroreflex and activation of atrial depressor *C* fibers). Atrial distension also decreases sympathetic output to renal afferent arterioles, resulting in vasodilation, while the hypothalamus receives neural input, which decreases the release of vasopressin (antidiuretic hormone) that acts to increase urine flow.⁷⁶ A rapid loss of free water into the urine helps return circulating blood volume to normal values. In addition to these neural responses, ANP and brain natriuretic peptide (BNP) are released into the bloodstream.⁷³ ANP is produced in atrial cardiocytes in response to atrial distension and increases sodium excretion by the kidney with an accompanying increase in water loss.⁷⁴ Similarly, BNP, produced by ventricular muscle cells, depends on increases in ventricular filling pressures and myocardial stretch and becomes elevated during myocardial dysfunction.⁷³

Ventricular mechanoreceptors located in the ventricular endocardium discharge in parallel with changes in ventricular pressure and produce effects that help to regulate systemic blood pressure and myocardial work. Ventricular distension, however, also stimulates powerful depressor reflexes that decrease heart rate and peripheral vascular resistance, resulting in bradycardia and hypotension (Bezold-Jarisch reflex).⁸³ The activation of ventricular nonmyelinated *C* fibers serves as the basis for this reflex response. Impulses initiated by either ventricular distention or the injection of certain chemicals (e.g., capsaicin or serotonin) into the coronary arteries can produce the Bezold-Jarisch reflex, which is also called the *coronary chemoreflex*.⁸³

The carotid artery and aortic arch contain specialized sensory chemoreceptors termed the *carotid and aortic bodies* (Fig. 4.29).⁷⁶ The carotid and aortic bodies receive the highest blood flow per gram of tissue weight of any organ within the body. These chemoreceptors are sensitive to changes in arterial oxygen and carbon dioxide tension, hydrogen-ion concentration (pH), and temperature. The chemoreceptors of the carotid and aortic bodies help to regulate respiratory function in response to decreases in pH and the arterial partial pressure of oxygen and increases in the arterial partial pressure of carbon dioxide. Afferent activity from the carotid body is carried by the glossopharyngeal nerve and from the aortic body by the vagus. These sensors are most sensitive to changes in hydrogen-ion concentration and respond proportionally to the magnitude of the change from their set point. The set point for activation is a pH below 7.40. The approximate set point for carbon dioxide is 40 mm Hg and for oxygen 80 mm Hg. Increases in afferent activity from the chemoreceptors in-

crease minute ventilation, restoring arterial blood pH, carbon dioxide, and/or oxygen to normal. Hypoxia, hypercarbia, and nonrespiratory acidosis may cause bradycardia, coronary vasodilation, and an increase in systemic arteriolar resistance. This effect is pronounced if the normal increase in ventilation is prevented, for example, during anesthesia. Chemoreceptors located in the ventricular epicardium respond to hypoxia or ischemia by initiating the coronary chemoreflex (Bezold-Jarisch reflex), producing bradycardia and hypotension (Table 4.8).

Central Nervous System Integration

No single brain nucleus or center controls cardiovascular function; rather, multiple regions modulate the autonomic nervous system. When afferent impulses from peripheral sensors arrive in the brain, they are integrated to produce a neural and/or humoral response. The nucleus tractus solitarius (NTS) in the medulla is the relay station for afferent impulses from peripheral sensors (Fig. 4.31). Neurons originating in the NTS send information to the vagal nucleus and to various regions collectively referred to as the *vasomotor center*. Vagal nuclei send nerve fibers directly to the heart. Nerve cell bodies for the sympathetic nervous system are located in the thoracolumbar spinal cord and are linked to the NTS through axons traveling in the bulbospinal tract (Fig. 4.32). The bulbospinal tract contains both excitatory and inhibitory axons that cause either increases or decreases in sympathetic output. Centers in the hypothalamus link the somatic and autonomic responses necessary for animals to adapt to their environment. The centers initiate adrenergic constriction of resistance and capacitance vessels and cholinergic dilation of vessels supplying skeletal and cardiac muscle during the fight-flight response. Hypothalamic centers modulate the cardiovascular response (cutaneous vasoactivity) to body temperature changes during shivering, sweating, or panting. The hypothalamus also modulates the cardiovascular response to exercise and may be involved in blood pressure regulation.⁷⁶ Finally, the cerebral cortex influences cardiovascular function by modulating the cardiovascular response to exercise, emotion, ischemia, and hypoxia.⁸³

Efferent Output

The autonomic nervous system, which is the efferent link between the CNS and the cardiovascular system, provides rapid control of both blood pressure and blood flow.⁷⁶ Efferent impulses are carried by sympathetic and parasympathetic nerves. Adrenergic and cholinergic receptors in target organs initiate the intracellular changes that produce a cellular response to the signals arriving from the CNS (Table 4.9).

Sympathetic Nervous System

Sympathetic pathways originate in the intermediolateral columns of the thoracolumbar segments of the spinal cord.^{74,76} Both inhibitory input and excitatory input arrive at preganglionic sympathetic nerve cell bodies via axons traveling in the bulbospinal tract (Fig. 4.32). Descending inhibitory pathways are serotonergic; descending excitatory pathways are adrenergic. The balance between these two types of input determines the prevailing level of sympathetic tone to the periphery.

Table 4.8. Cardiovascular and pulmonary reflexes and signs

1. Branham's sign: slowing of the heart rate following compression or excision of an arteriovenous fistula (e.g., patent ductus arteriosus ligation).
2. Bainbridge reflex: an increase in heart rate caused by a rise in blood pressure in the great veins as they enter the right atrium.
3. Bezold-Jarisch reflex: afferent and efferent pathways in the vagus nerve—stimulation of cardiac, primarily ventricular, chemoreceptors or stretch receptors (mechanoreceptors), induce sinus bradycardia, hypotension, and peripheral vasodilation. Stretch of ventricular mechanoreceptors are responsible for syncope when standing.
4. High-pressure baroreceptor or pressoreceptor reflex: decreases in heart rate initiated by increases in arterial blood pressure. A decrease in arterial pressure produces hyperventilation, and an increase in arterial blood pressure causes respiratory depression and ultimately apnea.
5. Atrial stretch-receptor reflex: atrial distension causes the release of atrial natriuretic peptide (ANP) from the atria, resulting in diuretic activity, vasodilation, inhibition, and aldosterone secretion. ANP is an endogenous antagonist of angiotensin II. This response was previously considered to be a low-pressure baroreceptor response, but has since been demonstrated to be dependent on atrial stretch, not pressure. Sinus and supraventricular tachycardias are common stimuli for this response.
6. Vasovagal reflex: initiated by a decrease in venous return to the heart (e.g., hypovolemia, orthostasis, compression of the inferior vena cava, and regional analgesia), causing sinus bradycardia and vasodilation. The term has come to include neurocardiogenic syncope, carotid sinus syndrome, and micturition syncope in human patients.
7. Craniocardiac reflex: stimulation of cranial nerves (olfactory, ophthalmic, and trigeminal), resulting in bradycardia and hypotension (depressor effects).
8. Abdominocardiac reflex: mechanical stimulation of the abdominal viscera causes changes in heart rate, usually slowing; rarely causes extrasystoles.
9. Oculocardiac reflex (Aschner's reflex): compression of the eyeball causes slowing of sinus heart rate.
10. Hering-Breuer reflex: effects of the vagus in the control of respiration—lung inflation arrests inspiration, and lung deflation initiates inspiration.
11. Pulmonary chemoreflex: stimulation of C-fiber endings (juxtapulmonary capillary receptors [J receptors]) by tissue damage. Fluid accumulation of cytokines produces sinus bradycardia, hypotension, shallow breathing and apnea, bronchoconstriction, and mucous secretion (e.g., isoflurane administration).
12. Venorespiratory reflex: increases in right atrial pressure stimulate increases in respiration.
13. Cough reflex: stimulation of the larynx, trachea, or main bronchi or chemical stimulation throughout the respiratory tree result in cough.
14. Vagovagal reflex: afferent and efferent pathways in the vagus nerve—stimulation or irritation of the larynx or trachea by a laryngoscope or endotracheal tube precipitates bradycardia.

Preganglionic sympathetic nerves send axons via the ventral roots of the spinal cord to paravertebral ganglia located just outside of the vertebral column. Many of the preganglionic fibers ascend the paravertebral chains and synapse with postganglionic neurons in the cranial, middle, and caudal (stellate) cervical ganglia (Fig. 4.33). Here they synapse with postganglionic sympathetic neurons, which send their fibers to the heart, blood vessels, and viscera. Postganglionic cardiac sympathetic nerve fibers innervate the sinoatrial node, the atrioventricular node, the atria, and the myocardium (Fig. 4.32). Postganglionic sympathetic fibers release the neurotransmitter norepinephrine, which binds to adrenoreceptors on cardiac cell membranes (Table 4.9).

Postganglionic sympathetic nerve fibers also leave the paravertebral ganglia via spinal nerves to innervate vessels throughout the body. Normally, sympathetic tone maintains a partial state of contraction in vascular smooth muscle, providing the resistance necessary to maintain adequate systemic blood pressure and aid in the control of the fractional distribution of cardiac output to body tissues.^{73,76} The extent of innervation to the resistance vessels (arterioles) varies with tissue type. The kidney, spleen, gastrointestinal tract, and skin are extensively innervated by the sympathetic nervous system. Redistribution of blood flow away from these tissues during times of crisis preserves blood flow to the brain, heart, and skeletal muscle.

Sympathetic Neurotransmission

The vast majority of sympathetic postganglionic fibers are adrenergic, releasing norepinephrine at their neuroeffector junctions. The amino acid tyrosine is the substrate used by these nerves to produce norepinephrine. Tyrosine is actively transported across the nerve cell membrane into the neural axoplasm, where it is converted by tyrosine hydroxylase and decarboxylation to dopamine, which is stored in vesicles within the nerve. Inside the storage vesicles, a final hydroxylation step takes place to produce the neurotransmitter norepinephrine. Nerve action potentials increase intracellular calcium, causing the vesicles to fuse with the nerve cell membrane and release norepinephrine into the synaptic cleft, where it binds to a variety of adrenoreceptors (Table 4.9). There are presynaptic receptors on the nerve cell membrane and postsynaptic receptors on the effector organ. Postsynaptic receptor binding of norepinephrine triggers a cascade of intracellular events that ultimately produce a cellular action. The effective half-life of norepinephrine after release into the synaptic cleft is very short. Norepinephrine is degraded locally at the neuroeffector junction by the enzymes, monamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT). Most of the norepinephrine released into the synaptic cleft undergoes reuptake into adrenergic nerve terminals, where it reenters storage vesicles. This neuronal amine-uptake system is designated *uptake 1* and has a high affinity for norepinephrine, a lower affinity for epinephrine, and little affinity for the synthetic β -adrenergic agonist isoproterenol. Norepinephrine may rapidly diffuse out of the synaptic cleft, where it undergoes reuptake at extraneuronal sites or is carried into the venous blood and metabolized in the lung. The extraneuronal reuptake pathway has been designated *uptake 2* and has a low affinity for norepinephrine, a higher affinity for

Fig. 4.31. Mechanoreceptors in the carotid sinus and aortic arch send impulses via the carotid sinus nerve, a branch of the glossopharyngeal nerve, and the vagosympathetic trunk, respectively, to the solitary tract nucleus in the brain stem (cardiovascular centers). Changes in the activity of these mechanoreceptors caused by changes in arterial blood pressure result in adjustments in sympathetic and parasympathetic outflow to the heart and resistance (arterial) and capacitance (veins) vessels. Ach, acetylcholine; AV, atrioventricular node; NE, norepinephrine; and SA, sinoatrial node. Modified from Shepherd and Vanhoutte,¹⁰² p. 132.

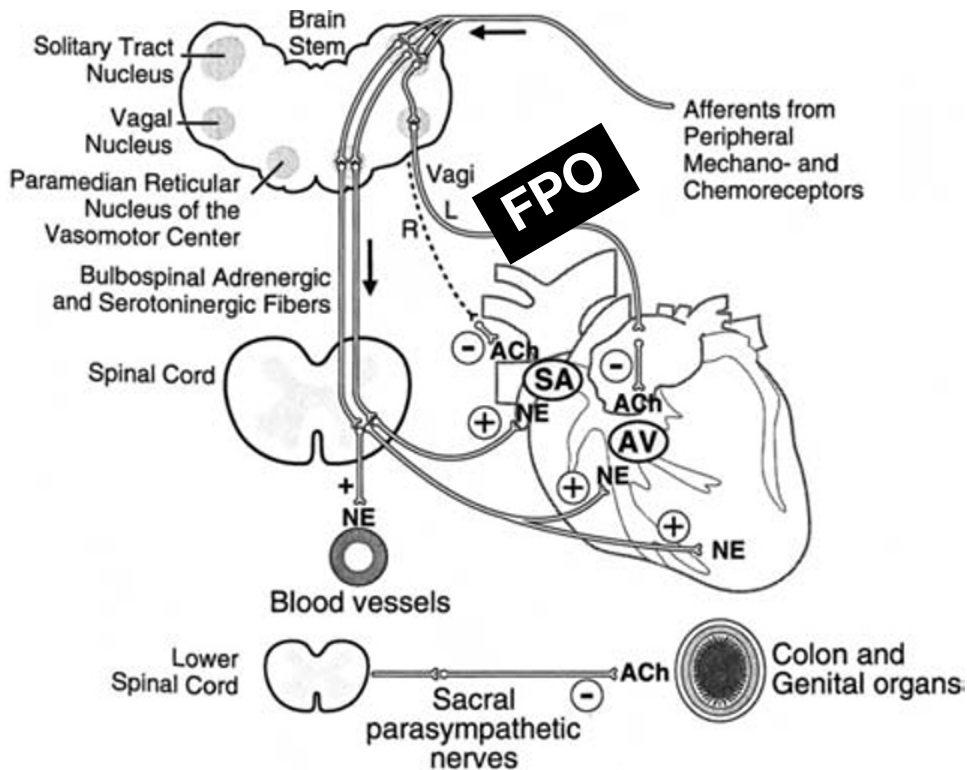

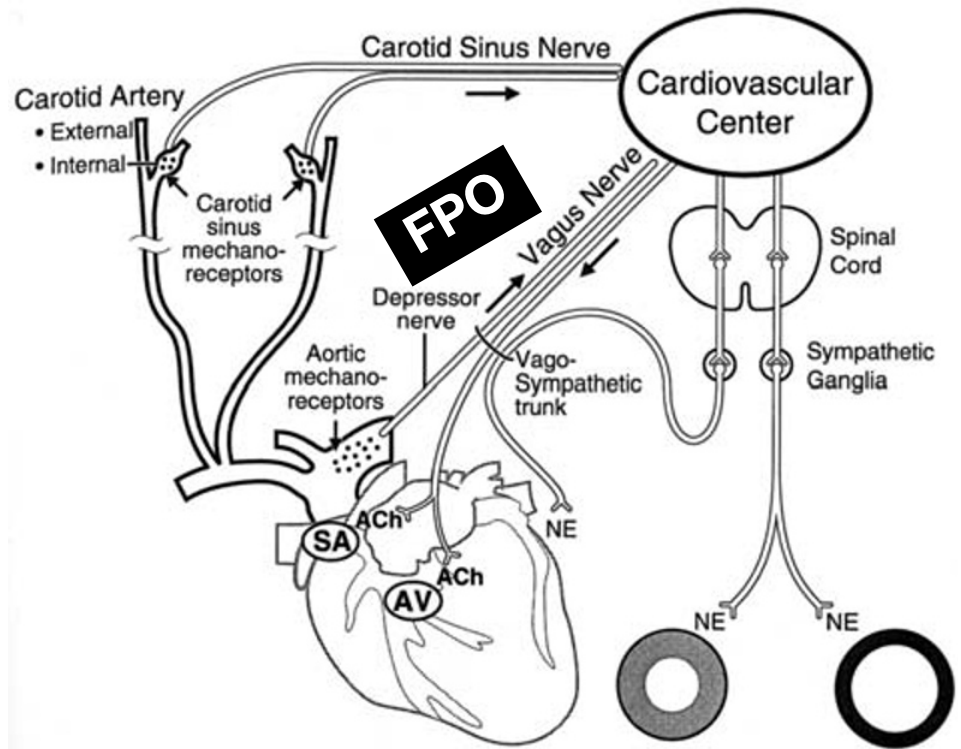

Fig. 4.32. Distribution of sympathetic and parasympathetic nerves to the cardiovascular system. The solitary-tract nucleus is the main receiving point in the brain stem for afferent input arriving from peripheral sensors and higher centers in the brain. Interneurons connect the solitary-tract nucleus to the vasomotor center, from which bulbospinal tract fibers descend to the spinal cord and synapse with preganglionic sympathetic nerves to the heart and blood vessels. Interneurons also connect the solitary-tract nucleus to the vagal nucleus in the brain stem, where neurons synapse with preganglionic parasympathetic nerve fibers, which are carried by the vagus nerve to the heart. Parasympathetic nerve fibers to the blood vessels of the colon and genital organs arise from centers in the sacral portion of the spinal cord. Ach, acetylcholine; AV, atrioventricular node; L, left vagus; NE, norepinephrine; R, right vagus; and SA, sinoatrial node. Modified from Shepherd and Vanhoutte,¹⁰² p. 124.

^aThree subtypes of α₁ and three subtypes of α₂ receptors have been identified.

Modified from Ganong.¹⁰⁸

epinephrine, and a very high affinity for isoproterenol. Uptake 2 is of the greatest physiological significance in the elimination of circulating catecholamines, primarily epinephrine, released by the adrenal gland, and has little physiological significance for norepinephrine released at postganglionic sympathetic nerve terminals.

Adrenoreceptors

The sequence of intracellular events initiated by receptor binding of norepinephrine is determined by the type of adrenoreceptor stimulated. The classification of adrenoreceptors continues to evolve based on both pharmacological and molecular criteria.^{83–87} All adrenoreceptors have a similar homology of structure and produce intracellular events by binding to membrane guanine nucleotide–regulatory proteins (G proteins).⁸⁸ The structure of the G-protein–coupled receptor consists of a single-subunit protein with seven hydrophobic transmembrane segments, three hydrophilic extracellular sequences, and three hydrophilic intracytoplasmic loops. These membrane-associated regulatory proteins

serve to convert the signal arriving at the cell membrane into a specific enzyme system response or ion-channel activity that produces a cellular response. Autonomic transmission in the cardiovascular system is initiated by stimulation of three different G proteins: G_s stimulates adenylate cyclase, causing a rise in intracellular cAMP. G_i inhibits adenylate cyclase, decreasing the concentration of intracellular cAMP (Table 4.9). G_p activates phospholipase C, which hydrolyzes phosphoinositol to inositol triphosphate (IP₃) and diacylglycerol (DAG). IP₃ causes the release of calcium ions (Ca²⁺) from the sarcoplasmic reticulum. DAG activates protein kinase C, which phosphorylates contractile proteins in the myocardium and vascular smooth muscle.

β-Adrenoreceptors are classified pharmacologically into three types—β₁, β₂, and β₃—based on their relative affinities for various agonists.⁸⁷ The physiological significance of the β₃ receptor is unclear, but appears to be involved in regulation of metabolism and energy regulation. The β₁- and β₂-adrenoreceptor subtypes, when activated by norepinephrine, epinephrine, or other β-

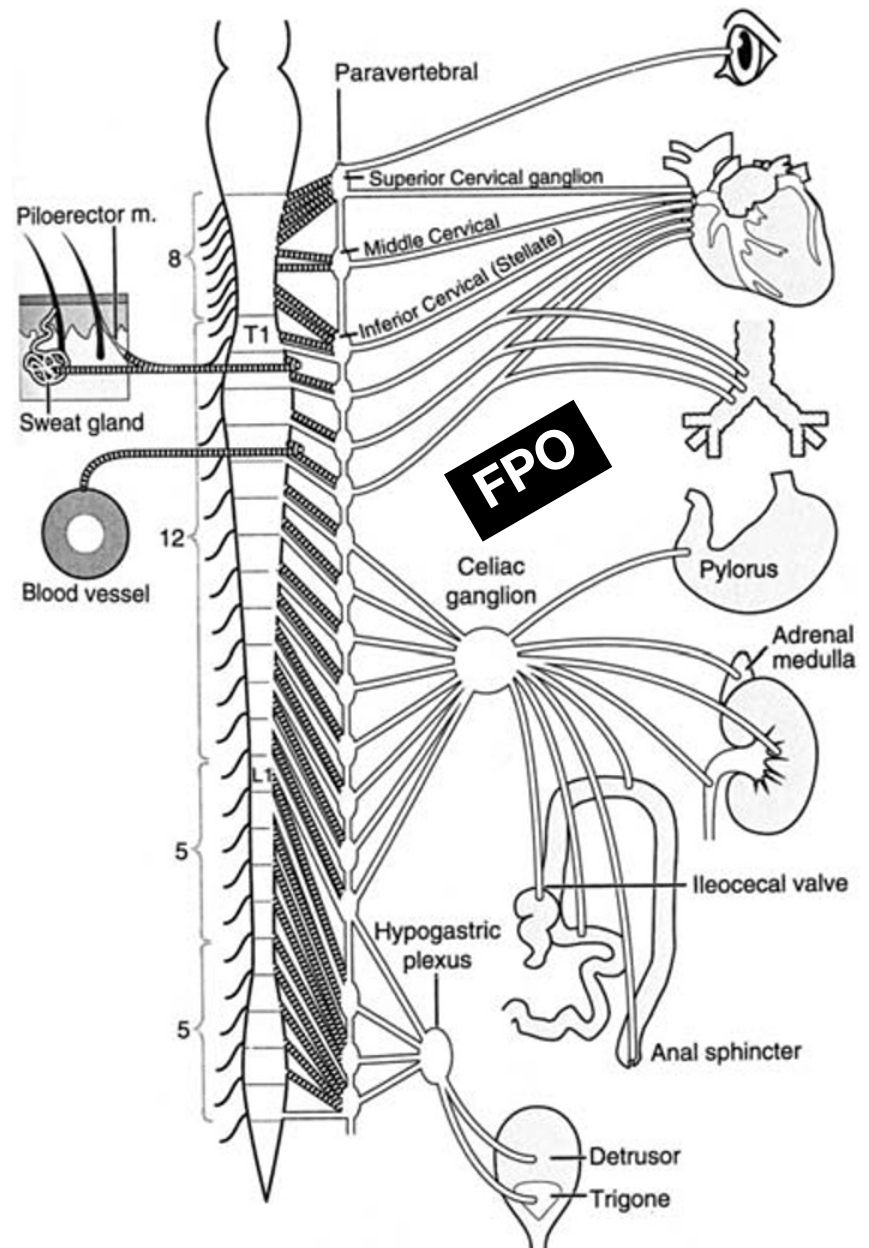

Fig. 4.33. The sympathetic nervous system. Note the location of the stellate and hypogastric ganglia. m, muscle. Modified from Guyton,¹⁰⁵ p. 668.

adrenergic agonists, stimulate the formation of the enzyme adenylate cyclase through the G_s protein, causing an increase in intracellular cAMP. β -Adrenoreceptors also activate L-type Ca^{2+} channels in myocardial and vascular tissue, thereby increasing intracellular calcium concentration (Table 4.9). Both β_1 - and β_2 -adrenoreceptors are found in the heart and are responsible for increases in heart rate and contractility during sympathetic stimulation (Table 4.10). β -Adrenoreceptor stimulation increases the slope of phase 4 diastolic depolarization in pacemaker tissues and subsidiary automatic cells. Increases in intracellular cAMP and Ca^{2+} increase cardiac contractility and facilitate cardiac relaxation. Although both β_1 - and β_2 -adrenoreceptors are present in the heart, β_1 -adrenoreceptors predominate during health, especially in the ventricular myocardium.

β_2 -Adrenoreceptors relax smooth muscle in vascular, bronchial,

gastrointestinal, and genitourinary tissues. β_2 -Adrenoreceptors in the vasculature are not innervated and therefore produce vasodilation in response to circulating catecholamines or drugs. Their location in specific vascular beds suggests a role in the distribution of blood flow, especially during exercise.

Three α_1 -receptor subtypes have been classified according to their affinity to adrenergic agonists.^{86,87} The receptor subtypes are designated α_{1A} , α_{1B} , and α_{1C} , but their distribution is not universal across species or within specific tissue beds. All α_1 -adrenoreceptor subtypes currently identified produce their intracellular effect by activation of the enzyme phospholipase C via the G_p protein. Phospholipase C hydrolyzes phosphoinositol and releases Ca^{2+} from intracytoplasmic stores, causing the contractile response seen in myocardial or vascular smooth muscle cells (Tables 4.9 and 4.10).

Table 4.10. G-protein-coupled receptor superfamily of genes and gene products in cardiac tissue^a

Receptor Type and Subtype	Location	G Protein	Biological Response	
Adrenergic	β_1	Myocardium	G_s	AC stimulation, positive inotropic and chronotropic responses
		Coronary vascular	G_2	AC stimulation, vasodilation(?)
	β_2	Myocardium	G_s	AC stimulation, positive inotropic and chronotropic responses
		Coronary vasculature(?)	G_s	AC stimulation, vasodilation(?)
	α_1	Myocardium	G_p	PI hydrolysis stimulation, positive inotropic response(?)
Coronary vasculature		G_p	PI stimulation, vasoconstriction	
Muscarinic	m_2	Myocardium	G_i	Shorten atrial action potential; slow sinus rate; slow AV conduction; AC inhibition, negative inotrope, and chronotrope
		Coronary smooth muscle	$G_p(?)$	PI stimulation, vasoconstriction
	m_3	Coronary endothelium	$G_p(?)$	EDRF production, GC stimulation, vasodilation

^aAC, adenylate cyclase; EDRF, endothelium-derived relaxing factor or nitric oxide; GC, guanylate cyclase; PI, phosphatidylinositol. Modified from Opie,¹⁰⁶ p. 164.

Three subtypes of α_2 -adrenoreceptors— α_{2A} , α_{2B} , and α_{2C} —have been identified by pharmacological studies, although the tissue distribution of these subtypes is unclear.⁸⁹ α_2 -Adrenoreceptors inhibit adenylate cyclase through the G_i protein. Inhibition of adenylate cyclase attenuates cAMP production in target cells. This mechanism is important in platelets and renal tubules; however, in vascular smooth muscle, an alternative signal transduction mechanism is responsible for the vasoconstrictor response. α_2 -Adrenoreceptors are located presynaptically and extrasynaptically in vascular smooth muscle. Stimulation of extrasynaptic α_2 -adrenoreceptors by α -adrenergic agonists activates a receptor-operated calcium channel that increases the concentration of calcium intracellularly, producing vascular smooth muscle contraction that complements the contractile effect of α_1 -adrenoreceptors activated by stimulation of sympathetic nerves. Because of their extrasynaptic location, α_2 -adrenoreceptors respond to circulating catecholamines, such as epinephrine and norepinephrine, and aid in maintaining generalized sympathetic vasoconstriction in response to catecholamine output from the adrenal gland. This later response is important in the fight-flight response that occurs in crisis situations such as trauma or hemorrhage.

The α_1 - and α_2 -adrenoreceptors coexist in the vasculature as described earlier.⁸⁷ There is a greater response to α_2 stimulation on the venous side of the circulation compared to the arterial side. Therefore, α_2 -adrenoreceptor-mediated vasoconstriction may be most important in mobilizing blood volume from veins, leading to an increase in cardiac filling, which is an important first step in increasing cardiac output during stress situations such as exercise or hemorrhage. Receptor-operated calcium channels in vascular smooth muscle can be blocked by calcium antagonists (e.g., verapamil, diltiazem, or nifedipine).⁸⁹

The α_1 - and α_2 -adrenoreceptors can cause complementary or antagonistic responses, depending on their location. For exam-

ple, norepinephrine stimulates α_1 -adrenoreceptors located on the postsynaptic cell membrane, causing contraction of vascular smooth muscle and vasoconstriction. Norepinephrine also binds to presynaptic α_2 -adrenoreceptors, producing a negative-feedback effect that decreases the release of norepinephrine from the nerve terminal. Thus, α_2 -adrenoreceptors help to modulate the vasoconstrictor response initiated by α_1 -postsynaptic-receptor stimulation. The α_2 -adrenoreceptors help to ensure that only a short-term vasoconstrictor response occurs after sympathetic nerve stimulation.

Dopamine is the immediate metabolic precursor of norepinephrine in adrenergic nerves and functions as a neurotransmitter in the CNS (Table 4.9).⁹⁰ Disorders of dopamine transmission in the CNS are recognized clinically in human patients as Parkinson's disease. Peripheral dopamine receptors (DA_1 and DA_2) are particularly important in regulating blood flow to the mesenteric and renal vascular beds. Postsynaptic DA_1 receptors in the renal and mesenteric vascular beds cause vasodilation, increasing perfusion to renal and splanchnic tissues. DA_2 receptors, located presynaptically on postganglionic sympathetic nerves, inhibit the release of norepinephrine, much like the presynaptic α_2 -adrenoreceptors.

Stimulation of postganglionic sympathetic fibers supplying vascular smooth muscle causes not only the release of the neurotransmitter norepinephrine, but also the release of the cotransmitter neuropeptide Y.^{90,91} Neuropeptide Y is present in vesicles contained in postganglionic sympathetic nerve terminals, is synergistic with the effects of norepinephrine on the peripheral vasculature, and produces vasoconstriction. Neuropeptide Y is also found in the adrenal medulla. Circulating levels of neuropeptide Y inhibit renin release and stimulate the release of ANP. The role of neuropeptide Y in cardiovascular regulation has not been fully characterized; however, it may be an important mediator in the central control of blood pressure.

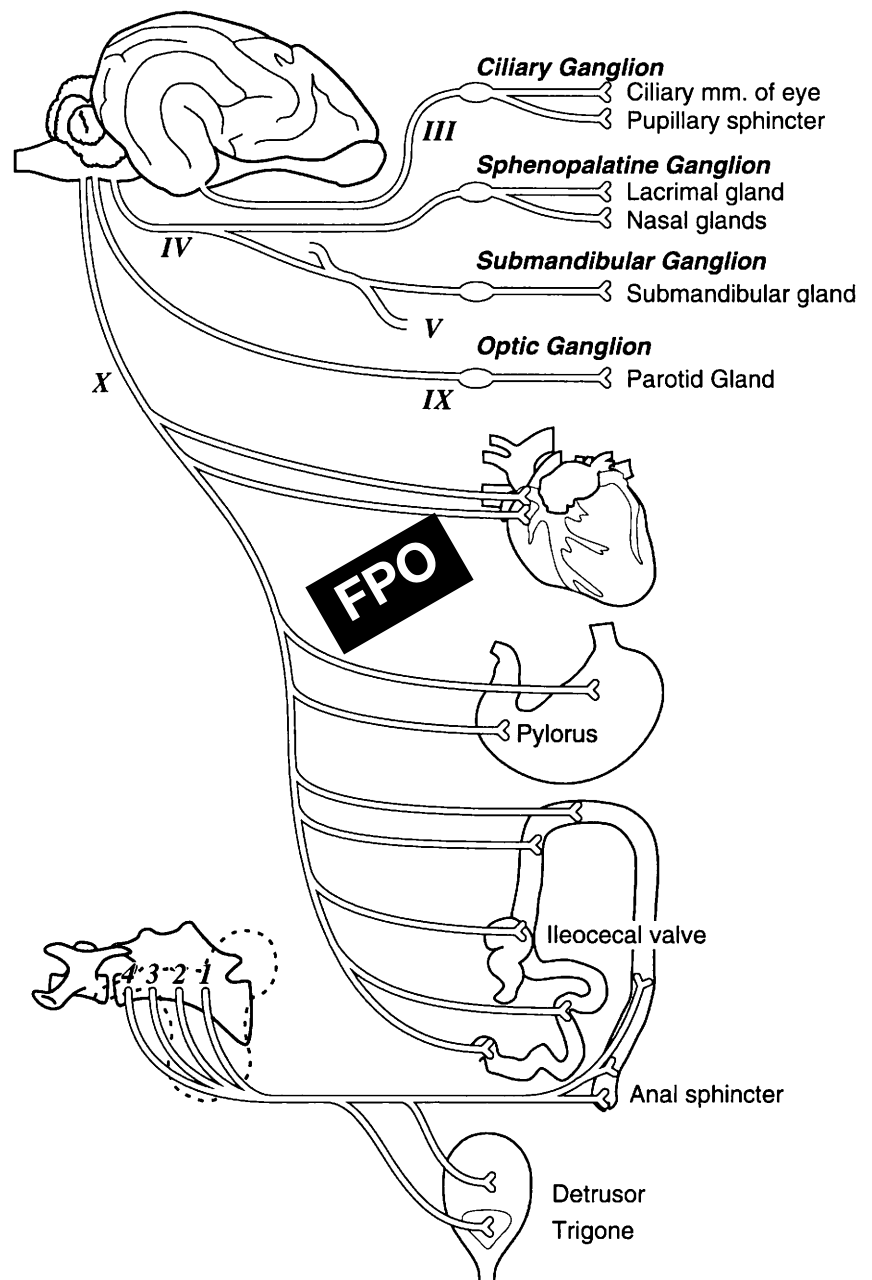

Fig. 4.34. The parasympathetic nervous system. Note the distribution of cranial nerves III, IV, V, IX, and X. mm, muscles. Modified from Guyton,¹⁰⁵ p. 669.

Sympathetic cholinergic nerve fibers originate in the cerebral cortex and send descending fibers to the spinal cord. These nerve fibers synapse in the sympathetic ganglia and send postganglionic fibers to precapillary vessels in skeletal muscle.⁸³ Postganglionic cholinergic sympathetic nerve fibers are activated only during times of high sympathetic tone (fear, pain, or exercise) and release acetylcholine, which produces vasodilation in skeletal muscle.

Parasympathetic Nervous System

The parasympathetic nervous system (PNS) originates from two sites within the CNS: cervical spinal cord and sacral spinal cord (Fig. 4.34). Long preganglionic parasympathetic nerve fibers located in the CNS synapse with relatively short postganglionic

parasympathetic neurons in ganglia located in the target organ. The cranial portion of the parasympathetic nervous system originates in the medulla oblongata. Axons travel via the vagus nerve to synapse with postganglionic parasympathetic nerves that terminate in the heart and blood vessels.^{76,83}

Parasympathetic Neurotransmission

Acetylcholine is the neurotransmitter released at autonomic ganglia and from postganglionic parasympathetic nerves. Cholinergic nerves actively transport choline from the extracellular fluid into the neural axoplasm, where it is acted upon by the enzyme choline acetyltransferase, combined with acetyl coenzyme A, and converted to acetylcholine, which like norepinephrine is stored in vesicles within the nerve. Cholinergic nerve ac-

tion potentials increase intracellular calcium, causing vesicular and nerve cell membrane fusion and the release of acetylcholine into the synaptic cleft. Acetylcholine binds to specific receptors, mediating a cellular response that varies with the tissue innervated and the type of cholinergic receptor involved. The actions of acetylcholine are rapidly terminated by hydrolysis into choline and acetic acid by the enzyme acetylcholinesterase. The acetylcholine that diffuses out of the synaptic cleft and into the extracellular fluid or plasma is hydrolyzed by plasma butyrylcholinesterase (pseudocholinesterase). The choline produced from this metabolism is rapidly taken up by the nerve cell and used in the resynthesis of acetylcholine.

Cholinoreceptors

Cholinergic receptors are either nicotinic or muscarinic and are totally unrelated in location, structure, and function (Tables 4.9 and 4.10). Nicotinic receptors are located in autonomic ganglia, in the adrenal medulla, and at the neuromuscular junction of skeletal muscle. Muscarinic receptors are located at postganglionic parasympathetic nerve terminals.⁹²

Nicotinic receptors are pentameric membrane proteins that form a nonselective ion channel in the cell membrane. Postsynaptic nicotinic receptors, located in the autonomic ganglia or the neuromuscular junction, when stimulated by acetylcholine, open their ion channel, allowing the flow of cations into the nerve or muscle cell, resulting in depolarization and ultimately nerve cell transmission of an electric impulse or muscular contraction. Nicotinic receptors are subclassified into N_G receptors, located at autonomic ganglia, and N_S receptors, located in the neuromuscular junction and within the CNS.

Muscarinic receptors are located in the autonomic effector organs of the parasympathetic nervous system, for example, the heart, smooth muscle, and the exocrine glands.⁹² They are G protein coupled and show more homology to adrenergic and dopaminergic receptors than to the nicotinic cholinergic receptors. Five different cholinergic receptors have been distinguished through molecular binding techniques. Muscarinic receptors m_1 , m_3 , and m_5 are functionally similar and, when bound to their respective G proteins, stimulate phosphoinositol hydrolysis through activation of phospholipase C (Table 4.10). Muscarinic receptors m_2 and m_4 show similarity in that they both attenuate the actions of adenylate cyclase intracellularly.

The vagus nerve innervates the sinoatrial node, the atrial myocardium, the atrioventricular node, and to a much lesser extent the ventricular myocardium. Stimulation of m_2 receptors by acetylcholine activates several different membrane G proteins, resulting in inhibition of adenylate cyclase, activation of potassium channels, and activation of phospholipase C, which hydrolyzes phosphoinositol. These effects cause a decrease in the slope of phase 4 diastolic depolarization in pacemaker and subsidiary automatic tissues, and hyperpolarization of cardiac cell membranes through activation of membrane potassium channels. Heart rate is decreased, as are the rate of conduction of impulses through the atrioventricular node and cardiac contractility. High levels of parasympathetic tone can produce atrioventricular block (first-degree, second-degree, and third-degree heart block) and

temporary cardiac asystole. Stimulation of the parasympathetic nervous system produces minimal effects on most peripheral blood vessels. Acetylcholine binds to m_2 receptors in vessels, which mediates an endothelium-dependent vasorelaxation (Fig. 4.35).

The sacral division of the parasympathetic nervous system has preganglionic nerve cell bodies located in the intermediolateral column of the spinal cord.^{76,83} Parasympathetic nerves in this region congregate to form the *nervi erigentes* or pelvic nerves that innervate the intestines, colon, rectum, bladder, and genitalia (Fig. 4.34). Stimulation of the parasympathetic nerves also causes increased blood flow to salivary glands and genital erectile tissue.

Humoral Mechanisms

The autonomic nervous system functions to produce acute changes in cardiovascular function that can be large in magnitude, but are generally brief. Sustained changes in cardiopulmonary function are produced by humoral mechanisms (Table 4.7).⁷⁵⁻⁷⁷ The adrenal medulla is a modified sympathetic ganglion innervated by preganglionic sympathetic fibers and is part of the sympathetic nervous system. The neuronal cells of the adrenal medulla, rather than sending axons to target organs, release the neurotransmitters, epinephrine and norepinephrine, into the circulation. Precipitating factors for the release of catecholamines from the adrenal medulla include pain, trauma, hypovolemia, hypotension, hypoxia, hypothermia, hypoglycemia, exercise stress, and fear (fight-flight). Circulating catecholamines produce a variety of effects, including increases in metabolic rate, glycogenolysis in the liver and skeletal muscle, gluconeogenesis in the liver, and an increase in the availability of free fatty acids, an important nutrient source for the myocardium. Circulating catecholamines increase heart rate and cardiac contractility, dilate vascular beds in skeletal and cardiac muscle, and constrict splanchnic and cutaneous arterioles, diminishing blood supply to organs that are less essential during a fight-flight response.⁶⁶ The actions of the adrenal medulla are complementary to the effects of sympathetic nerve stimulation. Together the autonomic nervous system and humoral mechanisms provide both rapid (nervous system) and sustained (humoral) responses to stressful situations.^{75,76,83}

The kidney is the major site for activation of the renin-angiotensin system.⁷⁵ Renin is produced in the kidney during sodium depletion, decreases in extracellular fluid volume, or increases in sympathetic output (Table 4.11). Secretion of renin into the systemic circulation converts circulating angiotensinogen, produced by the liver, to angiotensin I. Angiotensin I is converted to angiotensin II by an angiotensin-converting enzyme that is present in pulmonary vascular endothelium. Angiotensin II produces arteriolar constriction, producing increases in blood pressure, and stimulates the adrenal cortex to release aldosterone, a hormone that causes renal reabsorption of Na^+ and water, effectively increasing thirst and the extracellular fluid volume (Fig. 4.36).

The hypothalamus is directly involved in the central neural

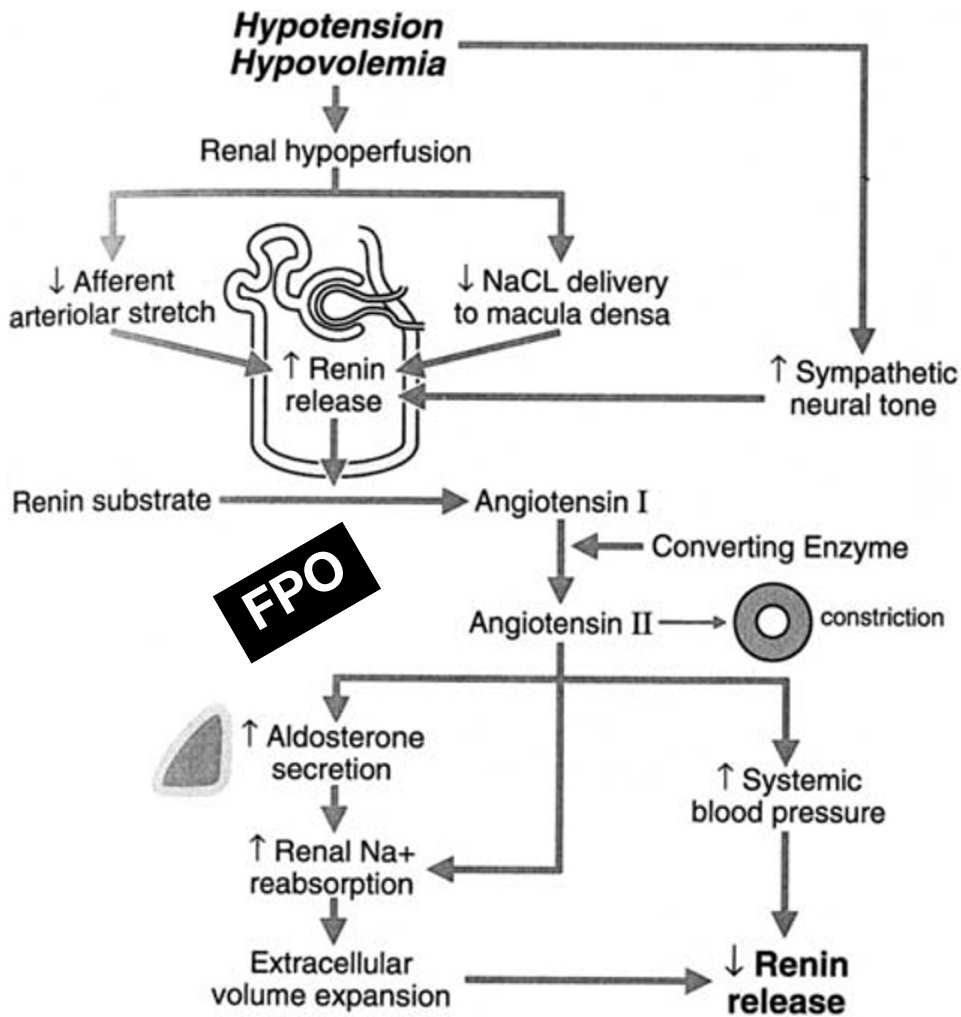

Fig. 4.36. The renin-angiotensin system. Note that either hypotension or hypovolemia can cause renal hypoperfusion and activation of the sympathetic nervous system, which increase renal renin release.

nomenon, also termed *reactive hyperemia*, occurs in arterioles less than 25 μm in diameter. The myogenic mechanism is responsible for reactive hyperemia after short occlusion periods (<30 s). As flow returns to the previously occluded arteriole, blood flow velocity increases, which increases wall shear stress, causing the release of nitric oxide from the vascular endothelium.⁹³ The metabolic component of reactive hyperemia occurs after longer periods of occlusion (30 s). Decreases in oxygen tension release a vasodilatory prostaglandin that maintains blood flow until normal oxygen tension is reestablished. Endothelial damage in small arterioles eliminates the reactive hyperemic response altogether, since both nitric oxide and prostaglandins are products of vascular endothelial cells.^{66,79,82,93} Hyperbaric oxygen conditions also eliminate the metabolic component of reactive hyperemia by maintaining elevated oxygen tensions in tissues despite vascular occlusion. Stretch of vascular smooth muscle opposes the myogenic vasodilator response seen in larger vessels (Bayliss effect).⁶⁶ The proposed mechanism for the Bayliss effect is a pressure-induced depolarization of the endothelial cell mediated through an inwardly rectifying potassium channel. The effects of anesthetic drugs on reactive hyperemia and the Bayliss effect are incompletely understood and highly variable.

Capillary blood flow is linked to the rate of tissue metabolism and oxygen tension. The exact mechanism involved in this linkage is not completely understood, although a number of mechanisms may be responsible for regulating capillary blood flow.⁶⁸ The number of open precapillary sphincters is approximately proportional to the level of metabolic activity in the tissue supplied. As metabolic activity increases, the local oxygen tension decreases until a critical level of tissue hypoxia occurs, inducing vasodilation. Precapillary sphincters are also responsive to mediators that are released as by-products of tissue metabolism, such as lactic acid, carbon dioxide, and potassium.

Peptides and other substances are important in regulating tissue blood flow (Table 4.12). The actions of local enzymes produce kinins such as bradykinin from the substrate kallikrein. Kinins produce vasodilatory effects that are short-lived because of rapid inactivation by peptidases in the plasma. Arachidonic acid metabolism produces a variety of prostaglandins that tend to be compartmentalized and produce very specific local effects. Stimulation of arachidonic acid metabolism in the pulmonary vasculature results in the production of the vasodilatory prostaglandin prostacyclin (prostaglandin I_2 [PGI_2]). Renal hypoperfusion initiates the production of PGI_2 , which acts to re-

Fig. 4.37. The relationship between blood flow and perfusion pressure in peripheral vascular beds is characterized by an autoregulatory range over which blood flow changes very little regardless of increases or decreases in perfusion pressure. The normal autoregulatory range for most vascular beds is between 60 and 180 mm Hg. Some vascular beds (brain, gut, and skeletal muscle) acutely collapse when the perfusion pressure approximates 15 to 30 mm Hg (critical closing pressure). Modified from Shepherd and Vanhoutte,¹⁰² p. 95.

store renal blood flow, urine volume, and sodium excretion. The preanesthetic administration of nonsteroidal anti-inflammatory analgesics (NSAIDs) may interfere with the production of these important prostaglandins by cyclooxygenase enzyme inhibition. There are specific receptor sites on vascular endothelium for a variety of agonists (including acetylcholine, bradykinin, and histamine) that when bound by the appropriate agonist induce the formation and release of nitric oxide. Nitric oxide is rapidly deactivated by hemoglobin and therefore is only important as a local mediator. Nitric oxide relaxes vascular smooth muscle through stimulation of guanylate cyclase, increasing intracellular cGMP (Fig. 4.35). Vascular endothelial cells also produce a po-

tent vasoconstrictor substance known as *endothelin* that acts upon endothelin receptors on vascular smooth muscle cells.^{66,83} Endothelin is released by the endothelium in response to increased intraluminal pressure, contributing to the Bayliss effect, and is selective for certain vascular beds, including coronary vessels, renal afferent arteries, and venous capacitance vessels. It is both a positive inotrope and a chronotrope. Endothelin increases plasma levels of other humoral mediators, such as atrial natriuretic factor, renin, aldosterone, and circulating catecholamines. Endothelin receptors have been located in several areas of the brain involved in modulation of autonomic nervous system efferent activity (Table 4.12).

Diseases of the Cardiovascular System

Heart Disease

Historically, heart disease has been categorized based on cause, structural defect, and functional changes. Heart disease can produce heart failure, which is characterized by neurohumoral activation, sodium retention, and tissue proliferation (cardiac hypertrophy). One clinically useful method for categorizing heart disease is based on clinical signs (exercise intolerance, ascites, edema, cough, etc.). *Acute* and *chronic heart failure* are differentiated on the basis of the rapidity of development of clinical signs. Chronic heart failure usually takes many months to years to develop and is associated with a variety of compensatory neuroendocrine, physiological, and pathophysiological adjustments. *Congenital* or *acquired* heart disease identifies the condition as being present since birth or developing in association with a specific developing cardiac lesion. Congenital or acquired heart disease can be acute or chronic. *Right-sided* or *left-sided heart failure* identifies the right or left ventricle as the primary cause of heart failure. *Systolic dysfunction* and *diastolic dysfunction* refer to the phase of the cardiac cycle that is most severely compromised. *Forward heart failure* refers to cardiac diseases that cause a low cardiac output secondary to an impediment to ventricular ejection (increased afterload), decreased inotropy, or both. *Backward failure* refers to situations that cause pulmonary and

Table 4.12. Summary of factors affecting the caliber of the arterioles

Constriction	Dilation
Increased noradrenergic discharge	Decreased noradrenergic discharge
Circulating catecholamines (except epinephrine in skeletal muscle and liver)	Circulating epinephrine in skeletal muscle and liver
Circulating angiotensin II	Circulating atrial natriuretic peptide
Circulating arginine vasopressin (ADH)	Activation of cholinergic dilators in skeletal muscle
Locally released serotonin	Bradykinin
Endothelin I	Histamine
Neuropeptide Y	Substance P (axon reflex)
Circulating Na ⁺ -K ⁺ ATPase inhibitor	Nitric oxide and endothelium-derived relaxing factor
Decreased local temperature	Prostacyclin and prostaglandin E ₂
	Increased carbon dioxide tension
	Decreased pH
	Lactate, potassium ions, adenosine, etc.
	Increased local temperature

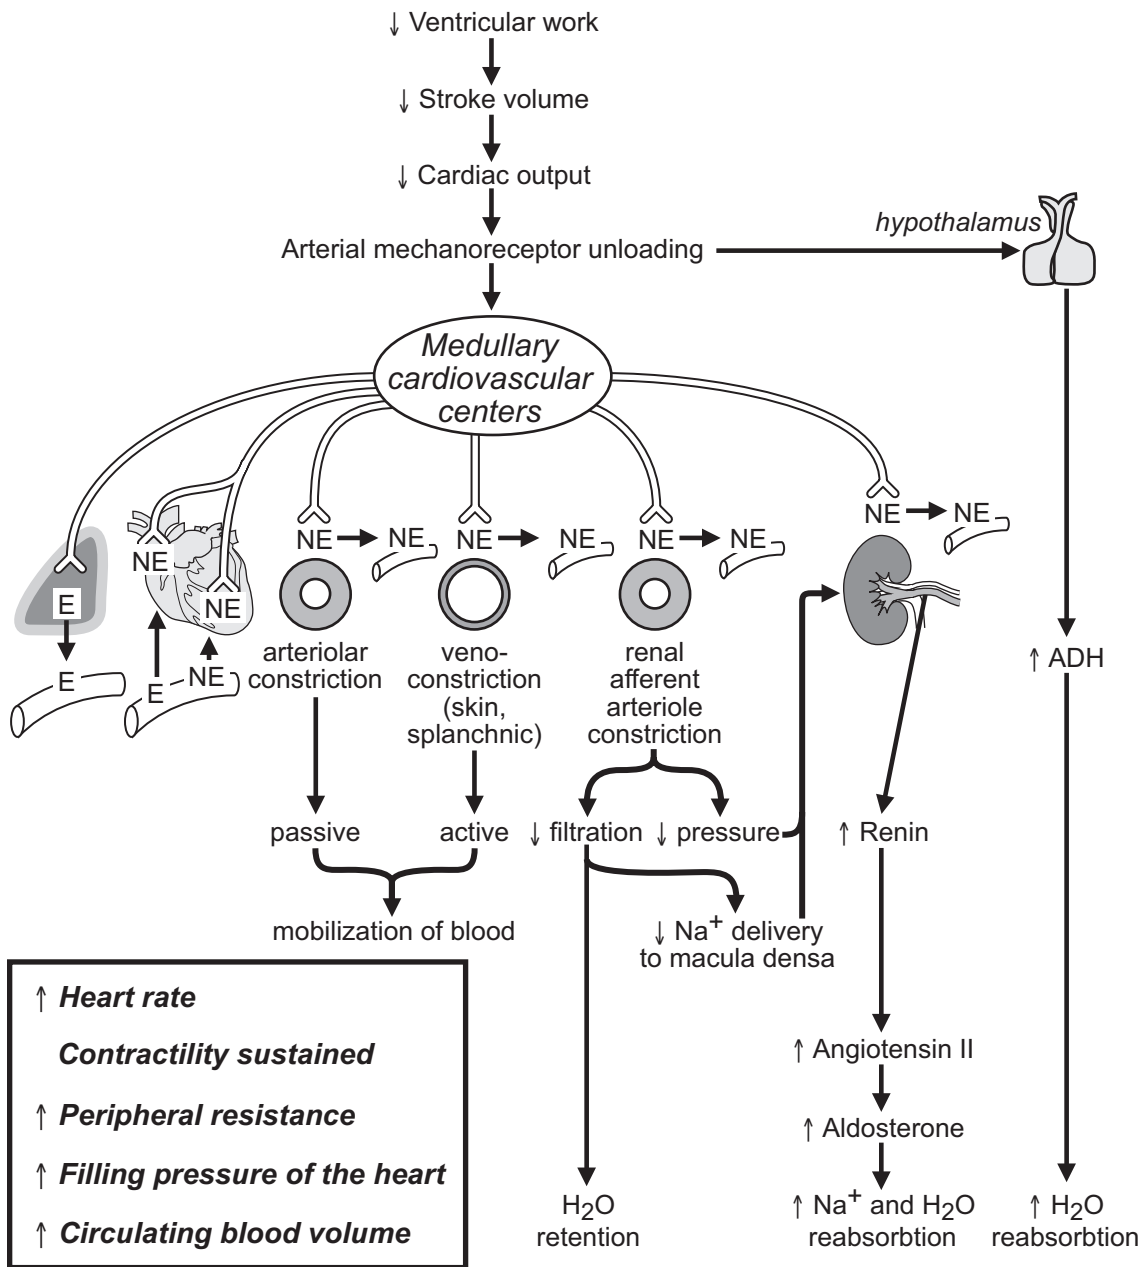

Fig. 4.38. Reflex adjustments to heart failure and decreased ventricular work include increases in heart rate, peripheral vascular resistance, vascular capacity, filling pressure of the heart, and circulating blood volume. Cardiac contractility is sustained by increases in sympathetic tone. These changes help to maintain cardiac output. ADH, antidiuretic hormone; E, epinephrine; and NE, norepinephrine. Modified from Shepherd and Vanhoutte,¹⁰² p. 259.

systemic venous congestion (congestive heart failure). *Low output failure* occurs when cardiac output is below normal and *high output failure* when (and regardless of cardiac contractile function) cardiac output is above normal (e.g., septic shock). It should be clear that the terms that have evolved to categorize heart failure (acute, chronic; right-sided, left-sided; systolic, diastolic; forward, backward; and low output or high output) are for the most part descriptive and that an appreciation of their meaning must be considered in association with the pathophysiological compensatory changes that occur.

Heart disease from any cause usually progresses through three phases: overload (excessive work), compensatory, and pathological.⁹⁴ Whatever the inciting cause, ventricular overload brought about by excessive work leads to increases in both the oxygen and the nutrient requirements of the heart. Initial compensatory changes include increases in sympathetic tone and a variety of neurohumoral responses that act to sustain or increase cardiac inotropy and promote the retention of salt and water (Fig. 4.38). These responses are usually followed by compensatory ventricular hypertrophy associated with decreases in both the rate of ven-

tricular pressure development and the rate of relaxation. The pathological phase of heart failure exists when an abnormality in cardiac function and excessive or maladaptive compensatory responses become responsible for a decrease in cardiac output to a degree that is insufficient to meet the oxygen and nutrient requirements of metabolizing tissues or exercising muscle. It is important to realize that this definition incorporates situations in which the heart may be contracting normally or be hypercontractile. For example, cardiac output may be decreased during sinus tachycardia or bradycardia, cardiac arrhythmias, and the initial stages of valvular insufficiency (mitral insufficiency). Decrease in cardiac contractile performance is only one potential cause for a decrease in cardiac output and should be differentiated from other potential causes of heart failure in order to provide appropriate therapy and prevent drug-induced complications.

Ultimately, failure of the ventricular myocardium is caused by pressure overload, volume overload, or primary myocardial disease (cardiomyopathy). The cardiomyopathies have been further categorized as hypertrophic, dilated, restrictive (infiltrative myocardial disease), or constrictive (pericardial disease).⁹⁴ The cause for many forms of hypertrophic and dilated cardiomyopathy remains unknown. The signal for ventricular hypertrophy, although uncertain, is probably multifactorial, involving stretch-activated ion channels, increased ventricular tension, adrenergic factors, increased oxygen consumption (oxygen supply/demand imbalance), and ATP use or increases in the quantity of metabolic breakdown products. Regardless of stimulus, increased work initiates the production of growth factors that, through various proto-oncogenes (*c-fos* and *m-myc*) and in conjunction with the production of heat-shock proteins (HSP-70), stimulate transcription, variably change myofibrillar isoform ratios from fast to slow (V_1 to V_3), and increase cell growth.^{94,95} Clinically and experimentally, diseases that produce sustained pressure overload (aortic and pulmonic stenosis and hypertension) cause concentric ventricular hypertrophy, which is characterized by marked increases in ventricular wall thickness without increases in ventricular volume. Heart disease that is caused by volume overload is generally the result of valvular regurgitation (aortic or mitral incompetence) or congenital defects (atrial or ventricular septal defect or patent ductus arteriosus) and produces longitudinal or so-called eccentric hypertrophy. Longitudinal hypertrophy is characterized by increases in chamber volume without an increase in wall thickness. The type of ventricular hypertrophy that develops is governed by processes that minimize myocardial oxygen consumption and work and maintain or maximize ventricular efficiency. Regardless, myocardial hypertrophy produces cellular changes that interfere with normal cellular metabolism and predisposes patients to systolic and diastolic dysfunction (Table 4.13). These intracellular changes and resultant abnormalities in ventricular function are further exacerbated by a decrease in capillary surface area to cell volume (capillary inadequacy), thereby limiting oxygen delivery, which increases myocardial fibrosis. Decreases in oxygen delivery, whether brought about by capillary inadequacy, low cardiac output, or anemia, can result in myocardial ischemia, tissue hypoxia, and lactic acidosis (Fig. 4.39). Subendocardial ischemia is particularly common in pa-

Fig. 4.39. Oxygen consumption (VO_2) is normally not limited by oxygen delivery ($DO_2 = CO \times CaO_2$) and oxygen extraction ($OE = CaO_2 - CvO_2$). However, decreases in cardiac output (blood flow) to critically low values (e.g., hemorrhagic shock or heart failure) produce situations where VO_2 can become DO_2 dependent. Oxygen deprivation (anaerobic metabolism) generates lactic acid, resulting in metabolic acidosis. CaO_2 , arterial oxygen content; CO , cardiac output; and CvO_2 , venous oxygen content.

Table 4.13. Receptors and signaling systems in heart failure

1. Receptors
β_1 -Adrenergic receptors downgraded, i.e., density decreased
β_2 -Adrenergic receptor density unchanged, function uncoupling
α_1 -Adrenergic receptors have increased activity
These receptors actually decrease in density, but affinity is considerably increased
2. G proteins
G_i increased with inhibition of adenylate cyclase
G_s normal or decreased
3. Adenylate cyclase
Decreased cyclase activity with less production of cAMP, related to G_i increase; still responds directly to forskolin
4. cAMP
Production impaired, presumably due to adenylate cyclase inhibition
5. Calcium transients
Transients with low peak and delayed fall in diastole
Calcium uptake by sarcoplasmic reticulum unchanged or decreased in situ
Calcium release by sarcoplasmic reticulum increased
Decreased myofibrillae
Sensitivity to calcium ion
Activity of single calcium channels is normal
Amount of calcium entry via calcium channel may be abnormal

cAMP, cyclic adenosine monophosphate.

Modified from Opie,¹⁰⁶ p. 409.

Fig. 4.40. During normal conditions, the cardiac action potential is transmitted through modified muscle fibers (specialized fibers) to the atrial and ventricular muscle cells, causing depolarization followed by repolarization. The action potential is not perpetuated because the surrounding tissues at the end point of activation remain refractory to reactivation (normal). During various disease processes (ischemia, hypoxia, inflammation, or fibrosis) and in the presence of some drugs (intravenous and inhalation anesthetics), the action potential may be blocked (unidirectional block) as it travels in an antegrade direction through cardiac tissue (1). If the electrical impulse is delayed (conduction delay) as it travels through adjacent tissue, it may reenter and be conducted in a retrograde direction (retrograde conduction), thereby reactivating the same tissue segment (2) or more peripheral tissue segments (3). The longer the conduction delay, the more likely it is that the electric impulse will find the tissue to be reentered excitable (not refractory) and the greater the likelihood for reentry (dotted lines). Continuous reentry of cardiac tissue is called *circus movement* and can lead to sustained cardiac rhythm disturbances, including ventricular fibrillation. Reentry involving a small amount (several square millimeters) of cardiac tissue is called *microreentry*, whereas reentry that incorporates the specialized conducting system of the heart is called *macroreentry*.

tients with heart failure, because subendocardial perfusion is influenced by the difference between aortic diastolic pressure and ventricular end-diastolic pressure and the ventricular wall tension. Myocardial ischemia in turn causes abnormal cellular calcium cycling, intracellular calcium overload, oxygen wastage, cardiac arrhythmias, sarcomere contracture, and eventually cell death. Familiarity with the pathophysiological mechanisms of heart failure and cellular metabolism during heart failure and ischemia aids in the selection of appropriate preanesthetic and anesthetic drugs and suggests potential approaches for therapy.⁴⁴

Cardiac Arrhythmias

Cardiac arrhythmias include abnormalities in cardiac rate, rhythm, site of origin of the cardiac impulse, or pattern of atrial or ventricular depolarization. The cause for cardiac arrhythmias in intact hearts is attributed to abnormalities in automaticity, conduction, or both (Table 4.14). Ultimately, all changes in cardiac electric activity can be thought of in terms of alterations in one or more of the active or passive electrophysiological properties of the cell membrane.²⁴ Increases or decreases in normal automatic-

ity in spontaneously beating hearts, for example, result from changes in phase 4 depolarization, which is electrically initiated by calcium (I_{Ca}) and sodium (I_f) currents in sinoatrial and atrioventricular node or sodium (I_f) and potassium (I_{K1}) currents in Purkinje tissue. The ECG appearance of abnormal impulses due to abnormal automaticity, however, are most likely caused by changes in I_K or I_{Ca} . Abnormal electric impulses that occur as a direct result of prior electric activity are referred to as “triggered” and are in most instances caused by defects in I_{Ca} , leading to the development of both early (prior to repolarization) or delayed (after repolarization) afterpotentials arising from the cell membrane.²² Abnormal heart rhythm caused by abnormal conduction and random or ordered reentry can be caused by spatial differences in membrane refractory periods or discontinuous anisotropic (dissimilar in all directions) propagation (Fig. 4.40). The latter electrophysiological abnormality can occur as a result of cellular uncoupling owing to a decreased number of effective cellular connections (gap junctions) caused by fibrosis, ischemia, or drug effects.^{24,26,27} Regardless of cause, changes in either the active properties (ion-current movements) or the passive proper-

Table 4.14. Classification of arrhythmogenic mechanisms at the cellular level in terms of vulnerable parameters

Mechanisms of Arrhythmia	Vulnerable Parameter (Antiarrhythmic Effect)	Ionic Currents Most Likely to Modulate Vulnerable Parameter
Automaticity		
A. Enhanced normal automaticity	Phase 4 depolarization (decrease)	I_f ; I_{Ca-T} (block)
B. Abnormal automaticity	Maximum diastolic potential (hyperpolarize) or phase 4 depolarization (decrease)	I_{KACH} (activate) I_X ; I_{KACH} (activate) I_{Ca-L} ; I_{Na} (block)
Triggered activity		
A. Early afterdepolarizations (EADs)	Action-potential duration (shorten) or EADs (suppress)	I_X ; (activate)
B. Delayed afterdepolarizations (DADs)	Calcium overload (unload) or DADs (suppress)	I_{Ca-L} ; I_{Na} (block) I_{Ca-L} (block) I_{Ca-L} ; I_{Na} (block)
Conduction		
Reentry dependent on sodium channels		
A. Primary impaired conduction (long excitable gap)	Excitability and conduction (decrease)	I_{Na} (block)
B. Conduction encroaching on refractoriness (short excitable gap)	Effective refractory period (prolong)	I_K (block)
Other mechanisms		
A. Reentry dependent on calcium channels	Excitability and conduction (decrease)	I_{Ca-L} (block)
B. Reflection	Excitability (decrease)	I_{Na} ; I_{Ca-L} (block)
C. Parasystole	Phase 4 depolarization (decrease)	I_f (block)

Modified from the Task Force of the Working Group on Arrhythmias of the European Society of Cardiology.²⁴

ties (membrane characteristics) of the cardiac cell membrane can produce a wide array of cardiac rate or rhythm disturbances that are recordable at the body surface. Anesthetic drugs and various anesthetic techniques produce marked changes in cardiac cellular active and passive electrophysiological properties, resulting in the development of cardiac arrhythmias (Table 4.15). The inhalation anesthetics in particular are known to shorten the action potential and decrease refractoriness, thereby predisposing patients to conduction abnormalities and reentry. Halothane sensitizes the myocardium to catecholamines. Both α_1 - and β_1 -adrenoreceptors are involved in the cardiac sensitization phenomena.⁹⁶ Finally, most anesthetic drugs can produce pronounced effects on cardiac rate and rhythm because of their general membrane-depressant effects.

Vascular Disease

Primary diseases of the vascular system are not well recognized in veterinary medicine.⁹⁷ Arterial hypertension occurs in dogs and cats secondary to renal disease or endocrine disorders. Systemic hypertension is defined as a systolic blood pressure above 160 mm Hg and a diastolic blood pressure above 95 mm Hg. Chronic renal disease, especially glomerular disease, can be associated with systemic hypertension secondary to a decrease in renal blood flow and activation of the renin-angiotensin system, release of aldosterone, and an increase in sympathetic efferent activity.⁷⁵ Systemic vasoconstriction and renal retention of

sodium water contribute to the elevation of arterial blood pressure. Hyperadrenocorticism may cause systemic hypertension because mineralocorticoids cause retention of sodium and water, expanding the circulating blood volume. Pheochromocytomas secrete an excess of circulating catecholamines and perhaps neuropeptide Y, which induces systemic vasoconstriction, elevating blood pressure. No matter what the cause of systemic hypertension, myocardial work increases and can induce left ventricular hypertrophy and a decrease in cardiovascular reserve.

Canine heartworm disease can affect dogs and, rarely, cats.⁹⁷ Myointimal proliferation occurs in the pulmonary arteries, narrowing their lumen. Cellular debris from dying worms initiate the formation of thromboemboli that obstruct pulmonary arteries. Pulmonary vascular endothelial damage causes pulmonary vasoconstriction secondary to the loss of endothelium-derived relaxant factors. Right-sided congestive heart failure often develops secondary to the elevated pulmonary vascular resistance. Oxygen therapy (preoxygenation) and cardiovascular support may be required for heartworm patients prior to anesthesia.

Arteriovenous malformations cause an elevation in venous pressure that ultimately contributes to dilation and tortuosity of the vein. The arterial pressure downstream from the fistula may be decreased, impairing tissue perfusion. Arteriovenous malformations increase myocardial work by producing volume overload, similar to a ventricular septal defect or mitral insufficiency. The surgical correction of an arteriovenous fistula can produce reflex bradycardia (Branham's sign) at the time of shunt ligation.

Table 4.15. Cardiac arrhythmias produced by preanesthetic and anesthetic drugs

Drugs	Arrhythmia
Anticholinergics	
Atropine	Sinus tachycardia
Glycopyrrolate	Sinus tachycardia
Phenothiazine	
Acepromazine	Sinus tachycardia Sinus bradycardia (rarely)
α_2 -Adrenergic agonists	
Xylazine	Sinus bradycardia, first-degree and second-degree atrioventricular block, third-degree atrioventricular block (rarely), and sinus arrest (rarely)
Detomidine	
Medetomidine	
Romifidine	
Opioids	Sinus bradycardia
Morphine	First-degree and second-degree atrioventricular block
Oxymorphone	
Hydromorphone	
Fentanyl	
Benzodiazepines	
Diazepam	Arrhythmias rarely observed; sinus bradycardia and temporary cardiac arrest
Midazolam	
Intravenous anesthetics	
Thiobarbiturates (thiamylal and thiopental)	Bradyarrhythmias
Ketamine	Premature ventricular depolarizations
Other injectables (propofol, etomidate, and alfaxolone are most likely to cause bradycardias)	Ventricular tachycardia Sinus tachycardia and ventricular arrhythmias Sinus tachycardia and bradyarrhythmias (rarely)
Inhalation anesthetics	
Halothane	Sinus bradycardia
Isoflurane	Bradyarrhythmias
Sevoflurane	Premature ventricular depolarizations
Desflurane	Ventricular tachycardia Ventricular fibrillation or cardiac arrest (Note: Halothane sensitizes the myocardium to catecholamines.)

The same phenomenon can be seen at the time of ligation of a patent ductus arteriosus due to the sudden increase in arterial pressure and the bradycardia induced by arterial baroreceptors. The administration of antimuscarinics can minimize or prevent bradycardia at this critical time.

Blood Components and Volume

Preservation of the integrity of the circulation is a responsibility that many humoral factors share. The effects of drugs used for chemical restraint and anesthesia (phenothiazines, butyrophenones, barbiturates, inhalation anesthetics) on clotting time and bleeding time are incompletely understood, but generally considered to be important in most animals. Exaggeration of bleeding disorders most frequently occurs in animals with thrombocytopenia or hereditary coagulation-factor deficiencies (von Willebrand's disease). Many drugs inhibit platelet aggregation, which normally contributes significantly to hemostasis.⁹⁸ Phenothiazines, barbiturates, and halothane decrease platelet numbers and inhibit platelet aggregation, although little change in gross

hemostasis occurs. Decreases in platelet and other circulating cell (red and white cells) numbers have been attributed to hemodilution secondary to hypotension, margination of white blood cells along vessel walls, and sequestration of RBCs in the spleen. Finally, it should be recognized that most intravenous and inhalation anesthetics are known to suppress the immune system, which is an effect that is generally short-lived but may become clinically relevant in immunosuppressed animals.⁹⁹

The most important function of the cardiovascular system is to deliver oxygen and nutrients to metabolizing tissues.³ The blood volume and hematocrit are of primary concern in maintaining adequate oxygen delivery, providing cardiac output and the distribution of blood flow are maintained within normal limits. The importance of adequate oxygen delivery (DO_2) cannot be overemphasized, because reduced oxygen consumption (VO_2) is known to be the common denominator in all forms of shock, including hemorrhagic and anemic shock (Fig. 4.39). There are multiple reasons for this: First, oxygen transport is the major function of the cardiovascular system; second, oxygen is the most flow-dependent blood constituent because it has the highest

extraction ratio of any substance carried in the blood; third, oxygen cannot be stored; and, finally, oxygen transport and consumption are related to survival. Indeed, mortality is virtually 100% assured when the cumulative VO_2 deficit following hypoxemia, hemorrhage, or anemia exceeds 140 mL/kg.

Experimentally, hemorrhagic and anemic shock models are used to mimic clinical conditions where DO_2 and VO_2 are decreased. Popular models include a 50% to 75% decrease in blood volume (40 to 60 mL/kg; fixed-volume model), withdrawal of blood to a predetermined blood pressure (e.g., 40 mm Hg) and maintenance of this pressure for 2 h (fixed-pressure or Wigger's model), and a decrease of the hematocrit to 8% to 12% by acute exchange transfusion with crystalloid (lactated Ringer's) or colloidal (6% dextran 70) solutions (normoxic isovolemic hemodilution). These models produce acute reductions in DO_2 and a marked reduction in VO_2 , which, if not treated, result in death (irreversible shock). Reductions in VO_2 therefore can be viewed as the ultimate regulatory factor responsible for cardiovascular compensatory responses, including increases in heart rate, cardiac contractility, cardiac output, and vascular tone. Other changes in cardiovascular function are determined by the primary precipitating event. Hemodilution, for example, produces a marked decrease in blood viscosity, increases in stroke volume, and a redistribution of blood flow to the coronary and cerebral blood vessels.¹⁷ A decrease in blood viscosity facilitates capillary blood flow and can increase cardiac output by decreasing afterload. These hemodynamic changes have encouraged the clinical use of mild to moderate normovolemic hemodilution prior to anesthesia and surgery (Hb = 6 to 10 g/dL) in order to improve cardiac output, peripheral perfusion, and DO_2 . The effects of anesthetic and inotropic drugs on VO_2 , DO_2 , cardiac output, and the distribution of blood flow should be considered prior to their use in any hypovolemic, anemic, or normovolemic anemic patients.^{100,101} Fortunately, during anesthesia most patients' overall VO_2 is reduced because of decreasing body temperature and metabolism.

Introduction

Maintenance of adequate respiratory function is a prime requirement for safe anesthesia. Inadequate tissue oxygenation may lead to an acute cessation of vital organ function, especially of the brain or myocardium, and an anesthetic fatality. Excessive elevations in arterial carbon dioxide (CO_2) tensions (arterial CO_2 partial pressure [PaCO_2]) or sustained moderate hypoxemia may produce some level of organ dysfunction, which contributes to a less than optimum postanesthetic recovery. Delayed recovery of consciousness, postanesthetic myopathy in large animals, and postanesthetic renal, hepatic, or cardiac insufficiency can all originate from inadequate respiratory function during anesthesia.

During general anesthesia, there is always a tendency for arterial oxygen tensions (arterial oxygen partial pressure [PaO_2]) to be less than observed with the same species while conscious and breathing the same fraction of inspired-oxygen concentration (F_iO_2).¹⁻⁵ There is also a tendency for PaCO_2 to be elevated above the conscious resting values if the anesthetized animal is

breathing spontaneously, and for increases in airway resistance to occur unless an endotracheal tube is used. Some differences are seen, depending on the actual anesthetic regimen used, but the depth of anesthesia is often more of a factor. Species and breed differences exist, and some of these are illustrated in this chapter. Positioning during anesthesia, concurrent drug use, and the magnitude of preanesthetic cardiorespiratory dysfunction all affect respiratory function.

Respiratory dysfunction during general anesthesia and the postoperative period is caused by the disruption of many physiological mechanisms and, in the larger species especially, an exaggeration of anatomical and mechanical factors.^{1,2,4} An understanding of respiratory function as it relates to anesthesia requires consideration of (a) the neural control of respiration and its effect on alveolar ventilation (V_A); (b) the influence of anesthesia on the airway, chest wall, and lung volumes; and (c) the alterations in ventilation-perfusion (V/Q) relationships during anesthesia.⁴⁻⁶

It is assumed that the readers are already reasonably knowledgeable regarding basic pulmonary physiology, which is considered in detail elsewhere.⁵⁻⁷ The review by Robinson⁷ is particularly useful for undergraduate readers. Much of the information that is available about the effects of anesthesia on respiration comes from studies in humans, and this information is summarized in a recent review at a level of complexity suitable for individuals in a specialist training program.⁶ There are important differences, however, in the manner by which veterinarians generally administer anesthetics to animals when compared with anesthesia of people. In veterinary practice, intravenous anesthetics are often used without oxygen supplementation, at least under field conditions. There is much less use of peripheral-acting muscle relaxants in veterinary anesthesia, and, generally, intermittent positive-pressure ventilation (IPPV) is used on a "need to" rather than routine basis. During general anesthesia with inhalants, 100% oxygen is usually used as the carrier gas, whereas a 2:1 mixture of nitrous oxide and oxygen is commonly used as the carrier gas in human anesthesia. Dogs and cats have frequently been used for investigations of neural control and mechanical alterations associated with anesthesia, but often under experimental situations that differ quite markedly from how anesthetics are administered to veterinary patients. In addition, the range of body weight and size and, in many instances, unique physiological adaptations of domestic and nondomestic animals undergoing anesthesia mean that the respiratory response to anesthesia may well be different than as classically described for people.

Definitions

Respiration is the total process whereby oxygen is supplied to and used by body cells and carbon dioxide is eliminated by means of gradients. *Ventilation* is the movement of gas in and out of alveoli. The ventilatory requirement for homeostasis varies with the metabolic requirement of animals, and it thus varies with body size, level of activity, body temperature, and depth of anesthesia. Pulmonary ventilation is accomplished by expansion and contraction of the lungs. Several terms are used to describe the various types of breathing that may be observed:

1. *Eupnea* is ordinary quiet breathing.
2. *Dyspnea* is labored breathing.
3. *Tachypnea* is increased respiratory rate.
4. *Hyperpnea* is fast and/or deep respiration, indicating “over-respiration.”
5. *Polypnea* is a rapid, shallow, panting type of respiration.
6. *Bradypnea* is slow regular respiration.
7. *Hypopnea* is slow and/or shallow breathing, possibly indicating “underrespiration.”
8. *Apnea* is transient (or longer) cessation of breathing.
9. *Cheyne-Stokes respirations* increase in rate and depth, and then become slower, followed by a brief period of apnea.
10. *Biot’s respirations* are sequences of gasps, apnea, and several deep gasps.
11. *Kussmaul’s respirations* are regular deep respirations without pause.
12. *Apneustic respiration* occurs when an animal holds an inspired breath at the end of inhalation for a short period before exhaling.

To describe the events of pulmonary ventilation, air in the lung has been subdivided into four different volumes and four different capacities (Fig. 5.1). Only tidal volume and functional residual capacity can be measured in conscious uncooperative animals:

1. *Tidal volume* (V_T) is the volume of air inspired or expired in one breath.
2. *Inspiratory reserve volume* (IRV) is the volume of air that can be inspired over and above the normal tidal volume.

3. *Expiratory reserve volume* (ERV) is the amount of air that can be expired by forceful expiration after a normal expiration.
4. *Residual volume* (RV) is the air remaining in the lungs after the most forceful expiration.

Another term frequently used is the minute respiratory volume or *minute ventilation* (V_E). This is equal to V_T times the *respiratory frequency* (f). Occasionally, it is desirable to consider two or more of the aforementioned volumes together. Such combinations are termed *pulmonary capacities*:

1. *Inspiratory capacity* (IC) is the tidal volume plus the inspiratory reserve volume. This is the amount of air that can be inhaled starting after a normal expiration and distending the lungs to the maximum amount.

2. *Functional residual capacity* (FRC) is the expiratory reserve volume plus the residual volume. This is the amount of air remaining in the lungs after a normal expiration. From a mechanical viewpoint, at FRC the inward “pull” of the lungs due to their elasticity equals the outward “pull” of the chest wall.

3. *Vital capacity* (VC) is the inspiratory reserve volume plus the tidal volume plus the expiratory reserve volume. This is the maximum amount of air that can be expelled from the lungs after first filling them to their maximum capacity.

4. *Total lung capacity* (TLC) is the inspiratory reserve volume plus the tidal volume plus the expiratory reserve volume plus the residual volume, or the maximum volume to which the lungs can be expanded with the greatest possible inspiratory effort (or by full inflation to 30 cm H₂O airway pressure when a patient is anesthetized).

Ventilation and Gas Exchange in Conscious Animals

From an anesthetist’s viewpoint, it is useful to consider the ventilatory system in terms of its major components: neural control, the bellows mechanism (chest wall and diaphragm), upper airway, and lung parenchyma (Fig. 5.2). Alterations of (a) the neural control of ventilation by sedative, opioid, or anesthetic depression; (b) upper-airway or lower-airway patency by muscle

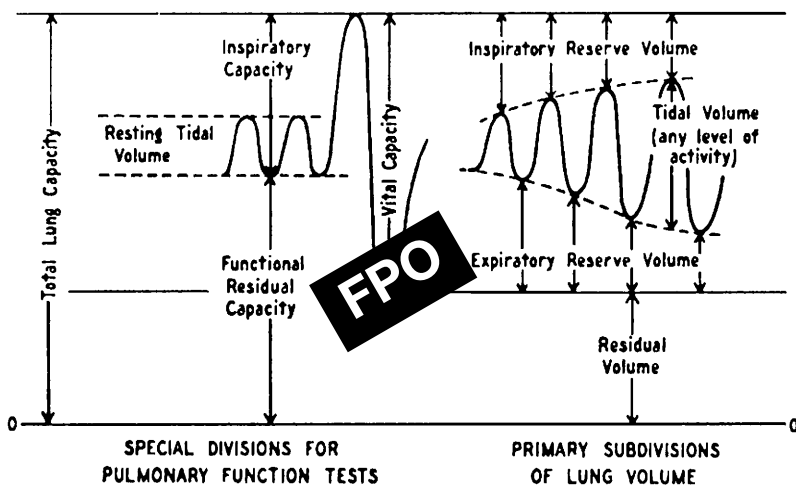

Fig. 5.1. Lung volumes and capacities. From Pappenheimer.²⁰⁶

Fig. 5.2. Diagrammatic representation of the neural control, bellows mechanism (diaphragm and thoracic wall), and matching of pulmonary artery blood and alveolar gas in the lung. F_I refers to fraction of inspired gases, and f is respiratory frequency. Tidal volume (V_T), anatomical dead space ($V_{D_{anat}}$), alveolar volume (V_A), and representative inspired (P_I), alveolar (P_A), pulmonary arterial or mixed venous ($P_{\bar{V}}$), and end-capillary ($P_{c'}$) partial pressures of oxygen and carbon dioxide are also illustrated. See the text for a detailed explanation.

relaxation or spasm; or (c) the bellows mechanism of the thorax through neuromuscular paralysis, space-occupying lesions of the thorax, or a change in the diaphragm shape, location, or function may all appreciably affect ventilatory adequacy and the efficiency of gas exchange. Within the parenchyma, less than optimum matching of fresh alveolar gas with pulmonary capillary blood will produce blood-gas alterations, particularly in regard to Pa_{O_2} .

Control of Respiration

With the aid of the circulation, respiration regulates the oxygen, CO_2 , and hydrogen-ion environment of the cell. Respiratory function is controlled by central respiratory centers, central and peripheral chemoreceptors, pulmonary reflexes, and nonrespiratory neural input. Control of respiration has been described as an integrated feedback control system.^{6,7} The central neural “controller” includes specialized groups of neurons located in the

cerebrum, brain stem, and spinal cord that govern both voluntary and automatic ventilation through regulation of the activity of the respiratory muscles. The respiratory muscles by contracting produce alveolar ventilation, and changes in alveolar ventilation affect blood-gas tensions and hydrogen-ion concentration. Blood-gas tensions and hydrogen-ion concentrations are monitored by peripheral and central chemoreceptors that return signals to the central controller to provide necessary adjustments in ventilation. Mechanoreceptors in the lungs and stretch receptors in the respiratory muscles monitor, respectively, the degree of expansion or stretch of the lungs and the “effort” of breathing, feeding back information to the central controller to alter the pattern of breathing. Adjustments also occur to accommodate nonrespiratory activities such as thermoregulation and vocalization.

Overall, this complex control system produces a combination of respiratory frequency and depth that is best suited for optimum ventilation with minimal effort for the particular species, and that adjusts oxygen supply and CO₂ elimination so as to maintain homeostasis (reflected by stable arterial blood-gas levels) over a wide range of environmental and metabolic situations. Sedatives, analgesics, anesthetics, and the equipment used for inhalational anesthesia may profoundly alter respiration and the ability of an animal to maintain cellular homeostasis.

Mechanical Factors

Transfer of gases to and from the lungs depends on developing a pressure gradient between the atmosphere and the alveoli, and is modified by the resistance to flow between these two regions and the elasticity of the lungs and chest wall. With spontaneous respiration, during inspiration active muscular effort serves to enlarge the pleural cavity through expansion of the thoracic wall and contraction of the diaphragm (Fig. 5.2). Intrapleural pressure is thereby reduced to a more subatmospheric pressure, and a mouth/nostril–alveolar pressure gradient is established. In contrast to inspiration, expiration is normally passive and depends on the return of the chest wall and lungs to a resting position, that is, to FRC. The horse is a notable exception in that abdominal muscle contraction plays a part in normal expiratory activity, producing a biphasic mode of exhalation.⁷ As the size of the pleural space decreases, intrapleural and consequently alveolar pressures are elevated, and the pressure gradient is reversed so that air flows from the alveoli to the atmosphere. Thus, fluctuating pressure gradients between the atmosphere and the alveoli cause air to flow in and out of the lungs. The factors that contribute to these pressure gradients and the measurement of their magnitude are referred to as *pulmonary mechanics*.

During assisted or controlled artificial or mechanical ventilation, atmospheric to alveolar pressure gradients also occur, but mouth pressure is more positive than alveolar pressure on inspiration: hence the term *positive pressure ventilation*. This has important circulatory consequences. Both the lungs and chest wall provide an elastic resistance to expansion on inspiration. The relationship between the pressure gradient (P) and the resultant volume (V) increase in liters (L) of the lungs and thorax is known as *total compliance* (C_T).⁶

$$C_T \text{ (L/cm H}_2\text{O)} = \Delta V \text{ (L)} / \Delta P \text{ (cm H}_2\text{O)}$$

The relationship of C_T to the individual compliance of the lungs (C_L) and chest wall (C_{CW}) is additive, because the lungs and chest wall are arranged concentrically and can be expressed as

$$1/C_T = 1/C_L + 1/C_{CW}$$

To measure C_T , V and the transthoracic pressure (that is, the pressure at the alveolus minus ambient pressure) must be known. In anesthetized animals, this is often determined by measuring the inspiratory volume delivered from a ventilator bellows or re-breathing bag while recording the change in airway (taken to be alveolar) pressure between end exhalation and end inspiration. If the lungs and/or chest wall are less compliant (i.e., stiffer), then higher transthoracic pressures are required to deliver a given tidal volume. Experienced anesthetists can often sense this change as an increased force required to mechanically squeeze a set volume from a rebreathing bag by hand. This may provide the first clue that an animal is developing a space-occupying problem in the thorax or abdomen (e.g., accumulation of air or blood), or that the end of the endotracheal tube has become repositioned in one main bronchus and is inflating only one lung.

Dynamic C_T is the volume change divided by the transthoracic pressure change at the point of zero airflow (end inspiration) when the previous inflow of air has been sufficiently rapid for dynamic factors to influence the distribution of air throughout the lung. For practical purposes, dynamic C_T is equal to the tidal volume divided by the peak airway pressure. *Static* C_T is determined when the preceding inflow of air has been sufficiently slow for distribution throughout the lung to be solely in accord with regional elasticity. Under these conditions, gas distribution to alveoli with faster and slower filling rates is equivalent, and as a result the static C_T (or C_L) value is usually greater than dynamic C_T (or C_L).

To determine the elasticity of the lung per se (C_L), V and the transpulmonary pressure gradient (that is, pressure at the alveolus minus pressure at the pleural space) must be known. This measurement is harder to determine accurately. In practice, the transpulmonary pressure gradient is generally determined by using a differential pressure transducer to determine mouth (considered equal to alveolar) and pleural pressure changes simultaneously. Pleural pressure changes are estimated from intrathoracic esophageal pressure swings recorded with a balloon-tipped catheter. Lungs develop a low compliance (become stiffer) with a reduction in lung volume or regional atelectasis; as a result of pulmonary edema or fibrosis; and, in the case of dynamic C_L , with regional differences in airway resistance.

For air to flow into the lungs, a pressure gradient must also be developed to overcome the nonelastic (airway) resistance to airflow. The relationship between the pressure gradient across the pulmonary system (P_L) and the rate of airflow is known as *airway resistance* (R_L):⁶

$$R_L \text{ (cm H}_2\text{O/L/s)} = \Delta P_L \text{ (cm H}_2\text{O)} / (\text{L/s})$$

The caliber of the airway and the rate and pattern of airflow all contribute to the pressure gradient along the airway. According to

the Hagen-Poiseuille law, laminar gas flow through a tube is proportional to the pressure gradient across the tube, the fourth power of the diameter of the tube, and inversely to the viscosity:

$$\text{pressure loss} = \text{constant} \times \text{viscosity} \times \text{length of tube} \times \frac{\text{flow rate}}{\text{diameter}^4} \times \text{flow rate}$$

The significance of this equation relative to anesthesia is to realize that changes in airway (or apparatus) diameter may markedly affect the resistance to airflow. If the diameter of the airway is reduced by 50%, for instance, by using too small an endotracheal tube, the resistance goes up 16-fold.

At higher flow rates that exceed the critical velocity of the system, or in the face of sudden changes in airway diameter, airflow will no longer be laminar and becomes turbulent. The significance of a transition from laminar to turbulent flow is illustrated by the fact that, at rates approximating critical flow, the resistance to flow increases by about 50% if the flow becomes turbulent. Airway resistance is measured by a variety of methods, most of which involve the simultaneous determination of instantaneous airflow with a pneumotachograph and of transpulmonary pressure (P_L), as described earlier.

Airway resistance increases with the rate of respiration and with narrowing of the airway by reflex contraction of the bronchiolar muscles, with small airway disease where there is edema of the airway wall and mucous accumulation, with a reduction in lung volume, or through aspiration of foreign material. Airway resistance during anesthesia can be minimized by using an airway that is as wide as possible and in which sudden alterations in direction or diameter are minimized.

Pulmonary Ventilation

The important factor in pulmonary ventilation is the rate at which *alveolar air* is exchanged with atmospheric air. This is not equal to the minute ventilation volume because a large portion of inspired air is used to fill the respiratory passages, rather than alveoli, and no significant gaseous exchange occurs in this air (Fig. 5.2). The *respiratory frequency* (f) and volume of each breath, *tidal volume* (V_T), determine the *minute ventilation* (V_E). The portion of each V_T that reaches only the upper airway and tracheo-bronchial tree fills the *anatomical dead space* and is referred to as *dead-space volume* ($V_{D \text{ anat}}$). The $V_{D \text{ anat}}$ is fairly constant; therefore, slow, deep breathing is more effective than rapid, shallow breathing. This is especially so during general anesthesia and with IPPV. The “effective” volume, or portion of V_T that contributes to gas exchange, is the *alveolar volume* (V_A), usually referred to as *minute alveolar ventilation* (V_A). Nonperfused alveoli do not contribute to gas exchange and constitute *alveolar dead space* (V_{DA}). In conscious healthy animals V_{DA} is minimal, whereas during general anesthesia it may increase owing to a fall in cardiac output (Q) and/or pulmonary artery blood pressure. *Physiological dead space* (V_D) includes $V_{D \text{ anat}}$ and V_{DA} (Fig. 5.2), and is usually expressed as a minute value (V_D) along with V_A , or as a ratio of V_D/V_T . In unsedated tracheostomized dogs breathing quietly through a standard endotracheal tube, V_D was 5.9 mL/kg and the ratio of V_D/V_T was 35%.⁸ This ratio of V_D/V_T is similar to that found in humans, but the V_D figure is larger, reflecting the in-

creased $V_{D \text{ anat}}$ in dogs on a body-weight basis. During methoxyflurane anesthesia with spontaneous respiration, V_D increased very little (about 0.5 mL/kg), but V_D/V_T increased to over 50% because V_T decreased. Others have shown similar results with other anesthetics. In larger species such as horses and cows, the V_D/V_T ratio in conscious animals is about 50%.⁹ Higher proportions of dead space have been reported, but such values probably reflect a tachypneic state or failure to subtract the added dead space associated with the use of the mask in gas collection. In unsedated cows, V_D is about 3.7 mL/kg and, in horses, about 5.2 mL/kg.⁹ Representative normal ventilation, blood-gas, and acid-base values for a range of species are listed in Tables 5.1 and 5.2.

Lung Volumes

The subdivisions of lung volume are shown in Fig. 5.1. Most of these volumes cannot be measured in conscious animals, because to do so requires cooperation of the test subject. Measurements of V_T and FRC can be obtained in conscious animals; TLC is generally estimated by inflation of the lung to above 30 cm H₂O inflation pressure in anesthetized animals. Values for TLC are reasonably similar among the domestic species when compared on a body-weight basis, but the total volume varies from less than 2.0 mL in mice to over 45 L in horses and cows (Table 5.3). This factor and the variation in V_T observed across species (Table 5.1) have quite significant implications relative to the design of suitable inhalant anesthetic apparatus and the relative importance of added mechanical dead space. A liter of apparatus dead space in a healthy conscious horse or cow constitutes only a small portion of the V_T and has little effect on V_A or blood gases,³⁸ whereas a dead space of even 15 mL in a cat amounts to 50% of V_T and will quite likely alter alveolar ventilation and PaCO₂ levels. In the smallest mammals, virtually all mask systems will lead to some rebreathing of CO₂ during anesthesia, unless a loose-fitting mask is used with a flow-through system.

The volume of gas remaining in the lungs at the end of a normal expiration (i.e., the FRC) varies considerably as the position of the diaphragm, in particular, changes. Abdominal tympany from any source (e.g., near-term gravid uterus, bowel distension, obesity, or tumor) will tend to move the diaphragm forward and lessen the FRC. Few actual measurements have been made of this phenomenon in relation to animals, but the consequences on ventilation and respiratory function during anesthesia are consistent with a decrease in FRC.

Intrapulmonary Matching of Blood and Gas

Matching of alveolar gas and pulmonary capillary blood flow is influenced by gravitational factors and by the pulmonary artery circulation being a low-pressure system. Intrapleural pressure is more subatmospheric in the uppermost part of the thorax than in the lowermost portion,³⁹ partly because of the weight of the lung in the thorax. Alveolar size is largest in the uppermost areas of the lung and smallest in the ventral regions. Since the larger alveoli have a lower compliance (they are less distensible), they expand less on inspiration, and air preferentially enters the more compliant lower alveoli, producing a vertical gradient of ventilation in standing animals breathing quietly.^{40,41} This tendency for

preferential ventral ventilation in the lung may also be associated with regional chest wall and diaphragmatic movement. During anesthesia, the distribution of ventilation becomes more uneven and may even reverse so that the uppermost lung of a laterally recumbent horse is receiving most of the ventilation.

The major effect of gravity on the lung in most animals is to produce a vertical perfusion gradient in the pulmonary circulation, with the lower region being perfused more. The distribution of these gravitational effects on lung perfusion is commonly divided and functionally described as a three-zone or four-zone system.^{41,42} At rest, the uppermost alveoli may be minimally perfused (Fig. 5.3, zone I), with alveolar pressure (P_A) greater than pulmonary artery (P_{pa}) and vein (P_{pv}) pressures. In zone II, P_{pa} is greater than P_A , and the difference between the two is the driving pressure for blood flow at the front end of the capillaries. The relationship between P_A and P_{pv} governs flow through the terminal aspect of the capillaries. In zone III, P_{pa} and P_{pv} both exceed P_A , and the vessels are fully distended, with the perfusion being determined by the pressure difference between P_{pa} and P_{pv} . In zone IV, the lung weight increases the interstitial pressure to a point that blood flow is reduced toward that of zone II, or less. These factors are important during anesthesia in that cardiac output is often reduced and P_{pa} may fall. Moreover, when the body

position is altered and an animal becomes recumbent, the pulmonary blood flow is thought to realign along gravitational lines consistent with the new body position.^{2,6} However, these relationships are not necessarily straightforward, especially in the larger species, perhaps because of the large decrease in FRC that accompanies recumbency and the generation of a larger zone IV area in the thorax.

It is also now apparent that gravitational effects may not be the dominant factor influencing regional pulmonary blood flow in conscious quadrupeds.^{43,44} There appears to be a preferential distribution of blood flow to the dorsal region of the lung in these animals, especially during exercise. It is not known whether this species tendency is universal in quadrupeds or whether the phenomenon persists during general anesthesia.

A simplified diagrammatic representation of altered V/Q is shown in Fig. 5.4.⁴⁵ One extreme is to have a perfused alveolus or area of the lung with no ventilation so that the blood is not oxygenated while passing the region. Other extremes are for the alveolus to be ventilated but not perfused, or alternately for an alveolus or region to be neither ventilated nor perfused. Often the alteration of V/Q within the lung is somewhere in between these extremes and is characterized by alveoli throughout the lung that are only relatively underventilated or underperfused, producing

an increase in the alveolar–arterial oxygen gradient. Since CO₂ is more diffusible across the alveolar capillary membrane, diffusion and V/Q problems commonly lead to decreased PaO₂ levels before there is a change in PaCO₂ levels. It is possible to compensate for nonventilation of portions of the lung through increased

ventilation of the rest of the lung in terms of CO₂ clearance, as occurs with tachypneic pneumonic animals. However, the same increase in ventilation of “good” lung areas will never compensate completely for areas where there is inadequate oxygen uptake. The hemoglobin oxygen-saturation curve is sigmoid shaped

Fig. 5.3. Diagrammatic illustration of pulmonary artery (P_{pa}), pulmonary vein (P_{pv}), pulmonary interstitial (P_{INT}), and alveolar (P_A) pressure-flow relationships in the lung. Modified from Porcelli (p. 243),⁴² with permission. See the text for a detailed explanation.

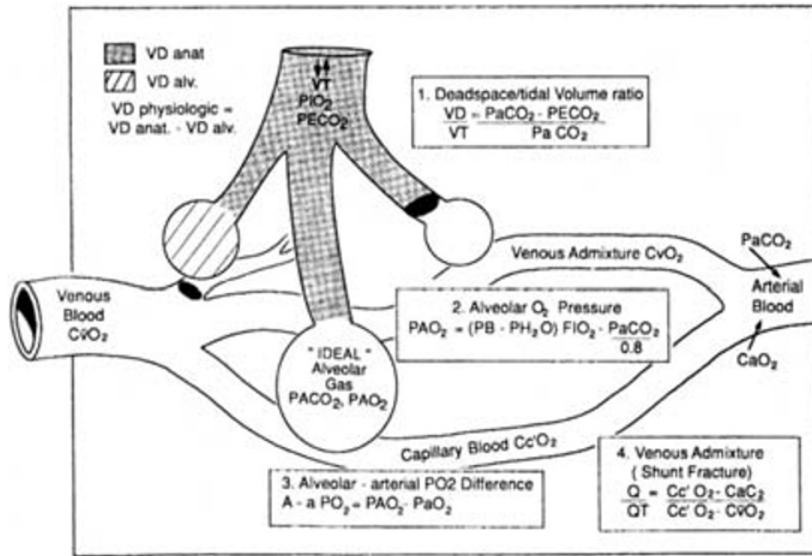

Fig. 5.4. Schematic of uneven ventilation and blood flow. The alveolus on the left is ventilated, but not perfused, and thus is considered to be alveolar dead space, whereas the alveolus on the right is perfused, but not ventilated, and thus contributes to venous admixture or so-called shunt flow. The center alveolus is perfused and ventilated equally and thus would have a V/Q ratio of 1.0. Relevant equations are shown respectively as Eqs. 1 to 4 for calculation of the dead space- $\text{tidal volume ratio}$, the alveolar partial pressure of oxygen (P_{AO_2}), the alveolar-to-arterial partial pressure of oxygen ($A-a PO_2$) difference, and the venous admixture (Q/QT) fraction. Reproduced from Robinson (p. 8),⁴⁵ with permission by Elsevier.

(Fig. 5.5), and hemoglobin is nearly fully saturated with oxygen at a PaO_2 of 90 to 100 mm Hg. Consequently, an increase in ventilation to the “good” areas of the lung cannot increase the oxygen content of blood very much, even though the alveolar partial pressure of oxygen (P_{AO_2}) increases. The clinical significance of this is that many pulmonary problems present as hypoxemia rather than hypercapnia.

Effect of Altered Alveolar Ventilation

For any given metabolic output, $PaCO_2$ and V_A are directly and inversely related: if V_A falls by 50%, $PaCO_2$ doubles; whereas, if

V_A is increased by 100% (say, by IPPV), $PaCO_2$ levels will fall by 50% once equilibrium is established (Fig. 5.6). This is an important concept to grasp in that it explains how an experienced anesthetist can make fairly good approximations about the resultant $PaCO_2$ level he or she will produce when an animal is put on a volume-limited ventilator at a particular f and V_T setting. For instance, in most anesthetized dogs with a body weight that is average for the breed, $PaCO_2$ will be near eucapnic levels when f is set at 8 to 10/min and V_T at 20 mL/kg. In anesthetized adult horses and cows, a comparative eucapnic setting would be f at 5/min and V_T at 15 mL/kg.

Fig. 5.5. Oxygen-hemoglobin dissociation curves. The center curve represents the relationship between the partial pressure of oxygen and the percentage hemoglobin saturation at normal body temperature and blood pH, and shows the arterial oxygen partial pressure (P_{aO_2}) and percentage saturation as blood goes through the lungs and tissues. The normal mixed venous PO_2 and oxygen saturation values are shown (\bar{v}) along with the P_{50} value, which is the PO_2 at which the hemoglobin of a particular species is 50% saturated with oxygen. There is a shift of the hemoglobin dissociation curve to the right with acidemia (e.g., pH 6.8) or an increase in temperature, whereas there is a shift to the left with alkalemia (e.g., pH 7.6) or a lower body temperature. The oxygen-content values on the left represent the blood oxygen content that would be expected if the hemoglobin concentration was the theoretical normal level of 15 gm/dL and body temperature and pH levels were also normal.

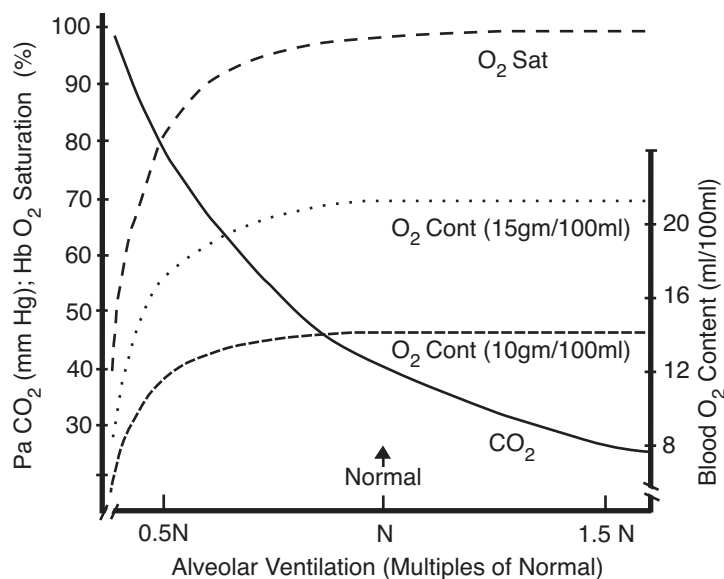

Fig. 5.6. Effect of altered alveolar ventilation on hemoglobin saturation, blood oxygen content, and arterial carbon dioxide partial pressure ($PaCO_2$) levels. As alveolar ventilation is halved, the $PaCO_2$ level doubles, illustrating the inverse and direct relationship between alveolar ventilation and carbon dioxide clearance. Note the difference in oxygen content with anemia (hemoglobin 10 g/100 mL instead of 15 g/100 mL), and the eventual sharp drop in hemoglobin oxygen saturation and oxygen content as alveolar ventilation decreases to less than 50% of the normal value. (See the text for further explanation.)

Hyperventilation occurs when V_A is excessive relative to metabolic rate; as a result, $PaCO_2$ is reduced. Hyperventilation may or may not be accompanied by an increased respiratory rate, referred to as *tachypnea*. *Hypoventilation* is present when V_A is small relative to metabolic rate, and $PaCO_2$ rises: hypoventilation may be accompanied by a slow (bradypnea), normal, or rapid *f*. A lowered $PaCO_2$ level is referred to as *hypocapnia* and an elevated level as *hypercapnia*, whereas normal $PaCO_2$ is termed *eucapnia*. Most, but not all, of the common mammalian species have a normal resting $PaCO_2$ level close to 40 mm Hg (Table 5.2). Hypercapnia and hypocapnia produce *respiratory acidosis*

and *alkalosis*, respectively, because CO_2 in the body is in dynamic equilibrium with carbonic acid (H_2CO_3) and, ultimately, hydrogen-ion concentration $[H^+]$:

Acidemia and *alkalemia* are respectively defined as a plasma pH significantly below or above the normal arterial or venous value for the species in question. Concurrent metabolic acid-base disturbances and the presence or absence of compensation through renal excretion will determine the actual degree of pH change accompanying hypocapnia or hypercapnia. During general anesthe-

sia, hypoventilation and hypercapnia are far more likely to occur in spontaneously breathing animals, whereas hyperventilation and hypocapnia most often occur when tidal volumes are too large in smaller animals during IPPV.

The relationship between V_A and oxygen saturation (and, in turn, the oxygen content of arterial blood) is not linear because of the sigmoid shape of the hemoglobin-saturation curve (Fig. 5.5). This factor has important clinical applications for anesthesiologists. With a 50% decrease in V_A , hemoglobin is still 80% saturated, and the actual oxygen content of blood (if hemoglobin concentration is 15 g/dL) will have fallen only from 21.2 to 16.8 mL/dL. Such an animal would not likely demonstrate cyanotic mucous membranes or even cardiovascular signs (tachycardia/bradycardia or increased/decreased blood pressure) associated with respiratory insufficiency. However, as the level of V_A decreases further, there is a sharp and potentially catastrophic decrease in the oxygen content of arterial blood so that, at a V_A that is 40% of normal, hemoglobin saturation is 50% and the oxygen content has fallen to 7.04 mL/dL. This degree of hypoxemia may well lead to cardiorespiratory collapse quite suddenly. An understanding of this nonlinear effect of V_A deficiency on oxygen content helps to explain why an apparently “okay” animal on an intravenous general anesthetic and breathing room air can suddenly stop breathing or go into cardiovascular collapse without any apparent change in the depth of anesthesia.

Figure 5.6 illustrates the important interrelationship between a lower hemoglobin level (e.g., 10 g/dL) and blood oxygen content with altered ventilatory homeostasis. The blood oxygen content is reduced by nearly 7 mL/dL with a decrease in hemoglobin from 15 to 10 g/dL even when hemoglobin saturation is 100%, and dangerously low blood oxygen contents occur with further ventilatory depression.

Hypoxia refers to any state in which the oxygen in the lung, blood, and/or tissues is abnormally low, resulting in abnormal organ function and/or cellular damage. *Hypoxemia* refers to insufficient oxygenation of blood to meet metabolic requirement. In spontaneously breathing animals, hypoxemia is characterized by PaO_2 levels lower than the normal for the species. Resting PaO_2 levels in domestic species generally range from 80 to 100 mm Hg in healthy, awake animals (Table 5.2). Some clinicians consider a PaO_2 below 70 mm Hg (ca. 94% hemoglobin saturation) as hypoxemia in animals at or near sea level, although the clinical significance of this degree of blood oxygen tension would vary depending on factors such as the health and age of an animal, hemoglobin concentration, and the duration of low oxygen tension in relation to the rate of tissue metabolism (e.g., hypothermic patients would be at less risk).

Oxygen Transport

Under normal conditions, oxygen is taken into the pulmonary alveoli and CO_2 is removed from them at a rate that is sufficient to maintain the composition of alveolar air at a relatively constant concentration. In the lung, gas is exchanged across both the alveolar and the capillary membranes.⁷ The total distance across which exchange takes place is less than 1 μm ; therefore, it occurs

Table 5.4. Composition of respiratory gases in humans.

Gas	Inspired Air (%)	Expired Air (%)	Alveolar Air (%)
Oxygen	20.95	16.1	14.0
Carbon dioxide	0.04	4.1	5.6
Nitrogen ^a	79.0	79.2	80.0

^aThere is no change in the absolute concentration of nitrogen. The change in percentage occurs because more oxygen is used than carbon dioxide produced.

rapidly. Other than at high exercise levels, equilibrium almost develops between blood in the lungs and air in the alveolus, and the partial pressure of oxygen (PO_2) in the blood almost equals the PO_2 in the alveolus. While diffusion of oxygen across the alveolar-capillary space is a theoretical barrier to oxygenation, it is seldom a practical problem during veterinary anesthesia unless considerable pulmonary edema is present.

There is a relatively steep concentration or *partial pressure gradient* of oxygen from room air to the various body tissues: nasal air = 160 mm Hg; alveolar air = 100 mm Hg; arterial blood = 90 to 95 mm Hg; interstitial fluid = 30 mm Hg; intracellular fluid = 10 mm Hg; and venous blood = 40 mm Hg. Little oxygen is lost in large blood vessels, and normally a continuous pressure gradient is present from the alveolus to the tissue cell.

The normal average alveolar composition of respiratory gases in humans is listed in Table 5.4. At body temperature, alveolar air is saturated with water vapor, which has a pressure at 37°C of 48 mm Hg. If the barometric pressure in the alveolus is 760 mm Hg (sea level), then the pressure due to dry air is $760 - 48 = 712$ mm Hg. Knowing the composition of alveolar air, one can calculate the partial pressure of each gas in the alveolus:

$$\begin{aligned} \text{O}_2 &= (760 - 48) \times 0.14 = 100 \text{ mm Hg} \\ \text{CO}_2 &= (760 - 48) \times 0.056 = 40 \text{ mm Hg} \\ \text{N}_2 &= (760 - 48) \times 0.80 = 570 \text{ mm Hg} \end{aligned}$$

Oxygen partial pressure in the lungs at sea level is thus approximately 100 mm Hg at 37° to 38°C. Under these conditions, 100 mL of plasma will hold 0.3 mL of oxygen in physical solution. Whole blood, under the same conditions, will hold 20 mL of oxygen, or about 60 times as much as plasma. CO_2 is similarly held by blood. Thus, it is apparent that oxygen and CO_2 in blood are transported largely in chemical combination, since both are carried by blood in much greater quantities than would occur if simple absorption took place. At complete saturation, each gram of hemoglobin combines with 1.36 to 1.39 mL of oxygen. This is the total carrying capacity of hemoglobin, or four oxygen molecules combined with each hemoglobin molecule. The ability of hemoglobin to combine with oxygen depends on the PO_2 in the surrounding environment. The degree to which it will become saturated at various oxygen partial pressures varies considerably (Fig. 5.5). It is adjusted so that, even when ventilation is inefficient or the supply of oxygen is sparse as at higher altitudes, the degree of saturation still approaches 100%. For instance, although it is probably not fully saturated until it is exposed to a

PO_2 of 250 mm Hg, hemoglobin is approximately 94% saturated when the PO_2 is only 70 mm Hg.

Although there is relatively little change in hemoglobin saturation between 70 and 250 mm Hg PO_2 , a marked change occurs between 10 and 40 mm Hg, a PO_2 characteristic of actively metabolizing tissues. Thus, as hemoglobin is exposed to tissues having partial pressures of oxygen within this range, it will yield its oxygen to the tissues. The lower the PO_2 of these tissues, the greater is the amount of oxygen that hemoglobin will yield. The degree to which hemoglobin yields its oxygen is influenced by environmental pH, PCO_2 , and temperature—all mechanisms that protect the metabolizing cell. As the pH decreases and the PCO_2 and local temperature increase, at any given PO_2 value, especially in the range of 10 to 40 mm Hg, hemoglobin releases oxygen to the surrounding environment more readily (Fig. 5.5). It is also interesting to note that nature has adapted for the relatively lower oxygen environment of the fetus, because fetal hemoglobin carries a greater percentage of oxygen at a lower partial pressure.

Certain enzyme systems aid dissociation of oxygen from hemoglobin, the most completely studied being the enzyme system producing 2,3-diphosphoglycerate (2,3-DPG). This system enhances dissociation of oxygen from hemoglobin by competing with oxygen for the binding site. A lowered level of this enzyme, as occurs with stored blood used for transfusion, increases the affinity of hemoglobin for oxygen and thus acts as though the dissociation curve is shifted to the left. The oxygen tension at which 50% saturation of hemoglobin is achieved (P_{50}) is used to measure affinity of hemoglobin for oxygen. P_{50} is reduced in septic patients and in carbon monoxide poisoning. The reverse has been encountered in chronic anemia. Since tissues require a given volume of oxygen per unit of time, the hemoglobin concentration of blood has a significant influence on oxygen content and delivery to the tissues.

Although an increase in the $P_{A}O_2$ above normal causes only a small increase in the oxygen-carrying capacity of hemoglobin, plasma carries oxygen in an amount directly proportional to the PO_2 in the alveoli. At normal atmospheric pressure, when the animal is breathing air at 38°C, 0.3 mL of oxygen is carried in solution in 100 mL of blood. If pure oxygen is administered, the PO_2 in the alveoli is raised from 100 to almost 650 mm Hg. Plasma oxygen is thus elevated almost seven times, that is, from 0.3 to 1.8 mL per 100 mL of blood. The result is an increase of about 10% in oxygen content of the blood. This is of some importance, because oxygen transfers from blood to tissues by diffusion, and the process occurs at a rate proportional to the difference in oxygen tension between plasma and body tissues.

A common misconception is that oxygenation of patients can be improved by increasing the physical (airway) pressure at which oxygen is administered. Except in hyperbaric chambers, oxygenation of patients is improved not by increasing the barometric pressure of the gas mixture, but by increasing the *proportion* or PO_2 in the mixture. At a positive alveolar pressure exceeding 40 mm Hg, the capillary circulation in the lungs is inhibited; therefore, it is not practical to administer oxygen at a pressure exceeding this pressure. During anesthesia, hypoxemic episodes

are best handled by reducing the level of inhalant anesthetic in the mask or rebreathing bag along with ensuring there is a high inspired-oxygen concentration, while instituting IPPV at a normal f , V_T , and inflation pressure (12 to 15 mm Hg in small animals, and 20 to 25 mm Hg in horses and cows).

In conscious, healthy animals, there is considerable capacity to increase the rate of oxygen supply to, and CO_2 removal from, the body tissues, with up to 30-fold increases seen in exercising horses. The gas transport is increased in conscious horses by a fivefold increase in cardiac output, a 50% increase in hemoglobin concentration, and a fourfold increase in the extraction of oxygen from the blood traversing skeletal muscle capillaries.⁷ The capacity for increasing oxygen supply is considerably less in more sedentary species.

During general anesthesia, these adaptive mechanisms to increase systemic oxygen supply are markedly compromised. Anesthetized animals are not likely to be able to appreciably increase their V_E or cardiac output, the spleen is often dilated and incapable of contracting to increase hemoglobin levels, and a key muscle (myocardial) cannot extract a greater proportion of oxygen from the blood going through the capillaries in response to an increase in demand or decrease in oxygen supply.

Carbon Dioxide Transport

Arterial CO_2 levels are a function of both CO_2 elimination and production, and under normal circumstances $PaCO_2$ levels are maintained within narrow limits. During severe exercise, the production of CO_2 is increased enormously, whereas, during anesthesia, production likely decreases. Elimination of CO_2 depends on pulmonary blood flow (cardiac output) and V_A . Normally, the production of CO_2 parallels the oxygen consumption according to the respiratory quotient: $R = VCO_2/VO_2$. Although the value varies depending on the diet, usually R is 0.8 at steady state. Because of the blood buffer systems, CO_2 transport to the lungs for excretion is effected with little change in blood pH. The importance of the lungs in excreting this volatile acid is illustrated by the fact that, in humans, the kidneys eliminate 40 to 80 mEq of hydrogen ions per day, while the lungs eliminate 13,000 mEq per day as CO_2 .

A CO_2 pressure gradient, opposite to that of oxygen and much smaller, exists from the tissues to the atmospheric air: tissues = 50 mm Hg (during exercise, this may be higher); venous blood = 46 mm Hg; alveolar air = 40 mm Hg; expired air = 32 mm Hg; atmospheric air = 0.3 mm Hg; and arterial blood = 40 mm Hg (equilibrium with alveolar air). CO_2 is carried from the mitochondria to the alveoli in a number of forms (Fig. 5.7).⁴⁵ In the plasma, some CO_2 is transported in solution (5%), and some combines with water and forms *carbonic acid*, which in turn dissociates into *bicarbonate* and *hydrogen ions* (5%). Most (ca. 90%) of the CO_2 diffuses into the red cells, where it is either bound to hemoglobin or transformed (reversibly) to bicarbonate and hydrogen ions through the action of the enzyme *carbonic anhydrase*. The formation of bicarbonate in the red blood cell is accompanied by the chloride shift (this accounts for approximately 63% of the total CO_2 transport). The excellent buffering capacity

Equine Anesthesia

Fig. 5.7. Transport of carbon dioxide in the blood. Carbon dioxide diffuses out of the tissues into the plasma and erythrocytes, undergoing a variety of reactions that result in the production of bicarbonate and hydrogen ions. The hydrogen ions are then buffered either by proteins in the plasma or by hemoglobin, minimizing the pH change. In the lung, all of the reactions that are shown in this figure are reversed. Reproduced from Robinson (p. 30),⁴⁵ with permission by Elsevier.

of hemoglobin enables changes in hydrogen-ion content to occur during this process with minimal change in pH. Under ordinary circumstances, the pH of venous blood is only 0.01 to 0.03 pH units lower than that of arterial blood. CO₂ is also carried in the red cell in the form of carbamino compounds. Amino acids and aliphatic amines combine with CO₂ to form unstable carbamino compounds. Hemoglobin (Hb) is the main protein acting in this manner, though many can do so. The efficiency of this reaction is greater with Hb than with hemoglobin-bound oxygen. Thus, as hemoglobin and oxygen dissociate, hemoglobin's capacity to carry CO₂ increases.

The mechanisms of CO₂ and oxygen transport are integrated in the blood in at least three ways: (a) The acidity of carbonic acid produced in the tissues favors release of oxygen without a change in oxygen tension, whereas the release of CO₂ in the lungs favors oxygen uptake (Bohr effect). (b) Release of oxygen favors CO₂ uptake and vice versa in the carbamino mechanism. Upon the release of oxygen, hemoglobin becomes a weaker acid and is more capable of accepting hydrogen ions, thereby facilitating its buffering effect (Haldane effect). (c) The two acid forms of the hemoglobin molecule favor dissociation by shifting from one form to the other. Oxygen uptake favors CO₂ loss and vice versa.

Just as the amount of oxygen transported by the blood depends on the PO₂ to which the blood is exposed, so is CO₂ transport likewise affected; however, the CO₂ dissociation curve is more or less linear. Thus, in contrast to the minimal effects on oxygen content (Fig. 5.6), hyperventilation and hypoventilation may have marked effects on CO₂ content of blood and tissues.

Upper-Airway Obstruction

With the onset of general anesthesia, the nasal alar and pharyngeal musculature relax and, in deeper planes, the cough reflex is abolished. The net effect is to predispose patients toward upper-airway obstruction. This is particularly evident in brachycephalic dogs suffering from stenotic nares, an elongated soft palate,

everted lateral laryngeal ventricles, and/or a hypoplastic trachea. In these animals, the onset of general anesthesia may produce serious and potentially fatal upper-airway obstruction unless the trachea is intubated. Experience has shown that it is preferable to perform endotracheal intubation in all anesthetized dogs, partly to protect against upper-airway obstruction, but also to protect against possible aspiration of secretions or refluxed gastric contents from the stomach. It is important, however, that the endotracheal intubation be done atraumatically. Routine use of a laryngoscope reduces trauma during intubation. In many domestic and laboratory species, the decision as to whether to use an endotracheal tube is a risk-benefit decision that must be determined based on the species involved, the anesthetic regimen employed and the experience of the anesthetist, the intended operation, the health of the animal, and the duration of anesthesia.

In ruminants, endotracheal intubation is required for all but the shortest-acting anesthetics, such as diazepam premedication with low-dose ketamine in sheep, calves, and goats, which only lasts about 5 min. The prime reason for endotracheal intubation is to protect against aspiration of rumen contents after active or passive regurgitation. In swine, endotracheal intubation is comparatively difficult and requires considerable experience if trauma is to be avoided. Swine have inherently small airways and are more likely to develop apnea than other domestic species. Nevertheless, for most brief surgeries (e.g., hernia repair or cryptorchidectomy) the risk-benefit balance is better served by not intubating swine, but instead by paying careful attention to the depth of anesthesia and to the character of respiration and head position so as to minimize the chance of serious upper-airway obstruction. In most species, the best airway is provided when the head is kept in a somewhat extended position: Pigs are unusual in that the best airway is provided with the head at a normal angle to the neck.

If significant upper-airway obstruction occurs in any species, and the depth of anesthesia is not excessive, the animal usually develops an exaggerated respiratory effort that is primarily abdominal in character. The chest wall may even move inward on

inspiration (paradoxical respiration) if the degree of upper-airway obstruction is moderate or severe. The only other clinical situation that produces this subtle, but distinctive, change in the character of respiration is extremely deep anesthesia. This usually occurs at an anesthetic plane just before complete cessation of respiratory drive—that is, apnea—ensues.

In rodents—such as mice, gerbils, hamsters, and guinea pigs—and in rabbits, endotracheal intubation may be difficult unless the anesthetist is experienced with the technique and has special equipment. In these species, longer, well-controlled periods of anesthesia for experimental purposes may well require endotracheal intubation. Shorter procedures in a veterinary practice may often be performed without using an endotracheal tube. A suitable face-mask and non-rebreathing administration system may be used for oxygen administration (in the case of injectable anesthesia) or for administration of an oxygen-inhalant regimen using a precision vaporizer. When the anesthetist is capable of performing atraumatic endotracheal intubation and has suitably small tubes (3 to 4 mm), it is preferable to intubate ferrets and rabbits, because surgical anesthetic planes produce considerable respiratory depression in both species, and it is much easier to deal with apnea if an endotracheal tube is already in place.

There is some controversy as to whether an endotracheal tube should always be placed in cats for shorter procedures (e.g., neutering). Cats tend to maintain a patent airway somewhat more effectively than do other species, unless drugs are used (e.g., ether) that increase the incidence of secretions and/or laryngospasm. Laryngospasm is comparatively rare when halothane, isoflurane, or sevoflurane are administered by mask, or when ketamine or propofol are used along with diazepam, acepromazine, or low-dose α_2 -agonist sedation for injectable anesthesia. Moreover, endotracheal intubation requires a deeper level of anesthesia than is needed for some minor surgical or diagnostic procedures. Laryngospasm is more likely to occur after anesthesia when the larynx has been traumatized during intubation or when the endotracheal tubes have been cleaned with some sort of detergent or disinfectant between animals without adequate rinsing. In a large morbidity and mortality study conducted in the United Kingdom, postanesthetic airway obstruction was one of the more frequently encountered problems in cats,⁴⁶ and the suspicion is that this might well be associated with trauma during insertion of an endotracheal tube into the airway. On the other hand, there can be no denying the many advantages associated with endotracheal intubation in cats, as with other species. A patent airway is immediately available if the animal needs IPPV because of apnea or respiratory insufficiency, the risk of aspiration of gastric contents is markedly reduced, and it is easier to scavenge anesthetic waste gases if an inhalant anesthetic is being used. In cats, laryngeal desensitization with lidocaine will help to reduce spasm and trauma associated with the placement of a tube. Endotracheal tube placement for shorter procedures is not mandatory, providing that emergency airway and oxygen are readily available and the patency of the airway is being continuously monitored.

Veterinary anesthesia textbooks have hitherto placed little emphasis on the need to provide for a secure airway in horses, primarily because regurgitation is very rare. Although it is true that

short-duration, injectable, field anesthetic techniques have been performed for many years without the use of an endotracheal tube, a considerable degree of upper-airway obstruction does occur in horses (Fig. 5.8), primarily because their nostrils no longer flare during inspiration. Therefore, placement of an endotracheal tube may be considered desirable in most circumstances.⁴⁷

This tendency toward upper-airway obstruction increases when a horse has been anesthetized for longer than 1 or 2 h, especially when in dorsal recumbency. It is thought that passive congestion and tissue swelling occur because the nasopharynx structures are lower than the heart in anesthetized animals, and that this predisposes animals to airway obstruction in the recovery period when the endotracheal tube is removed. As a result, many equine anesthetists now secure an orotracheal, nasotracheal, or nasopharyngeal airway during the recovery process whenever horses have been anesthetized for any extended length of time (e.g., over 30 to 45 min).^{48,49} Clinically, it appears that ensuring an adequate diameter patent airway while a horse is trying to stand up (and is breathing vigorously) prevents the panic associated with partial or complete airway obstruction and leads to more controlled recoveries. There is still a need for large-scale morbidity and mortality studies that address the issue of when and where endotracheal tubes should be used during routine veterinary anesthesia, especially in a practice setting.

Anesthetic Alteration of the Control of Respiration

Respiratory drive and the adjustment of f , V_T , and V_A are achieved in conscious animals through a complex neural regulatory mechanism. Respiratory rhythm originates in the medulla and is modified by inputs from higher brain centers and the activity of chemoreceptor, pulmonary, and airway receptors. The central neural control mechanisms regulate the activity of the primary and accessory respiratory muscles, producing gas movement into and out of the lung and tracheobronchial tree. These control mechanisms are described in detail elsewhere.^{5-7,50} Although there is certainly a similarity in the respiratory control mechanism between species, it is important to realize that various components may assume greater importance in different species.

Normal Control Mechanisms

As important as the detailed information referred to earlier is in helping us understand the respiratory adaptations to high altitude, disease, and exercise, for the successful management of clinical anesthesia a much simplified understanding of the control of respiration will suffice (Fig. 5.9). In conscious animals, V_E and V_A are primarily determined by central chemoreceptor responsiveness to PaCO₂ levels. The *central chemoreceptors*, located on the ventral surface of the medulla and bathed by cerebrospinal fluid, are exquisitely sensitive to changes in PaCO₂ levels because CO₂ is readily diffusible into cerebrospinal fluid and the central chemoreceptor cell. The changes in PaCO₂ are probably ultimately detected as a change in the pH within the chemoreceptor

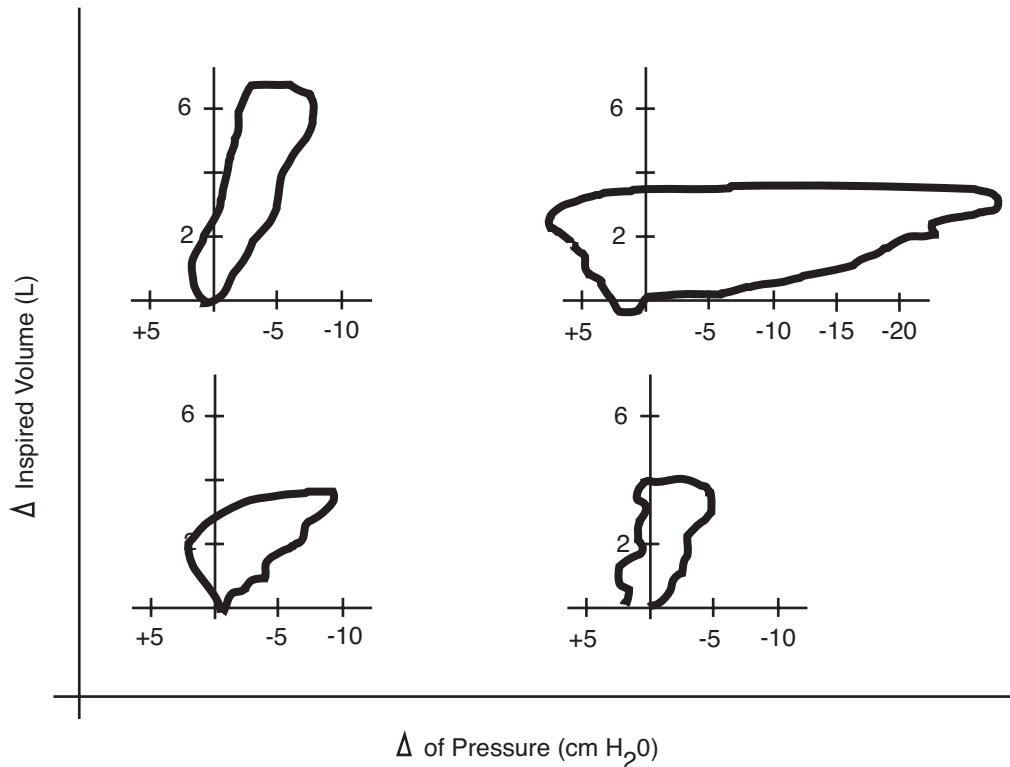

Fig. 5.8. Changes in nonelastic work of breathing with the onset of general anesthesia (thiobarbiturate) in a spontaneously breathing horse. The change in transpulmonary pressure (airway opening to esophageal balloon) is shown as the *abscissa*, and the change in volume (tidal volume) is shown on the *ordinate* scale. The area within the loops is a measure of the nonelastic work of breathing and is a reflection of the airway resistance, as well as a small component of tissue resistance. The *top left loop* was obtained from a conscious horse breathing quietly; the *top right loop* was obtained after 15 min of anesthesia with the horse in lateral recumbency and breathing without an endotracheal tube in place; the *bottom left loop* is after the horse was intubated with a 25-mm tube; and the *bottom right loop* was obtained once the horse stood in recovery with the tube removed. Note the large increase in nonelastic work of breathing during anesthesia until an endotracheal tube is inserted, and that fairly large negative pressures (10 to 15 cm H₂O) must be generated before there is an appreciable volume of inspired gas. This is indicative of upper-airway obstruction (W. McDonell, unpublished observations).

cell. This ventilatory response to CO₂ is often presented as a response curve wherein V_A or V_E is plotted against the PaCO₂, the alveolar partial pressure of carbon dioxide (P_ACO₂), the end-tidal CO₂ partial pressure (P_{ET}CO₂), or the inspired-CO₂ level (Fig. 5.10A). An increase in PaCO₂ of 3 to 5 mm Hg will produce a rapid doubling or tripling of V_A in an effort to return PaCO₂ to eucapnic levels. This response is a little less sensitive in horses^{51,52} and a lot less sensitive in burrowing and diving mammals.⁵³ In ruminants, the gas produced in the rumen may consist of more than 60% CO₂, and when it is eructated a significant proportion of this gas is inhaled, contributing to a cyclic breathing pattern.⁵⁰ A fall in arterial pH will also stimulate respiration through the central and peripheral chemoreceptors, as seen with metabolic acidosis: This response is slower. The central chemoreceptors are not responsive to alterations in PaO₂ levels.

The *peripheral chemoreceptors*, which are located in the carotid and aortic bodies, generally play a significant part in respiratory drive only when PaO₂ levels fall below 60 mm Hg.^{6,52} This is illustrated in Fig. 5.10B, drawn from a study on conscious horses.⁵⁴ As the F_IO₂ was decreased from 1.0 (100% inspired

oxygen) down to 0.16, there was no change in V_E . At an F_IO₂ of 0.16, the alveolar oxygen tension (P_AO₂) would be 60 to 65 mm Hg at sea level. In sheep, goats, calves, and ponies, however, carotid body denervation causes some hypoventilation, hypoxemia, and hypercapnia, and it is estimated that carotid body receptor activity is responsible for up to 30% of the resting V_A drive in calves at sea level⁵⁵ and up to 40% in miniature pigs.¹⁷

The activity of the central neural systems and the level of ventilatory drive are also influenced by the general level of central nervous system activity, especially by traffic through the reticular activating system (RAS). This is evidenced by the decrease in V_A and small increase in PaCO₂ that accompany sleep, and by the fact that exercising animals commonly become hypocapnic even if tissue oxygen delivery is adequate. Anesthetists make good use of this link between RAS activity and respiratory drive by using an increase in sensory stimulation (limb flexion, twisting a horse's ear, rolling a dog or cat over, or vigorously rubbing the body surface) to increase ventilatory drive during emergence from inhalation anesthesia, thereby speeding inhalant drug elimination and recovery.

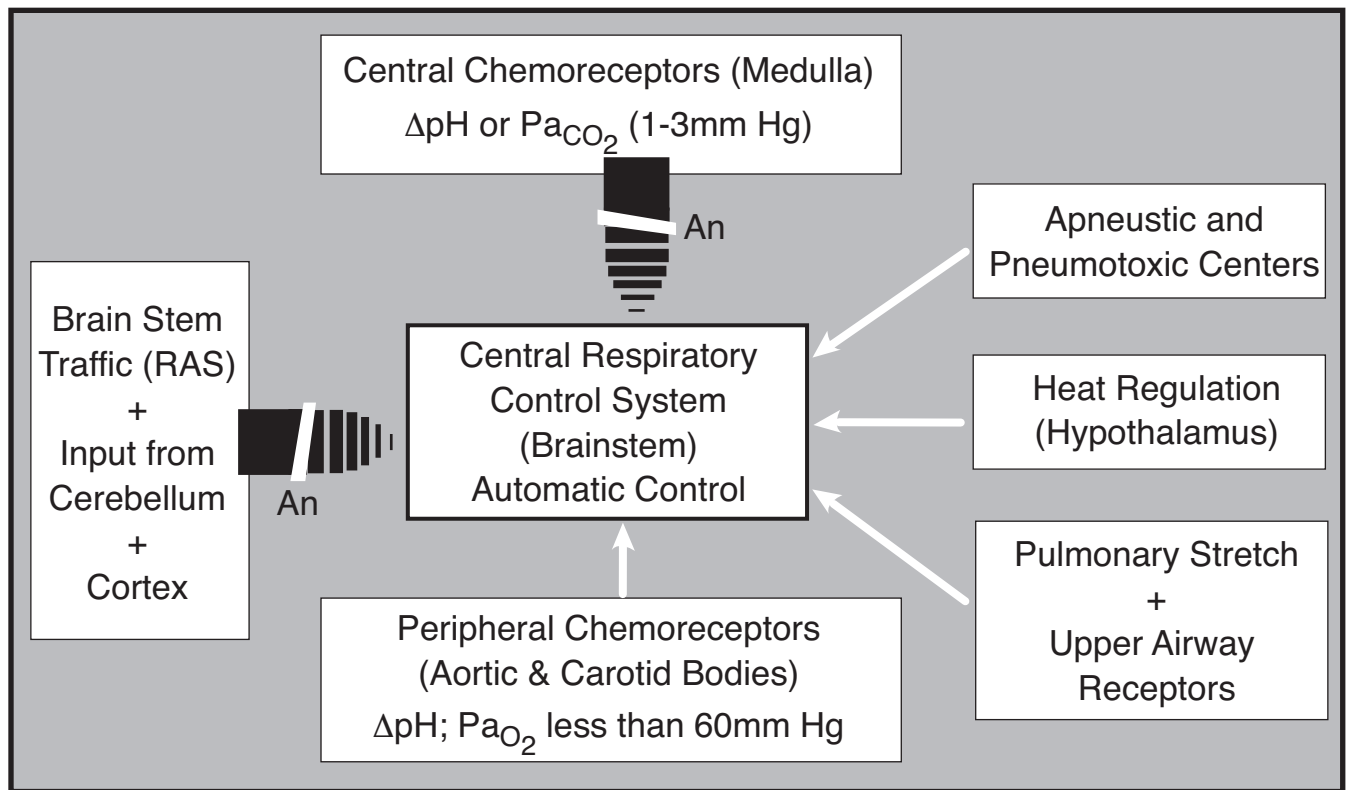

Fig. 5.9. Schematic diagram of the control of ventilation in conscious and anesthetized animals. In conscious animals, the level of alveolar ventilation is primarily determined by the arterial carbon dioxide partial pressure (PaCO_2) level (as sensed by the central chemoreceptors) and the level of brain-stem traffic, with the apneustic and pneumotoxic centers and the stretch receptors governing the relationship between tidal volume and frequency to achieve the required alveolar ventilation. General anesthesia (An) reduces brain-stem traffic and the chemoreceptor response to carbon dioxide, leading to an increase in PaCO_2 . In most species, the peripheral chemoreceptors begin to influence the level of alveolar ventilation if PaO_2 falls below 60 mm Hg. ΔpH , change in pH; and RAS, reticular activating system.

The apneustic and pneumotoxic centers, and pulmonary and airway receptors, are primarily responsible for adjusting the balance between f and V_T to achieve a given level of V_A , usually in a way that minimizes the energy cost of breathing. Although the function of these receptors is generally not considered to be greatly influenced by the action of anesthetic and perianesthetic agents, they may play a part in some of the species differences we see in response to a particular drug or group of drugs. For instance, as the inhaled dose of isoflurane is increased, f remains stable or increases in ferrets,^{56,57} whereas f decreases in rats⁵⁶ and rabbits.⁵⁷ In dogs and cats, as the dose of an inhalant agent increases, f often remains constant or increases,^{58,59} although there is some variation in response between drugs.⁶⁰ In horses, f remains more or less constant with increasing inhalant anesthetic doses.^{61–63} Respiratory rate is usually less with isoflurane, sevoflurane, or desflurane than with halothane at an equipotent dose, whereas V_T is larger.^{61,63} The barbiturates usually decrease f and V_T as the dose is increased, whereas the primary response to increasing inhalant doses is to reduce V_T (ether is an exception). In ruminants, general anesthesia is often associated with tachypnea and very shallow breathing.^{64,65} All of these differences might well originate from species and/or drug differences in the central inspiratory-expiratory switching mechanisms or

lung receptor activity (stretch receptors, irritant receptors, and C fibers), but so far the evidence is primarily speculative. Irritant airway receptor activity, especially in the larynx and tracheal regions, appears to differ quite markedly between species. Horses, for instance, have a weak laryngeal reflex, so it is rather easy to insert a nasoendotracheal tube in a conscious horse, even without the aid of local anesthesia. In contrast, swine and cats have a strong laryngeal reflex, and fairly deep anesthesia is required for easy endotracheal intubation unless local desensitization is produced using a topical anesthetic. The response of dogs is intermediate.

Apneic Threshold

The *apneic threshold* is the PaCO_2 level at which ventilation becomes zero; that is, where spontaneous ventilatory effort ceases (Fig. 5.10A). A PaCO_2 reduction of 5 to 9 mm Hg from normal values through voluntary hyperventilation (a conscious human), or by artificial ventilation of sedated or anesthetized animals, produces apnea. The distance between the resting PaCO_2 level and the apneic threshold is relatively constant (i.e., 5 to 9 mm Hg) irrespective of the anesthetic depth.⁶⁶ Veterinary anesthetists use the apneic threshold to control respiration (i.e., abolish spontaneous efforts) when putting an animal on a ventilator, or to tem-

porarily provide for a quiet surgical field without having to resort to the use of muscle relaxant drugs.

Drug Effect on Control of Ventilation

Anesthetics and some perianesthetic drugs alter the central and peripheral chemoreceptor response to CO_2 and oxygen in a dose-dependent manner.^{66–68} This has important clinical implications in terms of maintaining homeostasis during the perioperative period. There will also be a diminution in external signs in hypoxemic or hypercarbic anesthetized animals. Whereas unsedated animals usually demonstrate obvious tachypnea and an increase in V_T or respiratory effort in response to serious hypoxemia or hypercapnia, these external signs of an impending crisis may well be absent or greatly diminished in anesthetized animals.

Inhalants and Injectable Drugs

All of the general anesthetic agents in current use produce a dose-dependent decrease in the response to CO_2 .^{5,24,67} With commonly used inhalant agents, the CO_2 response is almost flat at a minimum alveolar concentration of 2.0 (Fig. 5.11).⁶⁹ The reduced sensory input and central sensitivity to CO_2 produce a marked fall in V_A , usually through a dose-related fall in V_T , with f being reasonably well maintained. A proportional increase in V_D/V_T occurs, because $V_{D \text{ anat}}$ is more or less constant. As a result of these changes, PaCO_2 levels increase as the anesthetic dose is increased when animals breathe spontaneously (Fig. 5.12A).^{58,70,71} In light anesthetic planes (e.g., minimum alveolar concentration of 1.2), PaCO_2 will generally remain moderately elevated, but stable, over

many hours of anesthesia, whereas, at higher concentrations or in ruminants, PaCO_2 increases progressively over time. The degree of hypercarbia at equipotent doses of inhalant (and intravenous) anesthetic agents varies with the species and the degree of surgical stimulation (Fig. 5.12B).^{61,72–74} Of the commonly used inhalant anesthetics, halothane produces the least increase in PaCO_2 during spontaneous respiration, whereas, at equipotent doses, isoflurane, sevoflurane, and desflurane produce somewhat higher and similar PaCO_2 levels in most species.^{57,60–63,75}

In ruminants, the degree of hypercarbia is greater with equipotent inhalant anesthetic doses than for horses, and horses show more respiratory depression than monkeys or dogs (Fig. 5.12B). Clinically, swine, ferrets, and rabbits also seem to be more prone to hypercarbia, whereas deep-diving seals may become totally apneic during light levels of anesthesia or even just opioid sedation.⁷⁶

During surgery the level of respiratory depression is usually less and the differences between drugs may disappear. For example, in dorsally recumbent, spontaneously breathing pregnant mares induced with xylazine and thiamylal sodium and maintained on halothane or isoflurane for laparotomy surgery, PaCO_2 levels increased from 53.8 to 58.3 mm Hg during halothane anesthesia and were 60.7 to 60.5 mm Hg during isoflurane anesthesia. There was no significant difference in PaCO_2 (or PaO_2) levels with the two agents from 30 to 90 min, although f was lower (4 to 5/min) with isoflurane than with halothane (8 to 10/min).⁷⁷

Barbiturates, propofol, and the cyclohexamines (ketamine, phencyclidine, and tiletamine) also produce a similar dose-

Fig. 5.11. Effect of halothane sedation (0.1 minimum alveolar concentration [MAC]) and anesthesia (1.1 and 2.0 MAC) on depression of the ventilatory response to hypoxia, hypercapnia, and doxapram expressed as a percentage of the awake control response. Reproduced from Knill and Gelb,⁶⁹ with permission.

related alteration in the CO₂ response, which may, in the case of barbiturates, outlast the period of actual anesthesia by some time.⁷⁸ Although it is generally considered that ketamine is not as much of a respiratory depressant as the barbiturates,⁶⁸ clinical

experience and survey studies have shown that safe, clinically effective doses of ketamine may induce apnea in some susceptible individuals.⁴⁶ The typical response to increasing doses of barbiturates is for both V_T and f to decrease. When injectable anesthetics are used before inhalation agents, as is commonly done in clinical veterinary anesthesia, the respiratory-depressant effects of both drugs are at least additive.⁷⁸

Although the control of ventilation during anesthesia is primarily determined by central CO₂ responsiveness (albeit reduced), during very deep barbiturate anesthesia CO₂ ventilatory drive may disappear and the drive may become hypoxic. Hypoxic drive sensitivity is also lessened appreciably by general anesthetics (at least inhalants) in a dose-related manner (Fig. 5.11).⁶⁹ It is interesting to note that, although the peripheral chemoreceptor response to PaO₂ at physiological levels (80 to 110 mm Hg) is virtually nonexistent in conscious animals, in anesthetized horses and ducks the PaCO₂ levels are greater at F_IO₂ 1.0 than at F_IO₂ 0.3.^{79,80} Therefore, the high oxygen levels used in most inhalant regimens might contribute somewhat to depression of ventilation while helping to ensure that the level of oxygenation is adequate.

Opioids

When given alone, opioids shift the CO₂ response curve to the right with little change in slope, except at very high doses. This means that the resting PaCO₂ level might be a little higher in an animal receiving a therapeutic dose of an opioid for premedication or postoperative recovery, but that the response to further CO₂ challenge (from metabolism, airway obstruction, etc.) will not be abolished. Clinically, when opioids are used at high doses

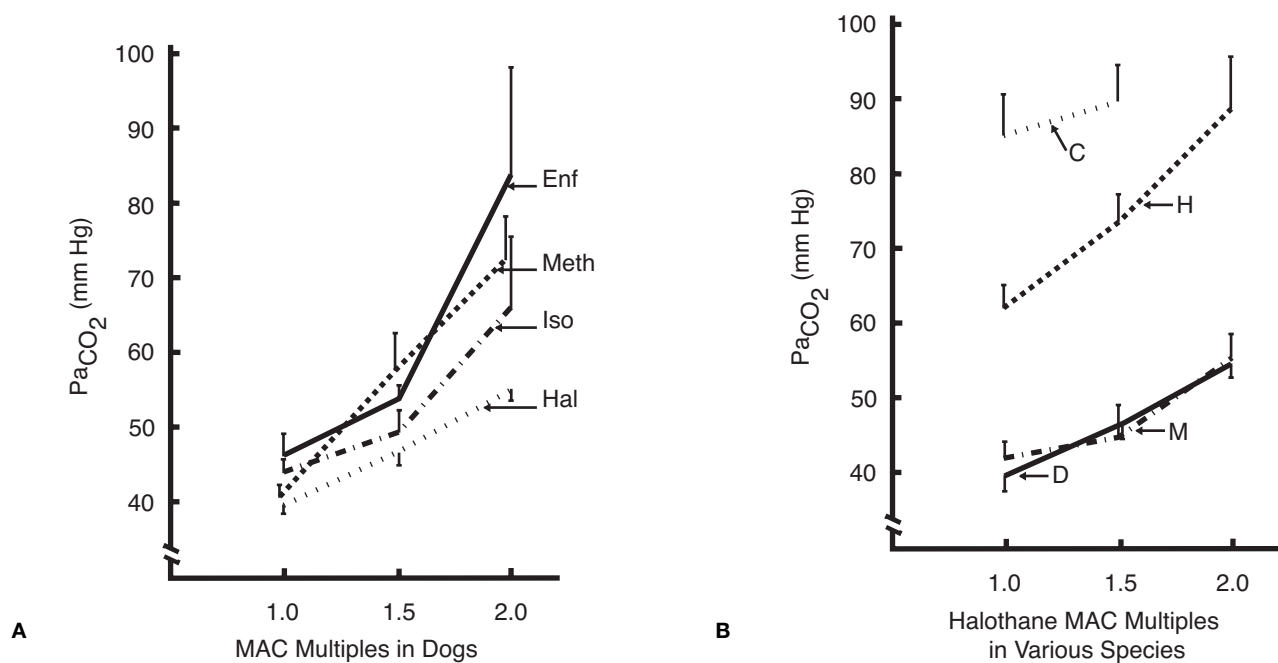

Fig. 5.12. **A:** Influence of increasing anesthetic dose (multiples of minimum alveolar concentration [MAC]) on arterial carbon dioxide partial pressure (PaCO₂) in spontaneously breathing dogs anesthetized with enflurane (Enf), methoxyflurane (Meth), isoflurane (Iso), or halothane (Hal). Data compiled from a series of studies done by Steffey and coworkers,^{58,70,71} with permission. **B:** Differences in the PaCO₂ with spontaneous breathing and increasing halothane levels (multiples of MAC) in calves (C), horses (H), monkeys (M), and dogs (D). Data compiled from a series of studies done by Steffey and coworkers,⁷¹⁻⁷⁴ with permission.

as part of a balanced anesthetic regimen, there is an additive effect of the opioid depression of the respiratory center and the general anesthetic, and considerable hypercarbia or even apnea may be produced.^{81,82} In addition, the μ opioids in particular tend to produce rapid, shallow breathing in dogs,⁸³ which may interfere with the subsequent uptake of an inhalant anesthetic.

At the doses commonly employed for routine opioid premedication or postoperative analgesia in veterinary practice, significant respiratory depression is very rarely seen, at least in terms of producing hypercapnia.^{83–85} Frequency of ventilation may decrease owing to a decrease in apprehension. In fact, effective alveolar ventilation may well improve when opioid analgesics are employed for postoperative pain relief.⁸⁶ The postoperative use of opioids has been implicated in the development of an increased incidence of postoperative atelectasis and hypoxemia in human patients, especially during sleep.⁸⁷ Clinical evidence would suggest that the incidence of similar problems in veterinary patients is rare, but it is an area that warrants further study.

The historical tendency to minimize the use of opioids for postoperative analgesia because of the fear of serious respiratory problems is simply not based on facts, as is now well recognized.⁸⁸ There is a ceiling effect and less respiratory depression associated with opioid agonists/antagonists (e.g., pentazocine, butorphanol, nalbuphine, and buprenorphine) when used at high doses than with the pure μ -agonists (meperidine, morphine, and oxymorphone).⁸⁹ Using the epidural route of administration helps to ensure that there is minimal postoperative respiratory depression with high-risk cases.^{90,91}

Tranquilizers

The phenothiazine and benzodiazepine sedatives often reduce the respiratory rate, especially if an animal is somewhat excited prior to administration, but they do not appreciably alter arterial blood-gas tensions.^{84,92,93} There are few studies of the effect of these drugs on CO₂ responsiveness, especially in animals. Horses sedated with acepromazine (0.65 mg/kg intravenously [IV]) responded similarly, in terms of V_E change, to unsedated horses until the level of hypoxia or hypercapnia was quite severe ($F_I O_2$ of 0.1 or $F_I CO_2$ of 0.06), at which time the response was lessened.⁵⁴ When used alone, diazepam (0.05 to 0.4 mg/kg IV) does not produce significant changes in PaO₂ or PaCO₂ in horses.⁹⁴ The respiratory-protective nature of these drugs is such that when they are combined with a general anesthetic, and the required dose of the general anesthetic is thereby lessened, ventilation is better than when an equipotent higher concentration of the general anesthetic (barbiturate or inhalant) is used alone. This may be one of the reasons why phenothiazine and benzodiazepine tranquilizers are widely employed as preanesthetic drugs in clinical practice.

Sedatives and Hypnotics

The α_2 -adrenoceptor agonists (α_2 -agonists) produce a more complicated effect on respiration. The usual clinical doses of xylazine and detomidine produce laryngeal relaxation in horses and alter pulmonary mechanics (dynamic compliance and pulmonary resistance).^{95,96} Some, but not all, of this effect is produced by the

change in position of the horse's head with sedation.⁹⁷ Certainly, the degree of laryngeal dysfunction produced by α_2 -agonist sedation in horses precludes using this type of sedation when carrying out diagnostic examination of the larynx. Although most studies have failed to demonstrate a significant increase in PaCO₂ levels after sedation of horses with xylazine, detomidine, or romifidine,^{98,99} a fall in PaO₂ of 10 to 20 mm Hg is often observed.^{95,97,98}

In sheep, it is apparent that clinically useful sedative doses of xylazine and other α_2 -agonists produce significant hypoxemia, as illustrated in Fig. 5.13, without producing hypoventilation.^{100,101} Sheep remain eucapnic or even become hypocapnic from the hypoxic stimulus. This response is associated with tachypnea, a fall in dynamic compliance of the lung (i.e., an increased stiffness), and an increase in the maximum change in transpulmonary pressure and pulmonary resistance during tidal breathing.^{100–102} This response can occur with even subsedative doses,¹⁰² and the hypoxemia can last longer than the period of sedation.^{100,101} On conventional and electron-microscopic histological examination, the initial response appears to be associated with internalization of the surface coat and activation of the pulmonary intravascular macrophages found in sheep (and all other ruminants).¹⁰³ It is hypothesized that these reactive cells release inflammatory mediators that lead to the rapid onset of bronchoconstriction and to leakage of the pulmonary vascular bed. By 10 min, there is obvious evidence of intra-alveolar edema and hemorrhage after clinical sedative doses of xylazine (Fig. 5.14) or medetomidine, and even after administration of the peripherally acting nonsedative α_2 -agonist ST-91.¹⁰³

It is unclear whether this toxic response also occurs in other ruminants, partly because the effect of a change in body position or the concurrent use of other drugs is hard to differentiate. In calves, PaO₂ levels decreased from 88 to 55 mm Hg after xylazine sedation¹⁰⁴ and, in goats, a fall from 90 to 65 mm Hg was observed.¹⁰⁵ When seven healthy adult Holstein cows positioned in left lateral recumbency (on a tilt table) were given 0.2 mg/kg xylazine IV, mean PaO₂ levels decreased from 79.0 ± 4.5 mm Hg (SEM) to 54.5 ± 2.7 mm Hg at 5 min and to 58.4 ± 2.6 mm Hg at 15 min after xylazine administration. PaCO₂ levels also increased significantly from 34.9 ± 2.0 mm Hg to more normal levels of 45.0 ± 2.1 and 45.6 ± 1.4 mm Hg at 5 and 15 min (R. Warren and W. McDonnell, unpublished data).

Hypoxemia is a significant problem when wild deer, bison, and wapiti are immobilized using drug combinations containing α_2 -agonists (or opioids).^{106–108} Treatment with supplemental oxygen is recommended and will increase PaO₂ to safer levels.¹⁰⁸

When used alone at sedative doses, the α_2 -agonists exhibit little evidence of true respiratory depression in healthy dogs or cats.^{109–113} There may be a decrease in respiratory rate and perhaps a small increase in PaCO₂ levels, but PaO₂ levels are well maintained. The peripheral cyanosis that has been reported in up to one-third of dogs sedated with medetomidine is believed to be caused by the low blood flow through peripheral capillary beds and venous desaturation, rather than a fall in arterial saturation.¹¹⁴

It is important to appreciate, however, that the degree of respiratory depression produced by any α_2 -agonist will be increased

Fig. 5.13. Arterial oxygen tension (arterial oxygen partial pressure [PaO₂]) in sheep after intravenous saline, diazepam, or α_2 -adrenergic agonist sedative administration in healthy adult sheep maintained in sternal recumbency. Baseline (BL) values over 1 h are shown for saline (◇), diazepam (□, 0.4 mg/kg), xylazine (■, 150 μ g/kg), romifidine (△, 50 μ g/kg), detomidine (▲, 30 μ g/kg), medetomidine (◆, 10 μ g/kg) and the peripheral acting experimental nonsedative α_2 -agonist ST-91 (●, 30 μ g/kg). Significant differences ($P \leq 0.05$) from placebo treatment for diazepam (*) and all other α_2 -agonists (#) are shown. Note the marked degree of hypoxemia with arterial oxygen partial pressure (PaO₂) values well below normal venous levels, and also the persistence of the hypoxemia over the full 1 h. This was well past the actual duration of sedation for a number of the agents. Data modified from Celly et al.,^{100,101} with permission.

(often substantially) when the agonist is given along with other sedatives or anesthetic agents. A number of studies have clearly demonstrated that medetomidine produces elevated PaCO₂ levels and PaO₂ levels in the mildly hypoxic range (i.e., 60 to 70 mm Hg) when combined with either μ or κ opioids, or with propofol or ketamine, at clinical doses in healthy animals. The decrease in PaO₂ levels is due in part to some degree of hypoventilation and to an increase in V/Q scatter, as described in the next section. Therefore, it is recommended that oxygen should be administered by face mask or endotracheal intubation whenever α_2 -agonists are used in combination with other sedatives or injectable anesthetics.¹¹⁴ This is especially true when dealing with geriatric or ill animals.

Ventilation-Perfusion Relationships During Anesthesia

The onset of general anesthesia^{3,5,6} or, in the case of larger animals, even a change in body position^{115–118} often produces lower PaO₂ levels than expected for the delivered concentration of in-

spired oxygen. This change can occur even without hypoventilation and during both spontaneous and controlled breathing. Lower PaO₂ is produced by altered ventilation-perfusion ratios within the lung. Much of what we know about this phenomenon of altered gas exchange is derived from studies of the human response to anesthesia, some experiments in dogs, and many studies on anesthetized horses. It is obvious when one looks at the collective results that there are important species differences, although the reason(s) for these differences are not always obvious.

Ventilation-Perfusion Scatter Under Normal Conditions

To understand how anesthesia alters ventilation-perfusion (or V/Q) relationships, it is first necessary to appreciate the scatter of V/Q ratios in the normal lung of unanesthetized animals and to appreciate the mechanisms by which regional matching of pulmonary blood flow and alveolar ventilation is optimized.^{7,41} Figure 5.15 is a schematic representation of V/Q relationships in conscious and anesthetized animals.

A

B

Fig. 5.14. Histology of sheep lungs 10 min after intravenous saline administration (A) or 150 µg/kg of xylazine (B). Note the degree of alveolar hemorrhage and edema present after xylazine administration. Euthanasia and fixation as reported elsewhere.¹⁰³ Images courtesy of C. Celly, with permission.

Intrapleural pressure is more subatmospheric over the uppermost areas of the lung than adjacent to dependent regions because of the “weight” of the lung within the thoracic cavity.^{39,119} Partly because of differences in lung density among species and partly because of differences in chest wall configuration, the total vertical gradient of intrapleural pressure over the whole lung apparently does not differ much among species, despite large differences in lung size and height. This is fortuitous, because otherwise there would be a tendency for too great a discrepancy between the size of the uppermost and lowermost alveoli. The gradient of intrapleural pressure means that in unanesthetized animals the uppermost alveoli (A in Fig. 5.15) are larger than alveoli in the middle and lower regions of the lung (C and D). Since the pressure-volume curve of the lung is sigmoid, the larger alveoli tend to be on the flat part of the curve and thus distend less for any given change of intrapleural pressure during inspira-

tion.^{6,120} Thus, the more dependent alveoli (D) receive proportionally more of an inspired tidal volume, unless a disease process (e.g., chronic airway obstruction or pneumonia) or a decrease in lung volume leads to intermittent or complete airway closure (E and F) or actual atelectasis (G).

At the same time, there is a vertical gradient of pulmonary blood flow, because the pulmonary artery is a low-pressure system affected by hydrostatic pressure.^{42,121} Some alveoli may receive no perfusion (A in Fig 5.15) and constitute an alveolar dead space, whereas alveolus D receives more perfusion than alveolus B. In most species, the increased ventilation of alveolus D is not sufficient to match the higher perfusion, and the V/Q ratio of alveolus D is 0.7, compared with the V/Q ratio of 1.7 for alveolus B. Overall, the collective scatter of V/Q ratios for the normal lung in resting individuals is 0.8 to 0.9.

Based on radioisotope-distribution evidence, the vertical gra-

Fig. 5.15. Schematic diagram of ventilation-perfusion (V/Q) relationships in the lung and the primary mechanisms whereby venous admixture and the alveolar-to-arterial gradient ($P_{(A-a)O_2}$) increases during anesthesia. The gradient of pleural pressure is shown with the uppermost aspect of the pleural space more subatmospheric than the dependent region, which may even become positive relative to atmosphere if lung volume decreases enough. The inflow of gas is represented by the *nonshaded area* in the tracheobronchial tree. This inspired gas may reach alveoli that are not perfused (A), may reach alveoli that are variably perfused (B to D), or may intermittently reach alveoli (E) through airways that open only later during the inspiration. Nonventilated alveoli (F) will usually become atelectatic (G), especially when high inspired-oxygen levels are used. The *finely shaded area* represents the flow of mixed venous blood from the pulmonary artery, and the *coarsely shaded area* represents postcapillary oxygenated blood. Blood flow from alveoli with low V/Q ratios (E), from nonventilated alveoli (F), or from anatomical shunt areas (H) will all contribute to the venous admixture effect and increase the alveolar-to-arterial gradient ($P_{(A-a)O_2}$). The venous admixture effect of low V/Q areas is abolished when high-oxygen mixtures are inhaled, because even poorly ventilated alveoli will have sufficient oxygen to oxygenate the blood going past.

dient of perfusion and ventilation is minimal in standing dogs with a horizontal lung,¹²² and matching of vertical perfusion and ventilation gradients in conscious horses is such that there is little difference in V/Q in different lung regions.¹²³ More recent studies using a multiple inert-gas washout method in horses suggest the scatter of V/Q ratios in conscious horses is very similar to that seen in people.¹²⁴ No regions of low V/Q were identified, but a minor shunt component (less than 3% of cardiac output) was observed. A high V/Q area was observed (constituting 3% to 17% of the total), and the extent of this area was correlated with lower pulmonary artery pressures.¹²⁴

When pulmonary artery blood flows through vascular channels not adjacent to alveoli (H in Fig. 5.15) or passes nonventilated alveoli (G and F), unoxygenated blood will pass from the right side of the circulation into the left side, leading to a lower PaO_2 .

In conscious animals, if regional ventilation is decreased, a local vasoconstriction (hypoxic pulmonary vasoconstriction [HPV]) tends to divert blood flow away from underventilated areas of the lung.¹²¹ There is an apparent difference in the strength

of the HPV response to whole lung hypoxia in various species,¹²⁵ based on high-altitude and excised lung studies.^{126,127} Cattle and swine have a strong reflex, whereas ponies, cats, and rabbits have an intermediate response. Sheep, cats, and dogs show less response. It appears, however, that under normal conditions even species with a weak hypoxic pulmonary reflex are capable of considerable blood flow diversion in response to regional areas of low alveolar oxygen content.^{125,128}

Measurement of V/Q Mismatch

When the barometric pressure, inspired-oxygen concentration, $PaCO_2$, and respiratory quotient are known, the P_AO_2 can be calculated by using one form of the alveolar air equation (Figs. 5.2 and 5.4). The difference between this value and the PaO_2 (i.e., the alveolar-to-arterial gradient [$P_{(A-a)O_2}$]) provides a convenient and practical measure of the relative efficiency of gas exchange. This measurement is commonly used in anesthetic studies. The measured $P_{(A-a)O_2}$ value increases as $F_{I}O_2$ goes up for any given V/Q situation, and it is imperative that the $F_{I}O_2$ level be taken into account when comparisons are made. In practice, most

$P_{(A-a)}O_2$ determinations are made at oxygen concentrations of 21% or near 100%.

The amount of venous admixture or pulmonary-shunt flow can be determined if mixed venous (pulmonary artery) and arterial blood oxygen contents are obtained along with a measurement of cardiac output and calculated P_{AO_2} . The terms *venous admixture* and *shunt flow* do not mean exactly the same thing, although they are often used interchangeably in the literature, which causes some confusion. *Venous admixture* refers to the degree of admixture of mixed venous blood with pulmonary end-capillary blood that would be required to produce the observed difference between the arterial and the end-capillary PO_2 .^{5,6} The end-capillary PO_2 is assumed to equal the alveolar PO_2 . Venous admixture is a calculated amount (i.e., a proportion of cardiac output) and includes the PaO_2 -lowering effect of low V/Q areas, blood flow past nonventilated areas, and true *anatomical shunt flow* (bronchial and thebesian venous blood flow). When the inspired-oxygen level is high, blood passing low- V/Q areas will be oxygenated (Fig. 5.15), and the $P_{(A-a)}O_2$ gradient and determination of venous admixture is a measure of all the total blood flow not contributing to gas exchange; hence the term *pulmonary-shunt flow*. Note that this flow includes both anatomical shunt flow and flow past nonventilated or collapsed alveoli.

If one knows the inspired-oxygen concentration and the PaO_2 , and assumes that the arterial-venous oxygen extraction is normal, an isoshunt diagram can be used to provide a convenient and reasonably accurate estimate of the magnitude of pulmonary-shunt flow (Fig. 5.16).¹²⁹ Figure 5.16 is a diagram that illustrates the poor response, in terms of improving PaO_2 , that will occur with increased inspired-oxygen concentrations when shunt flows are over 30%.

Fig. 5.16. An isoshunt diagram depicting the relationship between inspired-oxygen concentration, partial pressure of oxygen (PO_2), and various degrees of venous admixture or pulmonary shunt. Shunt flow is expressed as a percentage of cardiac output. The arteriovenous (a-v) oxygen-content difference is assumed to be 5.0 mL per 100 mL of blood, reflecting a normal cardiac output. The shunt bands have been drawn to include the range of hemoglobin (Hb) and arterial carbon dioxide partial pressure (Pa_{CO_2}) levels shown. Redrawn from Benetar et al. (p. 713),¹²⁹ with permission.

Effect of Positional Changes

Very few thorough studies of the respiratory consequences of positional changes in conscious domestic animals have been carried out because of the technical difficulties in doing such studies with uncooperative animals. In conscious human patients positioned in lateral recumbency, there is proportionately more ventilation to the lowermost lung.¹³⁰ There is a slight fall in FRC, but in individuals with normal lungs and body confirmation there is little change in PaO_2 . Conscious dogs positioned in sternal (prone), lateral, and dorsal (supine) recumbency showed no positional change in FRC (Fig. 5.17).¹³¹ Unsedated sheep,¹¹⁵ cattle,¹¹⁸ and ponies¹¹⁶ develop some degree of hypoxia when put into lateral recumbency, although this finding was not present in another group of ponies.¹³² Mean PaO_2 levels in unsedated adult cattle positioned in dorsal recumbency are in the range of 60 to 70 mm Hg, with some animals experiencing marked hypoxemia.^{117,118}

Although the evidence in conscious animals is mainly circumstantial and meager, it does appear that the main determinant of FRC is a decrease in lung volume in recumbent animals (Fig. 5.18), as has been reported in anesthetized animals.^{36,37} When conscious, sedated, 1400- to 4000-kg elephants voluntarily moved from a standing position to left lateral recumbency, PaO_2 levels decreased only from 96.2 to 83.8 mm Hg (at 10 min).¹³³ This relative protection against positional hypoxemia may be related to anatomical differences in the lung parenchyma, chest wall, and lung adhesion to the chest wall.¹³⁴

In standing cows and sheep, rumen distension and the associated increase in abdominal pressure produce a decrease in PaO_2 , and at very high rumenal pressures a reduction in V_E and cardiac output.^{135,136} In four standing ponies (two starved for 18 h and two nonstarved), FRC as measured by helium dilution decreased

Fig. 5.17. Effect of positional changes and general anesthesia on functional residual capacity (FRC) in dogs (D), cattle (C), ponies (P), and horses (H). FRC in the conscious state is shown by the open squares and in the anesthetized state by the solid squares. All measurements were obtained during barbiturate anesthesia. Note that FRC does not change appreciably in anesthetized dogs with positional changes and decreases markedly with the onset of anesthesia and recumbency in the larger species. In horses, FRC is markedly less in dorsal or lateral recumbency, compared with sternal recumbency. Data taken from various studies.^{35–37,117}

by 13.4% (range, 11.6% to 14.7%) after sedation with 0.04 mg/kg of acepromazine given intramuscularly. In another study, overnight starvation increased the FRC of five standing, unstarved ponies by about 16%.³⁷

Species Differences

As mentioned earlier, deep sedation and general anesthesia commonly produce a fall in PaO_2 levels even in healthy animals. Some of this decrease can be associated with hypoventilation (Fig. 5.6), but even when PaCO_2 levels are eucapnic, PaO_2 is generally decreased. The anesthetic-induced change in PaO_2 is associated with increases in the scatter of V/Q ratios, the $P_{(A-a)}\text{O}_2$ gradient, and the level of venous admixture.^{3,5,6} In the case of larger mammals, there may even be gross V/Q mismatch.^{1,137} It is generally appreciated that $P_{(A-a)}\text{O}_2$ gradients are always increased during general anesthesia in horses.^{1,2,138,139} Healthy horses may have low PaO_2 levels when anesthetized with injectable drugs.¹⁴⁰ In horses with diseased lungs or depressed cardiopulmonary function (e.g., anesthesia), it may be impossible to maintain PaO_2 levels above 70 mm Hg even with 100% inspired oxygen.¹⁴¹ The same response to 100% oxygen administration may be observed in adult cattle.⁶⁵

Recumbency per se does not produce significant hypoxemia in healthy dogs, cats, or people, and in the case of larger mammals produces less of an increase in the $P_{(A-a)}\text{O}_2$ gradient than is seen after the onset of anesthesia. What are the factors that produce hypoxemic changes in anesthetized animals? Research on the respiratory effects of anesthetics has focused on their influence on (a) HPV; (b) lung volume, chest wall, and pulmonary mechanical factors; and (c) the resultant distribution of regional pulmonary blood and gas flow.

Hypoxic Pulmonary Vasoconstriction

It appears that this important protective mechanism to optimize V/Q in the lung is obtunded by many anesthetics. Investigations

in intact animals and with excised lungs have established that most, if not all, inhalational agents reduce HPV, and that none of the injectable agents examined (narcotics, barbiturates, or benzodiazepines) have any detectable effect.¹²¹ There is at least one report that HPV is better maintained with sevoflurane and desflurane,¹⁴² but the practical importance of this finding is not yet clear. The onset of the interference with HPV is rapid with inhaled anesthetics and persists throughout anesthesia. The end result of this interference with HPV is that, for any given level of altered intrapulmonary gas distribution caused by reduced lung volume, intermittent airway closure, or regional atelectasis, a greater degree of hypoxemia exists. With an animal breathing 100% oxygen and HPV abolished, PaO_2 has been estimated to be only 100 mm Hg with 30% of the lung atelectatic, compared with a PaO_2 level of over 400 mm Hg with the same degree of atelectasis and an intact HPV response.¹²¹ No clinically relevant, controlled comparisons of $P_{(A-a)}\text{O}_2$ gradients have been performed using intravenous anesthesia compared with inhalational anesthesia in veterinary patients. There is some evidence that PaO_2 is better maintained in horses when a xylazine-ketamine-guaifenesin infusion is used instead of halothane to maintain anesthesia.¹⁴³

In anesthetized horses, there is evidence that pulmonary perfusion does not linearly increase from the uppermost lung areas to the lowermost areas solely on a gravitational basis, even when HPV is abolished.^{144,145} It has been demonstrated that the gravity-dependent pulmonary blood flow of conscious horses is altered when they are positioned in sternal, lateral, or dorsal recumbency during halothane anesthesia.¹⁴⁶ There was a reduction in blood flow to the cranioventral areas of the lung and a proportional increase in flow to dorsocaudal regions, irrespective of body position. A nongravitational pulmonary blood flow pattern in pentobarbital-anesthetized ponies has been demonstrated.¹⁴⁷ At least some of this diversion of pulmonary blood flow from the most dependent areas of the horse lung might be related to cre-

ation of a zone IV area of blood flow from reduced lung volume and an increase in interstitial fluid pressure (Fig. 5.3). This sort of diversion has been observed in persons at low lung volumes,¹⁴⁸ and in dogs when interstitial fluid pressures were elevated.¹⁴⁹ Whatever the cause, in laterally recumbent horses, the redistribution of pulmonary blood flow away from relatively nonventilated lower lung to better-ventilated upper lung has a beneficial effect in reducing the degree of venous admixture.¹⁴⁵ It is important to appreciate that redistribution is far from complete, and venous admixture or shunt flows in horses often exceed 20%.

Functional Residual Volume

In recumbent humans, FRC is reduced by about 0.5 L with the induction of general anesthesia,¹²⁰ which is 15% to 20% of the normal FRC. The mechanisms underlying this reduction in FRC remain unclear. Atelectasis, increased thoracic or abdominal blood volume, and loss of some inherent tone in the diaphragm at end exhalation all seem to be involved.^{3,87,120,130} Irrespective of the cause, there is evidence of a correlation between changes in FRC and the $P_{(A-a)}O_2$ gradient after induction of anesthesia.¹⁵⁰ Airway closure, atelectasis, and dependent regions of poorly aerated lung tissue have been demonstrated by using inert-gas elimination and computed tomographic techniques.^{151,152}

There is little information regarding FRC changes in dogs and cats, but in one well-controlled study the onset of general anesthesia did not alter FRC significantly in sternal, lateral, or dorsally recumbent dogs (Fig. 5.17).¹³¹ These were medium-sized mongrel dogs (13 to 28 kg), and larger dogs might show a different response. Differences in V/Q ratios during anesthesia have been noted between beagles and greyhound-type dogs.¹⁵³

In horses and cows, the decrease in FRC with the onset of recumbency and general anesthesia may be quite marked, as much as 50% to 70% (Fig. 5.17). This has been radiographically demonstrated^{154,155} and directly measured by helium dilution^{37,156} and nitrogen washout.³⁶ This change in FRC seems to be primarily related to the positional change from an upright posture to recumbency (Fig. 5.18) and, in horses at least, is greater in lateral or dorsal recumbency than when prone (Fig. 5.17).³⁶ In laterally recumbent animals, the dependent lung is poorly aerated radiographically^{154,155} and has a smaller FRC (as measured by helium dilution) (Fig. 5.19). Studies using nuclear scintigraphy¹³⁷ and computed tomography¹⁵⁷ have clearly demonstrated that there is markedly less ventilation of the dependent lung of horses in lateral recumbency during anesthesia. This reduction in lower lung volume is accompanied by actual atelectasis (Fig. 5.20) and may be influenced by the degree of obesity or body conformation.¹⁵⁸

The FRC of anesthetized horses can be increased and the $P_{(A-a)}O_2$ gradient reduced through the use of high (20 to 30 cm H_2O) positive end-expiratory pressure (PEEP).^{141,159,160} If PEEP of this magnitude is introduced, there is a marked decrease in venous return to the heart and in cardiac output. The mechanism by which PEEP reduces the $P_{(A-a)}O_2$ gradient and venous admixture is likely through increasing total and/or regional FRC, with subsequent prevention of the intermittent airway closure and rever-

Fig. 5.18. Functional residual capacity (FRC) in a xylazine-sedated pony (273 kg) while standing (conscious), after positioning in left lateral recumbency with hobbles (cast), and after induction of anesthesia with thiopental (anesthetized). The study was done twice: once after an 18-h period of starvation and once without starvation. FRC was measured by helium dilution.¹⁵⁶

sal of the atelectasis that is represented diagrammatically by alveoli F and G in Fig. 5.15. Moens and colleagues¹⁶¹ used a double-lumened endotracheal tube and differential IPPV (higher V_T and PEEP of 10 to 20 cm H_2O) to the lowermost lung of quite large laterally recumbent horses (420 to 660 kg). This technique increased PaO_2 levels by over 100% and decreased pulmonary-shunt perfusion by 33%. Similar beneficial effects have been reported using PEEP and selective mechanical ventilation of dependent areas of the lungs in dorsally recumbent horses (Fig. 5.21).¹⁶² With the onset of general anesthesia and positioning in lateral recumbency, PaO_2 levels were elevated to only about 250 mm Hg, rather than the expected above 500 mm Hg that should have occurred if there was no problem with gas exchange. When the horses were moved into dorsal recumbency, their mean PaO_2 level fell to below 100 mm Hg. Conventional IPPV of the whole lung did little to improve PaO_2 , whereas selective mechanical ventilation of the dependent areas of the lung with 20 cm H_2O restored PaO_2 to the level measured in lateral recumbency.

Chest Wall and Pulmonary Mechanics Changes

The evidence implicating alteration of chest wall (including diaphragm) and lung mechanical factors as causative agents in the increase in $P_{(A-a)}O_2$ during anesthesia is often conflicting. Certainly, there is a difference in the chest wall mechanics between people and dogs during general anesthesia.¹²⁰ It appears that most dog breeds (and probably cats) have a more compliant lateral chest wall that tends to contribute relatively little to the in-

Fig. 5.19. Functional residual capacity (FRC) of the left and right lungs, and both lungs, in a horse positioned in dorsal and right and left lateral recumbency. The horse was maintained under stable intravenous anesthesia, and FRC was determined by helium dilution using a double-lumen endotracheal tube to separate the two lungs.¹⁵⁶ Note that the FRC of the dependent lung decreases from the proportion measured during dorsal recumbency and becomes a small percentage of the total FRC, irrespective of which lung is dependent.

Fig. 5.20. Transverse computed tomographic scans of the thorax of a pony during anesthesia with thiopental/halothane in left lateral recumbency (**top left**) and in dorsal recumbency during spontaneous respiration (**top right**), mechanical ventilation (**bottom left**), and mechanical ventilation with positive end-expiratory pressure (PEEP) of 10 cm H₂O (**bottom right**). Note the appearance of large dense areas encircled by a white line in dependent lung regions. The heart is visible as a white area in the middle of the thorax. Reproduced from Nyman et al.,¹⁵⁷ with permission.

spiratory effort, compared with the diaphragm, with clinical doses of most anesthetics. In all species, dangerously deep planes of anesthesia are commonly associated with flaccidity of the thoracic wall and paradoxical inward movement during inspiration (paradoxical inspiration). If one watches closely, this same type

of respiration may be seen in cats, ferrets, and other small mammals, even with light levels of anesthesia.

In horses and cows, with the onset of anesthesia and movement into lateral recumbency, there is radiographic evidence of a marked change in the two-dimensional lung silhouette and the

Fig. 5.21. Arterial oxygen tension (arterial oxygen partial pressure [PaO₂], mean ± SEM) in an awake standing horse (F_IO₂ = 0.21), and during anesthesia in the lateral (Lat.) and dorsal recumbent positions (F_IO₂ > 0.92). SB, spontaneous breathing; MV, general mechanical ventilation; SV, selective mechanical ventilation of dependent lung regions with positive end-expiratory pressure (PEEP) of 20 cm H₂O; *, significantly different from awake value; #, significantly different from the previous value. Reproduced from Nyman et al.,¹⁶² with permission.

position of the diaphragm.^{154,155} In ponies anesthetized with halothane, the diaphragmatic outline moved forward rather uniformly in sternal (prone) or lateral recumbency, but the forward shift was considerably greater in lateral recumbency.¹⁵⁴ When the ponies were positioned in dorsal (supine) recumbency, the diaphragmatic outline sagged toward the now-dependent spine region. With minor variations, observations by Watney¹⁵⁵ in studying 315- to 400-kg cattle were very similar. The positional alteration of the diaphragmatic silhouette agrees nicely with the reduction in FRC noted by Sorenson and Robinson³⁶ when ponies were moved from sternal to lateral or dorsal recumbency. In lateral recumbency, the dorsal areas of the diaphragm moved more during inspiration than did the more ventral sternal area, while the uppermost crural movement exceeded that of the lowermost crural segment.¹⁶³ This is in contrast to awake and anesthetized recumbent persons, where the most dependent portions of the diaphragm are most active.¹⁶⁴ The tonic activity of the lateral chest wall, especially that provided by the serratus ventralis muscle, is greatly decreased in anesthetized horses, and it is postulated that this reduces the stabilization of the lateral chest wall.¹⁶⁵

Although it is generally accepted that halothane and isoflurane produce bronchodilation in humans,^{6,166,167} general anesthesia produces an apparent increase in the elastic recoil of the lung.¹²⁰ In anesthetized ponies, halothane, isoflurane, and enflurane had a mild bronchodilating effect,¹⁶⁸ whereas, in cows^{169,170} and in standing horses at subanesthetic concentrations,¹⁷¹ halothane did not produce bronchodilation. Interpretation of measurements of pulmonary resistance and compliance during anesthesia are made difficult because changes in lung volume per se will alter these values,^{6,169} as was demonstrated when nonstarved cows were studied over a 3-h anesthetic period.¹⁷² It would appear, however, that the chest wall and lung volume changes play a

much larger part in the generation of increased P_(A-a)O₂ gradients during anesthesia than any true alteration of lung mechanics.

Clinical Implications of Altered Respiration During Anesthesia

The complexity of the respiratory response to anesthesia in veterinary patients may seem more than a little daunting to novice anesthetists and to veterinary practitioners of necessity functioning without the benefit of appreciable advanced training in the discipline. This is made so, in part, because of the variety of species that we attend to, as well as the wide range of drugs and environments in which veterinarians find that they must sedate, chemically restrain, or anesthetize animals. In this section, we summarize the most important clinical considerations relative to respiratory management on a species basis for typical patients. This overview is based to a large extent on personal experience and on discussions over the years with academic colleagues and practicing veterinarians. Unfortunately, there are exceedingly few morbidity and mortality surveys of relevant case material upon which one might base more objective conclusions. It is important to appreciate that exceptions to these generalizations may exist, based on the inherent health of the animal being treated, and because the anesthetic response in an individual animal is not always “typical.” There is simply no safe alternative other than ongoing careful monitoring of the respiratory system during anesthesia.

Humans

Since so much of our knowledge of the altered physiology of anesthesia is derived from the literature on human patients, it helps to understand how human anesthesia differs from veterinary anesthesia. In anesthetized humans, alveolar dead space increases by about 70 mL, and venous admixture constitutes approximately 10% of the cardiac output, compared with 2% to 3% in unanesthetized individuals.¹⁷³ With this degree of venous admixture, an inspired-oxygen concentration of about 35% will usually restore a normal PaO₂ (Fig. 5.16). Thus, the upper limit for nitrous oxide in an oxygen–nitrous oxide mixture is commonly 66%, that is, a 1:2 ratio of O₂/N₂O. Muscle relaxants and comparatively high doses of opioids (on an “effect,” not milligram per kilogram, basis) are commonly incorporated into the anesthetic regimen, so IPPV is very commonly employed.^{5,6} The target when ventilating anesthetized patients is usually to produce eucapnia or slight hypocapnia. This was originally done because of an apparent potentiation effect of the anesthetic dose, but now is done primarily to prevent sympathetic stimulation with resultant tachycardia and hypertension, both of which are dangerous in a patient population prone to atherosclerotic disease. Eucapnia also minimizes the risk of increased intracranial or intraocular pressure, which is especially important in trauma patients, the elderly, or those with ocular and/or central nervous system disease.

Some form of airway protection (oropharyngeal or endotracheal tube) is almost always used, and continuous monitoring of airway pressure is employed to ensure that there is no inadvertent

Fig. 5.22. Protective effect of increased inspired-oxygen concentrations with various degrees of alveolar hypoventilation and hyperventilation. With 30% inspired oxygen, alveolar partial pressure of oxygen (alveolar P_{O_2}) levels are above 100 mm Hg even when alveolar ventilation is half normal. Modified from Nunn (p. 111),²⁰⁷ with permission.

disconnection from the anesthetic circuit of a paralyzed patient that cannot breathe spontaneously. Continuous end-tidal CO_2 and hemoglobin-saturation monitoring is now widely employed, using capnography and noninvasive pulse oximetry, respectively.¹⁷⁴ The reasons for the increased use of these monitoring devices are that the equipment is now cost-effective and user-friendly, provides medicolegal protection, and provides an early warning system of cardiorespiratory failure that decreases the mortality rate associated with general anesthesia.^{175,176}

Over the past decade in the field of human anesthesia, there has been considerable interest in the relationship between variable oxygen mixtures used for preoxygenation and during anesthesia and the development of atelectasis in the lung.^{177,178} The usefulness of PEEP and/or forced vital capacity maneuvers (sighs or purposeful expansion of the lung) are being evaluated and debated in terms of the effect on the circulation of compromised patients, efficacy, and duration of effect.^{179–183} The applicability of these findings is likely to vary among species, especially those that differ markedly in body mass from humans, or with increased communication (e.g., dogs) or decreased communication (e.g., ruminants) between alveoli through alveolar ducts or pores of Kohn.¹²⁵ In particular, it would be of great interest to know the highest $F_{I}O_2$ possible to administer during general anesthesia in cattle and horses without contributing to additional atelectasis beyond that produced by positional related changes in FRC.

Dogs and Cats

In reasonably healthy dogs and cats, the $P_{(A-a)}O_2$ gradient and the degree of venous admixture are less than in humans. Perhaps this is owing to the smaller lungs in these species or to the difference in the chest wall changes during anesthesia,¹²⁰ or perhaps because there is excellent collateral pulmonary ventilation in these species.¹²⁵ A high degree of collateral ventilation means that if an alveolus is not ventilated via the airway, it may well receive gas exchange through passages (pores of Kohn) leading to other alveoli that are ventilated.

Despite the relatively favorable situation in regard to V/Q mismatch in these species, a minimum inspired-oxygen level of 30% to 35% is still recommended. For the first few minutes after a barbiturate induction, PaO_2 may be as low as 50 mm Hg in nonventilated healthy dogs,¹⁸⁴ with less change in cats.¹⁸⁵ The degree of hypoxemia is somewhat less after a ketamine induction, but venous admixture still may be 20% to 25% for a few minutes after induction.^{92,93} Obese, deeply anesthetized animals, animals with a distended abdomen (e.g., pregnancy or bowel obstruction), or those with pulmonary disease or space-occupying lesions of the thorax (tumor, pneumothorax, hemothorax, or diaphragmatic hernia) are particularly at risk. Oxygen supplementation is needed nearly as much in deeply sedated animals as in those receiving a general anesthetic (intravenous or inhalant). As can be seen in Fig. 5.22, increasing the inspired-oxygen level also provides protection against hypoxemia caused by hypoventilation and, again, adequate protection is generally achieved with a venous admixture of 30% to 35%. This is why simple maneuvers such as placing a face mask with oxygen on a high-risk patient before and during induction or use of a nasal oxygen catheter in the postoperative period are beneficial.

When 100% oxygen mixtures are used with the common inhalant anesthetics in dogs and cats free of serious cardiopulmonary disease, the arterial PaO_2 level is generally 450 to 525 mm Hg whether the animal is breathing spontaneously or being ventilated^{58,70,186,187} and irrespective of body position. With such high inspired-oxygen levels, hypoxemia usually occurs only through disconnection of the animal from the anesthetic machine, or with faulty placement of the endotracheal tube, cardiac arrest, or total apnea for over 5 min. Nevertheless, even with such high PaO_2 levels, tissue hypoxia can occur if hemoglobin levels are low or circulation is inadequate (low cardiac output).

The decision to institute assisted or controlled IPPV is generally made to prevent or treat hypercapnia, rather than to achieve oxygenation. Nearly all spontaneously breathing dogs and cats show some degree of hypoventilation and hypercapnia ($PaCO_2$ of 45 to 55 mm Hg). The clinical importance of this in nonneuro-

logical cases is open to debate. Dogs and cats do not have atherosclerosis, and over the years hundreds of thousands of dogs and cats have been successfully anesthetized in practice while breathing spontaneously. From a practical viewpoint, with short-duration anesthetics (anesthesia of less than 1 h) in relatively healthy animals, the important aspects are to ensure that the airway is patent, that the animal is oxygenated, and that the animal does not become apneic; the development of moderate levels of hypercapnia is likely to be well tolerated. The need for IPPV increases as the depth of anesthesia has to be increased for certain types of surgery (e.g., hip replacement) unless local supplementation is used (e.g., epidural opioid or local anesthetic). It also increases when opioids are used as a major component of the anesthetic regimen; for obese, neonate, geriatric, or neurological patients; with certain body positions (e.g., perineal hernia repair or dorsal laminectomy); with prolonged operations; or when dealing with poor-risk patients.

Here are a few guidelines relative to the respiratory component of anesthesia for dogs and cats:

1. Nearly all canine anesthetics are better done with an endotracheal tube in place, and in many situations cats should be intubated.
2. Use at least 30% to 35% inspired oxygen in all anesthetized dogs and cats, even those on an injectable anesthetic mixture, or when deeply sedated.
3. Hypoxemia is rare in spontaneously breathing dogs and cats if breathing an oxygen mixture approaching 100%.
4. After a prolonged period of anesthesia in cats and smaller dogs, and with shorter anesthetics in larger dogs with deep chests, it is advisable to inflate the lungs to 30 cm H₂O of airway pressure (i.e., to “sigh” the lungs) periodically and at the end of anesthesia.
5. Prolonged immobility and excessive fluid administration can lead to increased venous admixture and a fall in PaO₂ in addition to that produced by anesthesia per se.¹⁸⁸

Small Ruminants and Swine

Ruminants are especially prone to develop regurgitation and aspiration, along with tachypnea and hypoventilation, during general anesthesia.^{64,65} For shorter procedures (45 to 60 min) hypoventilation and hypercapnia often may be safely ignored if an adequate oxygen supply is maintained. Sedation and local analgesia techniques are often used for anesthesia as a means of maintaining a secure airway and adequate respiration.¹⁸⁹ During clinical anesthesia in pigs, especially if a barbiturate is used in a field situation, particular care must be taken to ensure that the airway is patent and that apnea does not occur.

The degree of ventilation-perfusion mismatch and venous admixture is intermediate in these animals, and of such a magnitude that virtually all anesthetized animals breathing room air will have PaO₂ levels somewhat below normal. In dorsally recumbent, ventilated sheep anesthetized with pentobarbital-halothane, atelectasis of the dependent lung regions developed quite quickly.¹⁹⁰ The magnitude of this atelectasis was much less than the same group of researchers observed in ponies.¹⁵⁷ Pulmonary

disease is not uncommon in small ruminants and swine, and will lead to V/Q mismatch in addition to that induced by anesthesia, lowering PaO₂ levels further. Abdominal distension caused by the development of rumenal tympany or, in the case of swine, a full stomach will add to the degree of pulmonary dysfunction.

During inhalation anesthesia with 100% oxygen, PaO₂ is usually in the range of 200 to 350 mm Hg—well within safe limits.^{72,191} In spontaneously breathing sheep, changes in body position (dorsal and left and right lateral) do not seem to alter the PaO₂ appreciably, and the P_(A-a)O₂ gradient is rather constant when the sheep are sighed every 3 to 5 min.¹⁹¹ Clinical experience would suggest the situation is similar in goats and pigs. The following are guidelines for respiratory management during anesthesia:

1. General anesthesia in sheep, goats, and calves with a developed rumen (i.e., by 2 to 4 weeks) requires placement of an endotracheal tube if protection against regurgitation and aspiration is to be ensured. This is best done for all but the shortest and lightest anesthetics.
2. Endotracheal intubation is not advised for swine unless the operation is complex or prolonged, or the operator is skilled with the technique.
3. During intravenous anesthesia of more compromised animals, application of a face mask or insertion of a nasal or tracheal oxygen catheter and insufflation of 2 to 5 L oxygen/min will help to ensure that hypoxemia does not occur.
4. Ketamine-based anesthesia is less likely to lead to apnea or severe respiratory depression than is propofol or barbiturate anesthesia.
5. Prolonged inhalation anesthesia (longer than 45 to 60 min) may require IPPV to prevent hypercapnia and may be required to maintain a stable plane of anesthesia because of the tachypneic breathing pattern.
6. Mild to moderate hypercapnia is well tolerated, and serious hypoxemia is rare if inhalation anesthesia with 100% oxygen is used.
7. The combination of progressive abdominal tympany (even in animals starved for up to 24 h) and the rapid, shallow respiration tend to produce a progressive increase in P_(A-a)O₂ gradients. Periodic sighing of the lungs (every 10 to 15 min) by inflating them to 30 cm H₂O seems to minimize the progressive increase in venous admixture and is particularly advisable at the end of an operation before extubation and return to a room-air environment. Placement in sternal recumbency during recovery benefits pulmonary function and, in the case of ruminants, helps to protect against regurgitation and aspiration.

Adult Cattle and Horses

Adult cattle^{172,192} and horses^{1,2,139,193} develop very significant increases in P_(A-a)O₂ gradients and venous admixture when they are anesthetized and become recumbent. On the basis of inspired-oxygen concentration and PaO₂ levels, it can be calculated that spontaneously breathing halothane-anesthetized horses have pulmonary-shunt flows of 20% to 25%, with a reduction to about 15% in ventilated horses.¹⁹⁴ These were healthy horses, posi-

Fig. 5.23. Arterial oxygen partial pressure (PaO_2) values in ten spontaneously breathing, normal horses anesthetized with halothane over 5 h in lateral recumbency. Note the wide variability in the PaO_2 levels between horses and the relative stability of the value for an individual horse over time. The horses were starved overnight before the onset of anesthesia. Reproduced from Steffey et al.,¹⁹⁶ with permission.

tioned in lateral recumbency and subjected to no surgery. Over the intervening 25 years, others have reported PaO_2 levels and $P_{(A-a)}\text{O}_2$ gradients from many studies in other healthy horses that are reflective of pulmonary-shunt flows of at least the same magnitude.^{157,195–198} The degree of V/Q mismatch is greater in dorsal than in lateral recumbency,^{195,198–201} in larger horses, and perhaps in older horses.¹⁹⁵ Researchers have consistently noted that the actual variability between PaO_2 levels in similar horses receiving similar anesthetics is quite large (Fig. 5.23).¹⁹⁶ The reasons for this variability are not clear, but probably relate to

body conformation and perhaps the level of abdominal distension caused by obesity, gas distension, or ingesta in the large bowel. The $P_{(A-a)}\text{O}_2$ gradient in healthy starved animals does not generally increase over time,^{196,200} but the PaO_2 will fall progressively if the degree of abdominal distension increases. This was clearly illustrated in an interesting study of fed and nonfed cows, where the failure to starve the cows before the general anesthetic led to a progressive increase in $P_{(A-a)}\text{O}_2$ and pulmonary resistance, and a decrease in PaO_2 and dynamic compliance (Figs. 5.24A and B).¹⁷²

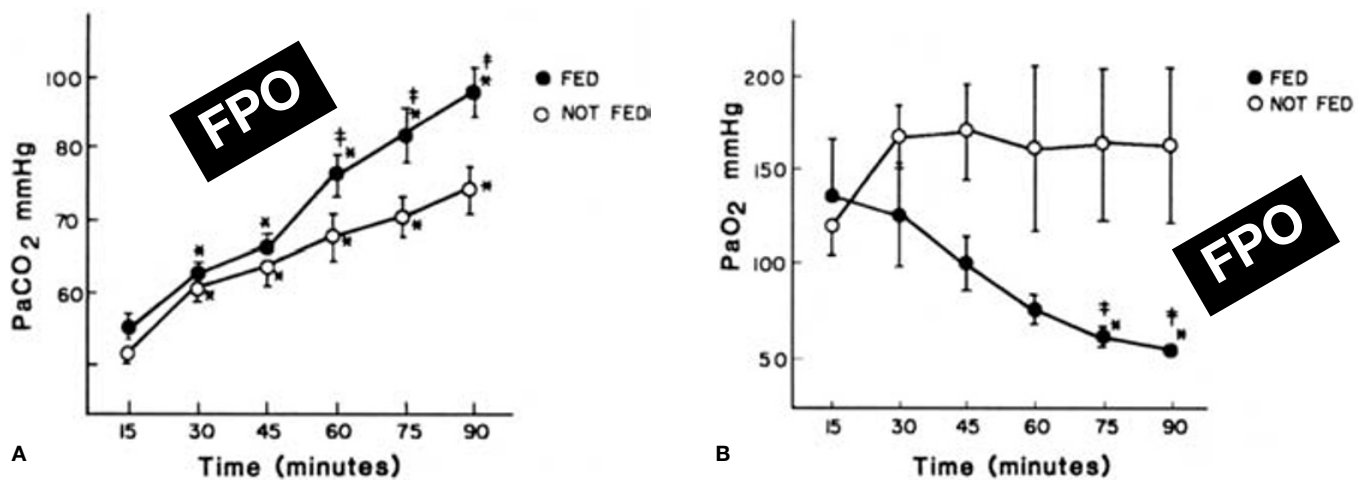

Fig. 5.24. Change in arterial carbon dioxide partial pressure (PaCO_2) (A) and arterial oxygen partial pressure (PaO_2) (B) levels in spontaneously breathing cows with and without prior starvation. Note the greater degree of hypercapnia in the fed animals and the progressively lower PaO_2 . This change was accompanied by an increase in the alveolar-to-arterial gradient ($P_{(A-a)}\text{O}_2$), an increase in airway resistance, and a decrease in compliance. These changes were probably associated with a decrease in lung volume from the development of abdominal tympany. Reproduced from Blaze et al.¹⁷² with permission.

When an anesthetized horse (usually during colic surgery or cesarean section) inhales 100% oxygen and has a resultant PaO₂ value of less than 70 mm Hg, it is clear from Fig. 5.16 that over 50% of the cardiac output is being shunted through the lungs without contributing to gas exchange. Although adult cattle also demonstrate fairly large P_(A-a)O₂ gradients during inhalational anesthesia, serious hypoxemia seems to be confined to very large animals, especially if they must be positioned in dorsal recumbency. Chronic pulmonary disease and lung consolidation are relatively common in cattle as an aftermath of juvenile respiratory disease. It is surprising that such animals do not demonstrate large increases in P_(A-a)O₂ levels during inhalant anesthesia, perhaps because pulmonary blood flow is also decreased in the non-ventilated lung areas.

When adult cattle are positioned in dorsal recumbency by using rope restraint, with or without sedation, some of them become quite hypoxemic.^{117,118} Horses anesthetized with the common injectable mixtures for brief field anesthesia also commonly have PaO₂ levels in the 55- to 65-mm Hg range.²⁰² Admittedly, the vast majority of animals so anesthetized survive with no obvious adverse after effects. This is more a credit to the inherent safety reserve that the animals have relative to oxygen supply and to the underlying good health status of most patients than to the anesthetic regimens per se. Nasal or nasotracheal oxygen insufflation (15 L/min) markedly improves the safety factor in restraining and anesthetizing such animals, and is always desirable if circumstances permit such treatment. Some guidelines relative to respiratory support of anesthetized adult cattle and horses include the following:

1. General anesthesia requires endotracheal intubation in adult cattle because the risk of regurgitation and aspiration is high, even with prior starvation. There is some risk of regurgitation and aspiration when cattle are restrained in a recumbent position with sedatives, including xylazine. The incidence of regurgitation, however, is fairly low, and routine intubation of nonanesthetized cattle is not practical.

2. Longer anesthesia in horses is better performed with an endotracheal tube in place, and this also facilitates oxygen insufflation.

3. Oxygen insufflation with 15 L/min, especially if the tip of the oxygen catheter tube is placed in the trachea, will usually prevent any serious hypoxia in relatively healthy horses and cattle during general anesthesia or recovery. This flow rate down the trachea will even maintain sufficient oxygenation to keep apneic animals alive for at least 10 min.¹⁹³

4. If oxygen supplementation is not possible, adult cattle and horses are better positioned in lateral than in dorsal recumbency (if the surgery permits the choice).

5. When preoperative starvation can be used, it is desirable, because it improves ventilation and oxygenation after the induction of anesthesia.

6. Nitrous oxide use is generally not advisable for cattle or in dorsally recumbent horses and, if used to supplement analgesia for orthopedic surgery in laterally recumbent horses, should not exceed an inspired concentration of 50% (e.g., 4 L of oxygen per 4 L of nitrous oxide).²⁰³

7. Inhalant general anesthetics lasting longer than 45 min in cattle almost always require IPPV to prevent excessive PaCO₂ elevations. In horses, operations lasting over 1 or 2 h will generally need IPPV if the need has not developed earlier. It should be appreciated that in dorsally recumbent horses breathing spontaneously, arterial hypoxemia is not always improved with initiation of IPPV, which may actually decrease PaO₂ and seriously decrease oxygen delivery to tissues.²⁰⁴ Moderate increases in PaCO₂ levels may actually produce useful hemodynamic stimulation without apparent adverse effects and seem to be well tolerated.²⁰⁵

8. Treatment of low PaO₂ levels with high levels of PEEP (20 to 30 cm H₂O) is feasible if the blood volume is adequate and inotropic support is used.^{141,155} Although differential lung ventilation with PEEP reduces hypoxemia experimentally,^{161,162} it is hard to see how this can be used clinically on those animals that actually need treating.

9. Periodic sighing of the lungs in adult cattle and horses probably does no harm, nor does it probably do much good. Full inflation of the lungs after the abdomen has been decompressed surgically, or when animals are positioned in sternal recumbency in recovery, can be quite useful in restoring adequate PaO₂ levels.

Exotic Species

It is very difficult to generalize how best to optimize respiratory function during anesthesia for the diverse range of exotic animals. Even if not used routinely, supplemental oxygenation and the means to establish an airway should be available, if at all possible. Chemical stimulation of respiration (e.g., with doxapram) or the availability of receptor-specific antagonist drugs can be lifesaving in the case of an inadvertent anesthetic overdose. Respiration is generally better supported with dissociatives than with propofol or barbiturate anesthetics. The larger the species, the more likely recumbency and positional changes may seriously interfere with cardiopulmonary homeostasis, although exceptions may exist (e.g., elephants). In general, it is desirable to keep larger terrestrial mammals in sternal rather than lateral or dorsal recumbency during restraint and/or anesthesia, unless such positioning is going to lead to excessive pressure on the limbs for a prolonged period.

Introduction

Anesthetic and analgesic drugs alter the nervous system; therefore, an understanding of normal nervous system anatomy, physiology, and function is important to anesthetists. Generally, the nervous system can be separated into central and peripheral divisions, although they are integrated and function together. The central division, composed of the brain and spinal cord, contains all of the important nuclei and is essential for integrating sensory and motor functions. The peripheral division is composed of nerves (including cranial nerves) and ganglia that connect the organs and tissues to the central nervous system (CNS).

Functionally, the nervous system can be divided into somatic and autonomic portions, each with efferent and afferent fibers. The somatic afferent fibers convey three sensory modalities from the periphery: pain, temperature, and pressure. In addition, specialized somatic afferents conduct impulses arising in the eye and ear to provide sight and hearing. The somatic efferent fibers have primarily motor functions and terminate in the motor end plates of skeletal muscle.

Autonomic afferent fibers transmit encoded information from specialized receptors in the mucous membranes and tissue of organs stimulated by distension or ischemia or by chemical compounds located in the lumen or tissues. Specialized autonomic afferent fibers mediate the sensations of smell and taste. Autonomic efferent fibers innervate glandular tissue, smooth muscle, cardiac muscle, and the involuntary muscles of the pharynx and larynx.

In summary, the somatic division controls superficial sensations and voluntary movement, whereas the autonomic system maintains visceral organ function and homeostasis, including regulation of heart rate, blood pressure, tissue perfusion, glandular secretion, peristalsis, sphincter tension, and pupil size, as well as thermoregulation. Anesthetic and analgesic drugs can alter function in both divisions.

Brain Anatomy

The brain is divisible into five regions based on embryological development: telencephalon, diencephalon, mesencephalon, metencephalon, and myelencephalon. Grossly, it can be divided into the cerebrum and the brain stem. The cerebrum consists of telencephalic and diencephalic portions. The telencephalic portion can be further divided into the cerebral hemispheres and basal ganglia (also known as the basal nuclei). Together, the right and left hemispheres comprise the cerebral cortex, which is organized into an outer cortical layer of gray matter that contains a high density of nerve cell bodies and an inner medulla of white matter consisting mainly of myelinated nerve fibers. The basal ganglia (corpus striatum, amygdaloid, and claustrum) are large masses of gray matter at the base of each cerebral hemisphere. The functions of the corpus striatum and claustrum are poorly understood, but they appear to contribute to the extrapyramidal motor system through inhibition of motor function and maintenance of balance between opposing muscle groups. The amygdaloid nucleus is a component of the olfactory and limbic systems.

The cerebral cortex is where sensory, motor, and associational activity occurs. The white matter of the cerebrum consists of corticocortical and projection fibers. The corticocortical fibers connect different functional areas located in the same hemisphere (association fibers) and in the opposite hemisphere (commissural fibers). Fibers connecting the cortical areas of the two hemispheres cross the midline in a large commissure: the corpus callosum. Projection fibers originate or terminate in the cortex and connect it with the basal ganglia, brain stem, or spinal cord. The fibers passing between the cortex and subcortical centers converge to form a compact organized group of fibers: the internal capsule.

The diencephalic portion of the cerebrum, which is located below and between the cerebral hemispheres, is the central area through which most of the information traveling into and out of the hemispheres must traverse. It consists of the thalamus, subthalamus, epithalamus, and hypothalamus, and is positioned be-

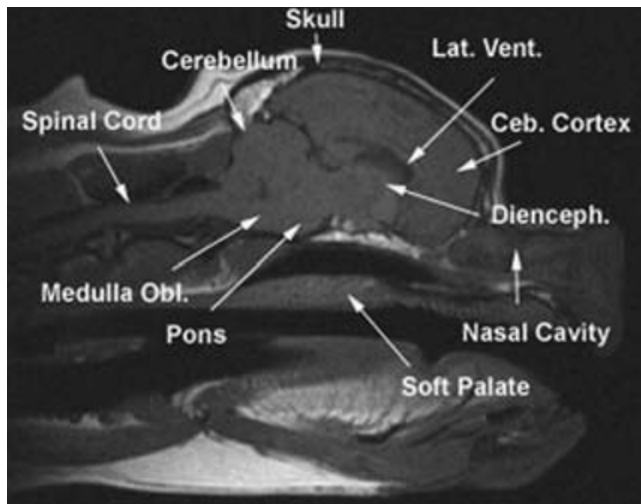

Fig. 6.1. Magnetic resonance image sagittal view of a canine brain and spinal cord. Lat. Vent., lateral ventricle; Ceb. Cortex, cerebral cortex; Dienceph., diencephalon; and Medulla Obl., medulla oblongata. Image courtesy of Igor Kuriashkin.

tween the telencephalon and the brain stem. Magnetic resonance images of the sagittal view of the canine and feline brain are shown in Figs. 6.1 and 6.2. The thalamus receives fibers from all sensory systems except olfactory and projects to sensory areas of the cerebral cortex. Evolutionarily and developmentally, the cerebral cortex is an outgrowth of the lower centers, especially the thalamus. As a result, for each area of the cortex, there is a smaller corresponding area within the thalamus. Thalamic nuclei participate in neural circuits related to emotional aspects of brain function (limbic system), are part of the ascending reticular activating system, and are incorporated into motor pathways from the cerebellum and corpus striatum to the motor cortex.

The subthalamus is comprised of a motor nucleus, sensory tracts that terminate in the thalamus, and tracts that project from the cerebellum and corpus striatum to the thalamus. The epithalamus is composed of the pineal gland and tracts mediating autonomic responses to olfactory and emotional changes. The hypothalamus is the primary center for integrative control of the autonomic nervous system. Parasympathetic responses—including slowing of the heart rate, vasodilation, decreased blood pressure, salivation, increased gastrointestinal peristalsis, contraction of the urinary bladder, and sweating—are elicited by stimulation of the anterior hypothalamus. Stimulation of the posterior and lateral hypothalamus elicits sympathetic responses, including increased heart rate and blood pressure, cessation of gastrointestinal peristalsis, dilation of the pupils, and hyperglycemia. The hypothalamus plays a major role in maintaining homeostasis through control of temperature, thirst, and appetite. Nervous system control of the endocrine system is via the hypothalamic neurohypophyseal hormones. One exception is the adrenal medulla, which is regulated by direct nervous system connections (i.e., the preganglionic sympathetic fibers).

The brain stem is comprised of the portion of the brain caudal to the telencephalon excluding the cerebellum (e.g., the mid-

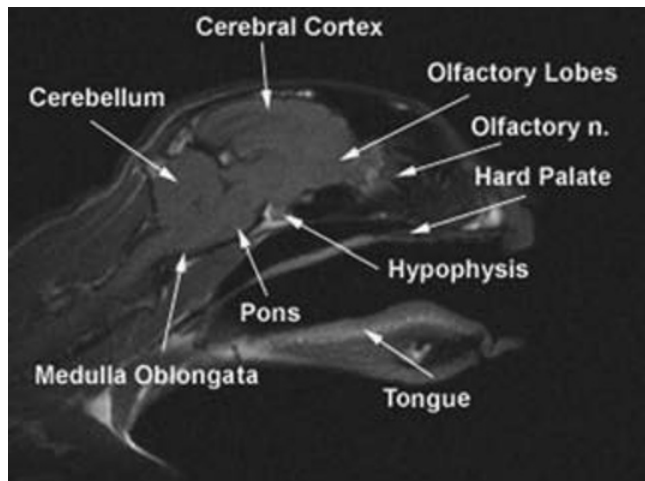

Fig. 6.2. Magnetic resonance image sagittal view of a feline brain and spinal cord. n., nerve. Image courtesy of Igor Kuriashkin.

brain, pons, and medulla oblongata) (Figs. 6.1 and 6.2). The mid-brain contains sensory and motor pathways, the nuclei of the third and fourth cranial nerves (oculomotor and trochlear), and two major motor nuclei: the red nucleus and the substantia nigra. The dorsal part of the midbrain is primarily involved with auditory function and visual reflex movements of the eyes and head. The cerebellum is connected to the midbrain by the superior cerebellar peduncles.

The pons consists of two distinct parts. The dorsal portion, like the rest of the brain stem, has both sensory and motor tracts. In addition, the dorsal pons contains nuclei associated with the fifth, sixth, seventh, and eighth cranial nerves (trigeminal, abducens, facial, and vestibulocochlear). The ventral pons functions as a large synaptic region, providing a connection between the cerebral motor cortex and the contralateral cerebellar hemisphere via the middle cerebellar peduncles.

Caudal to the pons is the medulla oblongata, and posterior to it is the spinal cord. In addition to nerve tracts, the medulla contains vital nerve centers that regulate respiration and circulation. Four pairs of cranial nerves connect to it: the glossopharyngeal (ninth), vagus (tenth), spinal accessory (eleventh), and hypoglossal (twelfth). The cerebellum is connected to the medulla by the inferior cerebellar peduncles.

The cerebellum, which lies dorsal to the brain stem, is formed by two hemispheres separated by a central portion: the vermis. The cerebellum receives input from the sensory systems and the cerebral cortex. The cerebellum modulates muscle tone in relation to equilibrium, locomotion, posture, and nonstereotyped movements based on experience. It is chiefly involved with muscular coordination.

Brain Physiology

The energy-consuming processes of the brain are divided into those of neuroprocessing and maintenance of cellular integrity.

Oxygen requirements for the conscious, healthy canine brain are approximately $5.5 \text{ mL} \cdot 100 \text{ g}^{-1} \cdot \text{min}^{-1}$, with 60% needed for neuroprocessing and 40% for maintenance of brain cell integrity.¹ If cardiovascular function is normal, adequate oxygen delivery and normal electroencephalogram (EEG) function is expected with a PaO_2 of approximately 100 mm Hg and cerebral blood flow (CBF) of $50 \text{ mL} \cdot 100 \text{ g}^{-1} \cdot \text{min}^{-1}$. Irreversible cerebral tissue damage is likely when PaO_2 drops below 20 to 23 mm Hg and CBF below $10 \text{ mL} \cdot 100 \text{ g}^{-1} \cdot \text{min}^{-1}$. In humans, normal function of the awake brain requires approximately $3.5 \text{ mL O}_2 \cdot 100 \text{ g}^{-1} \cdot \text{min}^{-1}$, or a total of about $50 \text{ mL} \cdot \text{min}^{-1}$ extracted from an average normal CBF of $57 \text{ mL} \cdot 100 \text{ g}^{-1} \cdot \text{min}^{-1}$. In the awake state, most of the brain's cellular energy stores are depleted within 2 to 4 min after oxygen delivery is interrupted. During the anoxic period, cellular lactate concentrations can increase three- to fivefold. Anesthesia, hypothermia, or brain injury can alter cerebral metabolic requirements for oxygen (CMRO_2) and must be considered when interpreting the adequacy of monitored cardiopulmonary parameters during anesthesia.

The mature brain in nonfasted animals uses oxidative metabolism of glucose as the primary source of energy. Under normal conditions, 95% of the glucose is metabolized by oxidative phosphorylation. The remaining 5% is metabolized by anaerobic pathways to lactate. Inadequate or marginal oxygen delivery to the brain will cause a rapid increase in anaerobic metabolism reflected by increased glucose consumption and lactate production.¹ Approximately $70 \text{ mg} \cdot \text{min}^{-1}$ of glucose are required for the adult human brain. Normal metabolism requires 5.5 mmol of oxygen for each millimole of glucose. The effects of analgesics and anesthetics on cerebral metabolism, CBF, and CMRO_2 are critical factors in producing safe reversible depression of the CNS in healthy and diseased animals.

Effects of Anesthetics on Brain Physiology

Anesthetic management of patients undergoing surgery on the nervous system requires that CBF be maintained at a level sufficient to meet the brain's metabolic demands. Autoregulation enables maintenance of a constant CBF over a wide range of systemic blood pressures. Autoregulation is not immediate; when systemic blood pressure changes, it takes about 2 min for CBF to return to normal.² There have been many studies on the effects of anesthetics on CBF and autoregulation, and the results have sometimes been confusing. All potent inhaled anesthetics tend to decrease cerebral metabolism and increase CBF and intracranial pressure (ICP), but vary in degree. Hyperventilation may prevent or reduce the increase in CBF and ICP associated with halothane or enflurane anesthesia, but only if instituted prior to induction. By comparison, hyperventilation may be effective in reversing the increase in CBF and ICP associated with isoflurane anesthesia, even if instituted after induction. For several years, isoflurane has been the preferred inhalant for use in neurological patients, because it apparently has the least negative effect on ICP and cerebral blood volume.³ Sevoflurane seems to compare favorably with isoflurane in maintaining satisfactory CBF and cerebral perfusion pressure, with minimal to no change in ICP.⁴ It is thought that desflurane also is similar to isoflurane in its effects on CBF,

cerebral metabolism, and responsiveness to carbon dioxide, in both normal patients and those with intracranial masses. The effects of desflurane on ICP are less clear: Low doses (0.5 minimum alveolar concentration [MAC]) do not seem to change ICP, whereas higher doses (1.0 MAC) have been associated with increased ICP in some patients.⁵ A study of pigs anesthetized at 0.5 and 1.0 MAC desflurane, isoflurane, or sevoflurane indicated that the three anesthetics did not differ much in their cerebral vasodilating effects at the lower dose, but, at the higher dose, desflurane induced more cerebral vasodilation than did the other two anesthetics.⁶ The use of sevoflurane and desflurane, being less soluble in blood than isoflurane, may be somewhat advantageous in that rapid recovery from anesthesia may facilitate early neurological assessment after diagnostic or surgical procedures.

Cranial Nerves

These consist of a peripheral segment, a nuclear center in the brain stem (except olfactory and optic nerves), and communicating connections with other parts of the brain (Fig. 6.3). All 12 cranial nerves are paired. Functionally, cranial nerves can be divided into motor (efferent), sensory (afferent), and mixed. Sensory and motor cranial nerves are associated with at least one nuclei, and mixed cranial nerves are associated with at least two nuclei (Table 6.1).

The *olfactory*, *optic*, and *vestibulocochlear* nerves serve the senses of smell, sight, and hearing and balance respectively. The *oculomotor* nerve innervates most muscles of the eye: dorsal, medial, and ventral rectus muscles; ventral oblique; levator palpebrae superioris; ciliary muscle; and the sphincter pupillae. The *trochlear* nerve innervates the dorsal oblique muscle of the eye, and the *abducens* nerve supplies the lateral rectus and retractor oculi muscles. Like most cranial nerves, the *spinal accessory* nerve arises from the medulla, but it also has fibers from all seven cervical nerves that course cranially to combine with the medullary roots. The spinal accessory nerve contributes fibers to the vagus nerve before coursing caudally to innervate the muscles of the neck and shoulder. The *hypoglossal* nerve innervates the muscles of the pharynx and the larynx, and the intrinsic muscles of the tongue.

The *trigeminal* nerve carries sensory information from most of the rostral structures and surfaces of the head and motor impulses to the muscles of mastication. It has three main branches: the ophthalmic, maxillary, and mandibular nerves. The ophthalmic is sensory to skin of the forehead, the eyeball (corneal and palpebral reflexes), and the skin of the lower eyelid. The maxillary is sensory to the skin of the muzzle, nose, and upper lip; the mucous membranes of the nose, nasopharynx, the hard and soft palate, and the teeth of the upper jaw. The mandibular branch supplies sensation to the lower part of the face, side of the head, lower lip, and teeth, ear, and tongue, and is motor to the muscles of mastication.

The *facial* nerve is motor to all the cutaneous muscles of the face, lips, nose, cheeks, ears, and ventral neck, and to the submandibular and sublingual salivary glands and the lacrimal gland. It is sensory to the taste buds and to the skin of the exter-

nal ear. The *glossopharyngeal* nerve is motor to the stylopharyngeus muscle and to the parotid and zygomatic salivary glands. It is sensory to the pharynx, tonsil, tongue (touch, temperature, pain, and taste), carotid bodies, and sinuses (chemoreceptors and baroreceptors).

The *vagus* nerve innervates organs and muscles in the neck, thorax, and abdomen. Long preganglionic parasympathetic fibers are supplied to the heart and to the smooth muscles and glands of the thorax and abdominal viscera. Motor innervation is also supplied to the pharynx, cricothyroideus muscle of the larynx, intrinsic muscles of the larynx, and striated muscle of the esophagus. The sensory fibers of the vagus nerve innervate the base of the tongue (touch, temperature, pain, and taste), pharynx, esophagus, stomach, intestines, larynx, trachea, bronchi, lungs, heart, aortic baroreceptors, and other viscera.

Spinal Cord

Caudal to the medulla, the CNS continues as the spinal cord, which is contained in the spinal canal. The spinal cord is a complex collection of fibers organized into ascending and descending tracts, interneurons, neuron-supporting cells, blood vessels, and

connective tissue. The cord is surrounded by the meninges, which support and protect it. From superficial to deep, they are the dura mater, arachnoid, and pia mater (Fig. 6.4).

The spinal cord is segmental in that it has paired spinal nerves that enter and leave it at each intervertebral space. The spinal nerves divide inside the vertebral canal: afferent fibers enter the cord via the dorsal root, and efferent fibers leave as the ventral motor root (Bell-Magendie law). In the fetus, all spinal nerves exit at right angles to the spinal cord. In the adult, however, owing to differential growth rates between the spinal cord and the bony vertebral canal, the nerves must run posteriorly to reach their respective intervertebral foramina. The cauda equina is composed of descending spinal nerves caudal to the termination of the cord (Fig. 6.5). In dogs, the cord and associated subarachnoid structures usually terminate at the level of L6-L7; in horses, ruminants, and swine, the cord terminates in the midsacrum; and, in cats, the cord terminates variably between L6 and the sacrum. Inadvertent subarachnoid administration of anesthetic or analgesic drugs is more likely in these noncanine species when the needle is inserted at the lumbosacral space.

The spinal cord has an H-shaped central core of gray matter containing nerve cell bodies. The gray matter functions as the ini-

Fig. 6.4. Transverse section of spinal cord within the vertebral canal. Note the adipose tissue and blood vessels in the epidural space. From Jenkins.⁴⁰

tial site for processing of incoming sensory information and as a relay for transmission of these signals to the brain. It also serves as the final site for processing descending motor impulses from the brain to the skeletal muscles. The gray matter can be divided into dorsal, ventral, and lateral horns. The dorsal horn is the “gate” through which impulses in sensory nerve fibers are passed or blocked before initiating impulses in ascending tracts. According to the *gate control theory of pain*, incoming sensory information as well as descending modulating signals can control the gate, thus modulating incoming afferent information.⁷ The lateral horns of the thoracolumbar segments contain the cell bodies of the preganglionic sympathetic nerves. The ventral horn of the gray matter contains the alpha and gamma motor neurons, which leave the cord via the ventral nerve roots to innervate the skeletal muscles.

There are three types of cells in the gray matter. Internuncial cells, which are the smallest, are most prevalent in the dorsal and intermediate zones. Internuncial cells receive afferents from dorsal root fibers and fibers in descending tracts of the white matter. Axons of internuncial cells terminate on motor and tract cell bodies and modulate their activity by releasing inhibitory or excitatory neurotransmitters. Motor nerve cell bodies are found in the ventral horn and consist of alpha and gamma motor neurons.

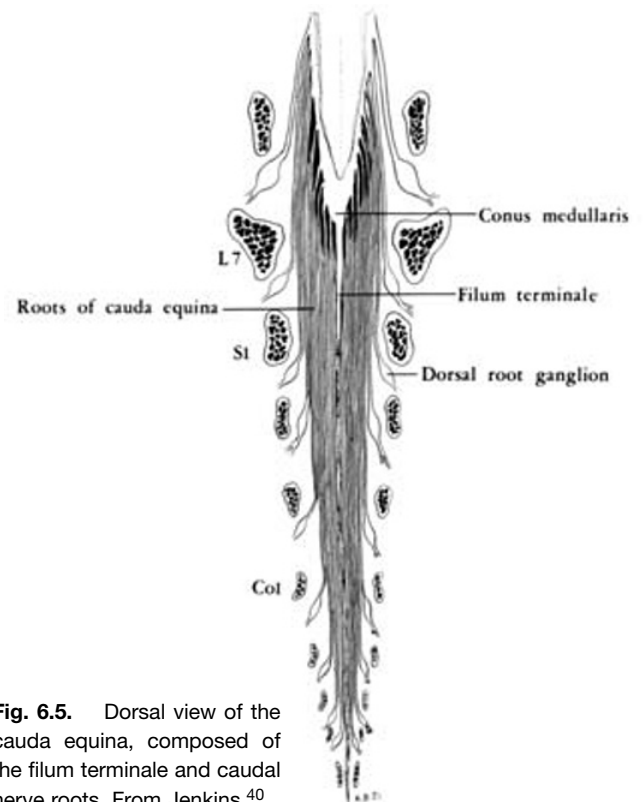

Fig. 6.5. Dorsal view of the cauda equina, composed of the filum terminale and caudal nerve roots. From Jenkins.⁴⁰

Axons of tract cells constitute the ascending fasciculi of the lateral and ventral white columns. Tract cells (transmitter cells) are located primarily in the dorsal and intermediate zones of the gray matter. Cells of the lateral horn and the sacral autonomic nucleus are preganglionic neurons of the sympathetic and parasympathetic systems, respectively.

In contrast to the brain, spinal cord gray matter is surrounded by white matter, which is comprised of myelinated axons of intermediate longitudinally running nerve fibers. This outer white matter is divided into three major columns: dorsal, lateral, and ventral. Within these columns are ascending and descending tracts. The nerve fibers of the white matter are organized into ascending afferent tracts that convey sensory information to the brain and descending efferent tracts that convey impulses to peripheral effector organs. The spinal cord also contains nerves that subservise important spinal reflexes. Afferent fibers arriving at the cord through the dorsal nerve roots carry sensory impulses, which can initiate spinal reflexes and/or be transmitted to the brain stem and cerebellum, where they enter various pathways.

Efferent fibers, originating within the ventral horn of the cord, transmit motor impulses from higher centers or from reflex centers within the cord to muscles and glands. Ascending and descending tracts within the cord connect the higher centers and the various cord segments with one another. For a more complete description of the spinal tracts in dogs, readers are referred to the work by Hoerlein.⁸

Similar to the brain, the meninges (dura mater, arachnoidea, and pia mater) surround the spinal cord (Fig. 6.4). Various spaces are associated with the meninges and are important in understanding spinal anesthesia and its nomenclature. The dura mater has two layers within the cranial vault: an inner or visceral layer and an outer layer adherent to the cranial periosteum. The inner or visceral layer invests the spinal cord and ventral and dorsal nerve roots; the outer layer is absent in the vertebral canal of some species. The epidural (also referred to as the extradural or peridural) space is that space within the spinal canal outside the visceral layer of the dura mater. In those species having both layers of dura, “epidural” drug administration is actually into the *intradural space*. The dura mater adheres to the periosteum of the foramen magnum, thereby preventing communication between the cranial and vertebral epidural spaces. The epidural space is not an empty cavitory space, but instead contains blood vessels, lymphatics, and epidural fat, and communicates with the paravertebral tissues via the intervertebral foramina. This communication may be interrupted in older animals by fibrous connective tissue and bony malformations associated with spinal arthritis, and in obese patients by fat. This is of clinical significance because epidural injection volumes are often reduced in older or obese animals to prevent excessive cranial spread of drugs.

The subarachnoid space is located between the arachnoidea and pia mater. The subarachnoid space contains cerebrospinal fluid (CSF) and is continuous between the cranial and vertebral segments. There is no direct communication between the epidural and subarachnoid spaces; however, drugs (especially lipophilic drugs) can diffuse across the arachnoidea and enter the CSF after epidural administration. The pia mater, which is one

cell layer thick, lies directly on the brain and spinal cord. The pia probably does not present a significant barrier to drug diffusion. The meninges cover the dorsal and ventral spinal nerve roots until they fuse, at which point they merge with the spinal nerve and extend no farther peripherally.

Cerebrospinal Fluid and Intracranial Pressure

Within the calvarium, CSF is found in both an internal (ventricular) system and an external (subarachnoid) system. The internal system consists of the bilaterally symmetrical lateral ventricles within the cerebral hemispheres, the third ventricle medially between the thalamus and hypothalamus, and the fourth ventricle, lying beneath the cerebellum and within the medulla (Figs. 6.6 and 6.7). CSF is produced by the choroid plexus, a fringelike fold of pia mater found on the floor of both lateral ventricles, in the fourth ventricle, and also by the ependymal lining of the ventricles.⁸ Figure 6.8 depicts a magnetic resonance image of a choroid plexus tumor following contrast intensification in the area of the third ventricle. CSF is formed from the blood by secretory and filtration processes. Fluid in the lateral ventricles empties into the third ventricle through the paired foramina of Monro. The third ventricle, in turn, empties into the fourth through the aqueduct of Sylvius. The central canal of the spinal cord is continuous with the fourth ventricle. The external or subarachnoid system overlies the brain and spinal cord. The bilateral foramina of Luschka enable fluid to pass between the ventricular and subarachnoid systems. In most primates, the unpaired foramen of Magendie is present and enables an additional connection between the fourth ventricle and the subarachnoid space. The foramen of Magendie is not found in most common veterinary species.

CSF is absorbed at the arachnoid villi located primarily in the subdural venous sinuses. The arachnoid villi are fingerlike projections of the arachnoidal membrane that penetrate the venous sinuses. Their endothelium is porous and highly permeable, al-

lowing free passage of water, electrolytes, proteins, and even red blood cells.

CSF cushions the brain and spinal cord. CSF normal pressure is approximately 10 mm Hg but can fluctuate within a narrow range. The composition of the CSF remains different from plasma because of the blood-brain barrier. The barrier is as much

an enzymatic and cellular transporter barrier as an anatomical separation. The concentration of sodium is equal to that of plasma, the concentration of chloride in the CSF is 15% greater, and the concentration of potassium and glucose is 40% and 30% less than in plasma, respectively. The specific gravity of CSF is 1.002 to 1.009.

The pH of CSF is closely maintained at 7.32. Carbon dioxide, but not hydrogen ions, readily crosses the blood-brain barrier. Bicarbonate ions are actively transported. As a result, the pH of CSF is rapidly altered by changes in PaCO_2 but not by changes in arterial pH. The pH of CSF, not the PCO_2 directly, is the major mechanism regulating ventilation in most mammals. The choroid plexus and the capillary membranes are highly permeable to water, oxygen, carbon dioxide, and most lipid-soluble substances, such as anesthetics. It is only slightly permeable to electrolytes, such as sodium, potassium, and chloride, and nearly impermeable to plasma proteins and large organic molecules. This is clinically significant because fluid therapy in patients with CNS disease and intracranial hypertension must not deliver free water (which rapidly equilibrates across the blood-brain barrier) leading to increased pressure. Instead, hypertonic saline solutions, osmotic diuretics, and colloid solutions are often used to limit fluid influx or move fluid out of the brain tissue and decrease ICP. Glucose is actively transported across the capillary endothelium (blood-brain barrier) to provide a source of cellular energy. The pia mater, which covers the brain and spinal cord, and the ependyma, which lines the ventricles, are freely permeable to many substances; therefore, drugs that cannot gain access to CNS tissues when delivered by the blood may penetrate nervous tissues when administered into the subarachnoid space.

The skull forms a noncompliant chamber filled with brain parenchyma, blood, and CSF. An increase in volume of one com-

Table 6.2. Classification of nerve fibers

	Terminology	Fiber Diameter	Conduction Speed (m/s)

From Wylie and Churchill-Davidson³⁸ and Gasser.³⁹

ponent must be accompanied by a compensatory decrease in the others or the ICP will increase (Monro-Kellie hypothesis). Normal ICP is less than 15 mm Hg. As the ICP increases, blood flow to the brain will decrease unless an increase in mean arterial pressure occurs to maintain cerebral perfusion pressure (cerebral perfusion pressure = mean arterial pressure – ICP). Arterial blood pressure should always be measured in animals suspected of having intracranial hypertension, because anesthetic-induced decreases in mean arterial blood pressure can lead to catastrophic cerebral ischemia even though arterial blood pressures were maintained above acceptable levels for healthy animals (e.g., mean arterial pressure of 60 mm Hg). Increased cerebral or spinal fluid pressure produces a reflex increase in heart rate and blood pressure (Cushing's response).⁹ It has been hypothesized that the increase in CSF pressure creates ischemia of neurons, and that this is the stimulus for increased sympathetic activity.

Drugs that reduce cerebral metabolic activity or CBF, osmotic diuretics, hypothermia, and mechanical normoventilation or hyperventilation may all be used to decrease ICP. It is imperative that anesthetic management focus on maintaining adequate cerebral perfusion pressure rather than on reducing CBF or ICP alone. Administration of analgesic drugs, especially opioids, must be carefully monitored in animals with intracranial disease, because of their potential to increase PaCO₂, which could lead to increased CBF and ICP. Ventilatory support may be required if respiratory depression occurs.

Peripheral Nervous System

Spinal Nerves

These supply efferent and afferent innervation to most of the body, with the exception of the head and viscera. They also form part of the autonomic nervous system, which controls homeostatic functions. Spinal nerves vary in number, depending on species. Nerves can be classified by their size and degree of myelination, which determine speed of impulse transmission. Large, heavily myelinated fibers have the highest conduction velocities, whereas small nonmyelinated fibers have lower conduction rates (Table 6.2). The largest fibers, type A, are subclassified as A-alpha, A-beta, A-gamma, and A-delta fibers. A-alpha fibers in-

nerve skeletal muscles and also subserve proprioception. A-beta fibers normally subserve innocuous touch and pressure, but can be involved in nervous system “windup” that can result in hyperalgesia and/or allodynia following chronic nociceptor stimulation. A-gamma fibers innervate the skeletal muscle spindles to maintain muscle tone. A-delta fibers subserve temperature, fast pain, and touch. Type B fibers are preganglionic autonomic fibers. Type C fibers are small nonmyelinated fibers responsible for postganglionic sympathetic innervation and transmission of visceral and slow pain, touch, and temperature sensations. Abnormal nociceptive C fiber activity causes many chronic pain syndromes best described in humans, with diabetic neuropathy and postherpetic neuralgia being two examples. Similar C-fiber dysfunction is likely in a variety of chronic pain conditions in other mammalian species.

After leaving the intervertebral foramen, each spinal nerve divides into dorsal and ventral branches. The dorsal branches generally supply the muscles and skin of the back, whereas the ventral branches supply the muscles and skin of the thorax, abdomen, and extremities (Fig. 6.9). Branches from several spinal nerves may combine to form plexuses such as the brachial plexus or major nerves such as the sciatic nerve (Figs. 6.10 and 6.11). A *myotome*, which is the mass of musculature innervated from one ventral spinal nerve root, is derived from the somite of an embryonic segment and forms the skeletal musculature originating from that segment. The area supplied by a single dorsal nerve root is called a *dermatome*. There is considerable overlap of areas supplied by adjacent roots. Knowledge of myotomes and dermatomes is essential for performing a neurological examination and performing regional anesthesia of the thorax, abdomen, and limbs.

Branching off the spinal nerves in the thoracic and lumbar areas are rami communicantes, which connect the spinal nerves with a chain of ganglia lying lateral to the vertebral bodies, termed the *vertebral sympathetic ganglia*.

Autonomic Nervous System

In contrast with the somatic nervous system supplying the striated muscles, the autonomic nervous system requires no conscious control. The autonomic nervous system is composed of

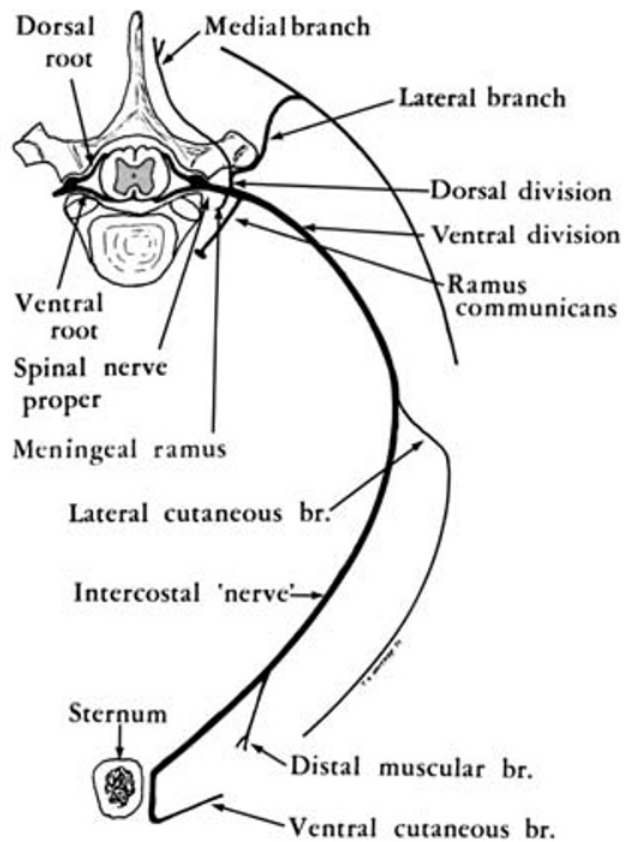

Fig. 6.9. Diagram of the anatomic components of a typical spinal nerve. br., branch. From Jenkins.⁴⁰

the efferent and afferent nerves innervating the viscera, glands, and other tissues required for homeostasis and the fight-or-flight response. Its primary homeostatic role is control of circulation, breathing, and excretion, and maintenance of body temperature. These regulatory functions are subject to modification by input from higher brain centers, especially as a result of reactions to the environment.

Visceral autonomic efferent pathways consist of two neurons rather than a single motor neuron as occurs in the somatic system. The cell body of the first neuron is in the brain stem or spinal cord. Its axon terminates on the cell body of the second, located in an autonomic ganglion. The axon of the ganglion cell terminates in the effector cell.

Autonomic visceral afferents are primarily sensory neurons similar to those in somatic tissues, although they tend to have wider receptive areas, leading to less ability to discriminate the anatomic origin of the afferent signals. They elicit reflex responses in viscera and a feeling of fullness of hollow organs, such as the stomach, large intestine, and bladder. Afferent impulses contribute to feelings of well-being or malaise and transmit signals from nociceptors. Specialized visceral afferents transmit encoded signals that are perceived as the senses of taste and smell. In general, visceral afferents have their cell bodies in the sensory ganglia of the cranial and spinal nerves that include the autonomic outflow. These neurons are of two types: physiologi-

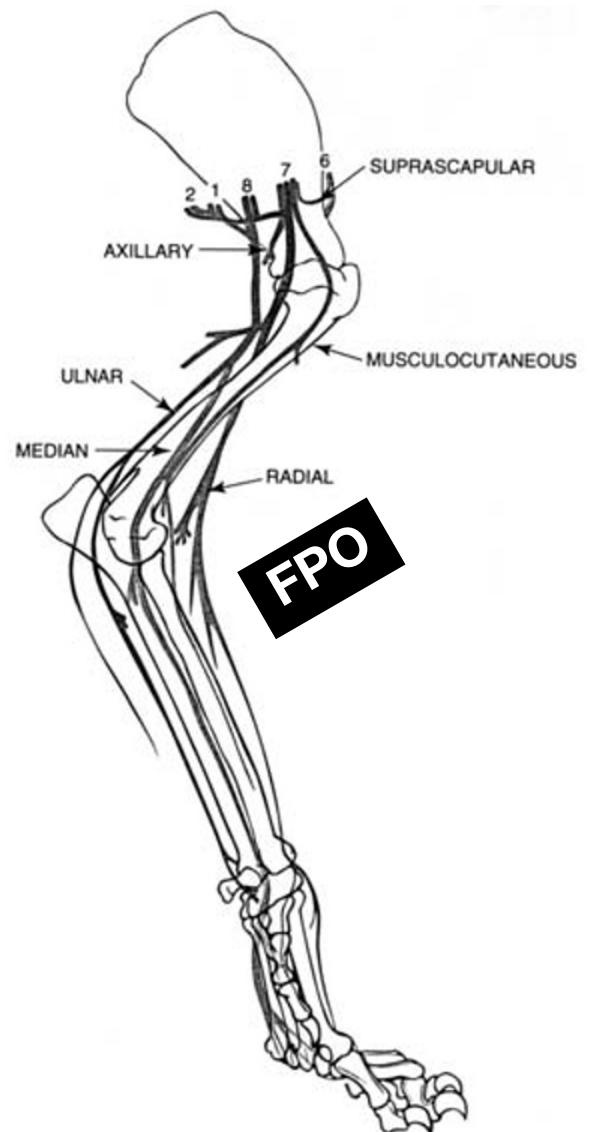

Fig. 6.10. A medial view of the canine front limb illustrating the relative course and distribution of the major nerves to the leg. Note the spinal nerves making up the brachial plexus, C6-7-8 and T1-2. From Hoerlein.⁸

cal afferents and pain afferents. Physiological afferents are present in both sympathetic and parasympathetic divisions, whereas pain afferents are almost exclusively associated with the sympathetic. The most important visceral physiological afferents are associated with the parasympathetic division and mediate cardiovascular, respiratory, and gastrointestinal reflexes (e.g., baroreceptor, chemoreceptor, Hering-Breuer, emptying of the rectum and bladder subject to conscious control, and feelings of fullness or hunger).

Visceral pain afferents are associated with the sympathetic division. Cell bodies are located in the thoracolumbar dorsal root ganglia. Their peripheral processes reach the sympathetic trunk via the white rami communicantes, run in the sympathetic trunk, and reach the viscera through the cardiac, pulmonary, or splanchnic

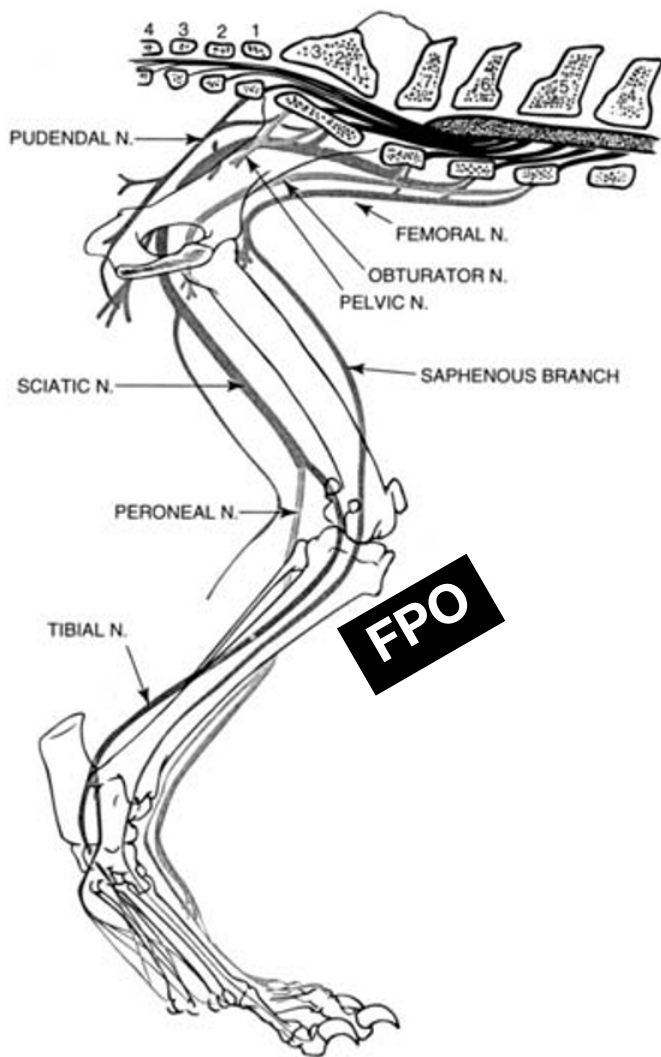

Fig. 6.11. A medial view of the canine hind limb illustrating the relative course and distribution of the major nerves. Note the spinal nerves making up the sciatic nerve. N., nerve. From Hoerlein.⁸

nic nerves. Central terminations are on transmitter cells in the substantia gelatinosa. Because the visceral pain afferents can travel cranially or caudally within the sympathetic trunk, the well-defined receptive fields seen with A-delta fiber-mediated pain are absent. Visceral nociceptor stimulation usually produces pain that is poorly localized. However, within the spinal cord, the ascending pathway for visceral nociception coincides at least in part with that for somatic nociception.

The hypothalamus is the primary area of the brain that controls the autonomic nervous system. The autonomic system can be subdivided into the craniosacral or parasympathetic system and the thoracolumbar or sympathetic system (Fig. 6.12). A characteristic of the autonomic nervous system is that both divisions are constantly active, resulting in a basal level of sympathetic and parasympathetic activity. Thus, each division can increase or decrease its effect at a given organ to regulate function more closely.

Parasympathetic System

This system functions to conserve and restore energy. Acetylcholine (ACh) is the neurotransmitter at both preganglionic and postganglionic neurons activating nicotinic receptors at the ganglion and usually muscarinic receptors on the effector cells. Each preganglionic fiber synapses with one to three postganglionic neurons, which terminate on a limited number of effector cells. ACh is normally rapidly inactivated by acetylcholinesterase at the synapse, resulting in a brief discharge and highly localized activity. However, with exposure to acetylcholinesterase inhibitors such as organophosphates or carbamates, prolonged and excessive parasympathetic nervous system activity ensues. Because of this, administration of antimuscarinic agents such as atropine prior to antagonism of competitive neuromuscular junction blockers with acetylcholinesterase-inhibiting drugs such as neostigmine is recommended.

Preganglionic fibers of the parasympathetic system arise in three areas: the midbrain (tectal outflow), the medulla (medullary outflow), and the sacral spinal cord (sacral outflow) (Fig. 6.12). These efferent fibers generally are long and synapse with one or two postganglionic fibers in a ganglion on or within the organ supplied. The tectal outflow originates in the Edinger-Westphal nucleus of the third cranial nerve (oculomotor) and synapses at the ciliary ganglion in the orbit to innervate the pupillary sphincter and ciliary muscles. The medullary outflow is comprised of the parasympathetic components of the seventh (facial), ninth (glossopharyngeal), and tenth (vagus) cranial nerves. The facial nerve parasympathetic fibers synapse at the submandibular ganglion to supply the submaxillary and sublingual glands, and at the pterygopalatine ganglion to innervate the lacrimal and nasal glands. The parasympathetic fibers of the glossopharyngeal nerve travel to the otic ganglion, where they synapse to innervate the parotid and orbital salivary glands.

The vagus nerves contain approximately 80% of the parasympathetic nerve fibers in the body. The preganglionic fibers are long and synapse in small ganglia that lie directly on or in the viscera of the thorax and abdomen. Efferent fibers are supplied to the heart, lungs, esophagus, stomach, small intestine, proximal colon, liver, gallbladder, pancreas, kidneys, and upper ureters. In the heart, they are distributed to the sinoatrial and atrioventricular nodes and, to a lesser extent, to the atria. There are few or no vagal parasympathetic fibers in the ventricles. In the intestinal wall, they form the plexuses of Meissner and Auerbach. The vagus also carries afferent fibers, arising from the nodose ganglion, that produce visceral reflexes but apparently not pain.

The sacral outflow originates in the second, third, and fourth sacral segments of the spinal cord. Preganglionic fibers form the pelvic nerves (nervi erigentes), which synapse in ganglia near the bladder, distal colon, rectum, and sexual organs. The vagus and pelvic nerves thus provide secretory, vasodilator, and motor fibers for the thoracic, abdominal, and pelvic organs.

Autonomic nerve endings in the effector organ may terminate within cells or on the cell membrane. Smooth muscle cells may have protoplasmic bridges so that neural stimulus of one causes many to react. No distinctive nerve ending exists comparable to somatic nerve endings within the myoneural junction.

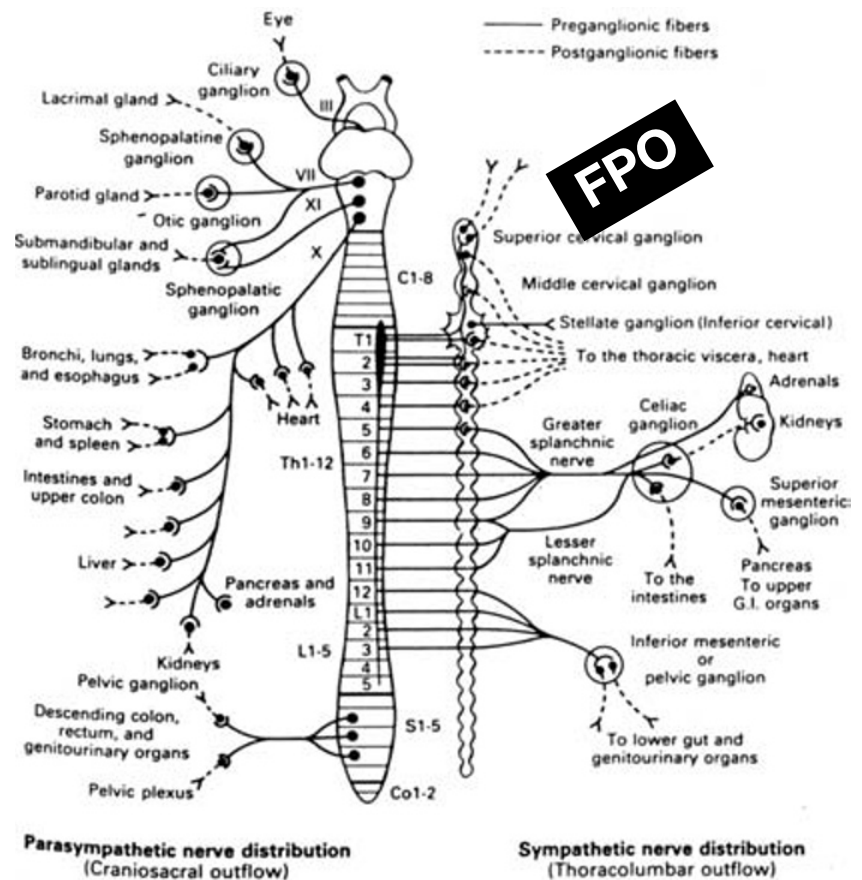

Fig. 6.12. Schematic distribution of the craniosacral (parasympathetic) and thoracolumbar (sympathetic) nervous system. Parasympathetic preganglionic fibers pass directly to the organ that is innervated. Their postganglionic cell bodies are situated near or within the innervated viscera. This limited distribution of parasympathetic postganglionic fibers is consistent with the discrete and limited effect of parasympathetic function. The postganglionic sympathetic neurons originate in either the paired sympathetic ganglia or one of the unpaired collateral plexi. One preganglionic fiber influences many postganglionic neurons. Activation of the sympathetic nervous system produces a more diffuse physiologic response rather than discrete effects. G.I., gastrointestinal. From Barash et al.⁴²

Sympathetic System

This mediates activities that accompany expenditures of energy, such as the *fight-or-flight response*. Thus, sympathetic activity is greatest during stress or times of emergency. Sympathetic activity in response to short-lived threats or pain is necessary for normal responses to these external stimuli (stressors). However, long-term stress, such as that seen with untreated pain, can lead to pathological changes, such as impaired immune system function and catabolic metabolism. As in the parasympathetic system, ACh acting on nicotinic receptors is the neurotransmitter between preganglionic and postganglionic neurons. However, the neurotransmitter between postganglionic neurons and effector cells is norepinephrine, which can act as an agonist at α_1 -, α_2 -, β_1 -, or β_2 -adrenergic receptors. An exception is the sweat gland, whose sympathetic terminals are cholinergic, except in horses, where sweat glands are under β_2 control.¹⁰ In contrast to the parasympathetic division, strong sympathetic stimulation produces generalized effects, because each preganglionic neuron synapses with 20 to 30 postganglionic neurons, each of which terminates on many effector cells, leading to a divergence of effect. In addition, norepinephrine at postganglionic synapses and epinephrine secreted by the adrenal medulla are deactivated slowly relative to ACh.

Sympathetic preganglionic fibers arise from cells in the intermediolateral columns of the first thoracic to the fourth or fifth lumbar cord segments (canine) (Fig. 6.12). Their axons pass through the ventral spinal roots and synapse in sympathetic gan-

glia with postganglionic nerve cells. There are three types of sympathetic ganglia: vertebral, prevertebral, and terminal. *Vertebral ganglia* are paired and lie in the lateral sympathetic chains paralleling the vertebral column. They are connected to one another by nerve trunks and to the spinal cord and spinal nerves by rami communicantes. White rami carry the preganglionic outflow from the spinal cord in myelinated fibers. These synapse with nonmyelinated fibers in the vertebral ganglia. The nonmyelinated fibers exit via the gray rami to join the spinal nerves supplying the blood vessels of skeletal muscle and the sweat glands, pilomotor muscles, and blood vessels of the skin.

Prevertebral ganglia, which are located in the abdomen and pelvis, consist mainly of the celiac, aorticorenal, and anterior and posterior mesenteric ganglia. The bladder and rectum are supplied by *terminal ganglia* located close to these organs. Since visceral nociceptive afferents can colocalize with these sympathetic fibers, neuroblockade at the sympathetic ganglion (e.g., celiac plexus block) has been used to treat difficult-to-manage visceral pain, such as that associated with cancer. Blockade does not result in loss of somatic sensations, but may interfere with regional sympathetic control of vasomotor or visceral functions.

Preganglionic fibers from the upper thorax form the cervical sympathetic chain and synapse with postganglionic fibers to form the sympathetic supply to the head and neck (sudomotor, pilomotor, vasomotor, secretory, and pupillodilator innervation) (Fig. 6.12). The upper thoracic chain supplies postganglionic

fibers that form the cardiac, esophageal, and pulmonary plexuses. The splanchnic nerves are formed from preganglionic fibers, which do not synapse until they reach the celiac ganglion. Postganglionic fibers from this and other prevertebral ganglia ramify widely to supply the abdominal viscera.

The adrenal medulla is unique in that it is embryologically, anatomically, and functionally homologous to the sympathetic ganglia. Chromaffin cells within the medulla originate from the neural crest and are innervated by preganglionic fibers. Activation of the sympathetic nervous system releases epinephrine and norepinephrine (approximately 80% and 20%, respectively), which act as systemic hormones, from the adrenal medulla. The response is similar to, but longer than (10 to 30 s), that which occurs with release from nerve terminals. Circulating norepinephrine causes vasoconstriction, inhibits gastrointestinal function, increases cardiac activity, and dilates the pupils. Circulating epinephrine has greater cardiac and metabolic effects than norepinephrine and, because of its increased β_2 -adrenergic receptor activity, induces vasodilation in skeletal muscle and bronchodilation. In addition, circulating norepinephrine and epinephrine have generalized metabolic effects in tissues that do not receive sympathetic innervation. Basal sympathetic tone is caused in part by adrenal medullary activity.

Nonadrenergic Noncholinergic Nervous System

A third division of the autonomic nervous system has been termed the *nonadrenergic noncholinergic* (NANC) nervous system. The NANC system (previously known as the enteric nervous system) is thought to regulate visceral organ function locally. It was first described with respect to the intestinal tract; thus, the name *enteric nervous system*. However, it has since been associated with some regulatory processes within other organs, such as the lung, and is therefore best termed *nonadrenergic noncholinergic nervous system*.

Neuron Function

Axonal Conduction

Nerve impulses are electrochemical currents that pass along the axon to the presynaptic membrane. From a pharmacological standpoint, there is an important distinction between electric *conduction* of a nerve impulse along an axon and chemical *transmission* of this signal across the synapse. Using electrodes, it can be shown that the internal resting potential of an axon is approximately 70 millivolts (mV) negative to the exterior of the axon. This is termed the *internal resting potential* and is caused by a relatively higher internal concentration of potassium and selective permeability of the resting axonal membrane to potassium.

When a resting axon is stimulated electrically, a nerve action potential is produced that travels the full length of the neuron in either direction. Most general anesthetics have little effect on nerve conduction velocity.^{11,12}

Neuroregulators

These play a key role in communication among nerve cells (Table 6.3) and may be subdivided into two groups. Small mole-

Table 6.3. Neuroregulators and modulators

Small-molecule, rapidly acting neurotransmitters

Calcitonin

cule neurotransmitters are synthesized in the cytosol of the presynaptic terminal, absorbed into the transmitter vesicles, and released into the synaptic cleft in response to the arrival of an action potential at the nerve ending. Release of neurotransmitters is voltage dependent and requires calcium influx into the presynaptic terminal. Following its release, the transmitter binds with the

postsynaptic receptor. The postjunctional membrane is excited by increased sodium conductance and inhibited when potassium or chloride conductance is enhanced. Some transmitters bind to receptors that activate enzymes, thus altering cellular function.

Neuropeptide modulators are synthesized in the neuronal cell body and transported to the nerve terminal by axonal streaming. They are released in response to an action potential, but in much smaller quantities than are the small molecule transmitters. The neuropeptides induce prolonged effects to amplify or dampen neuronal activity. They exert their effects through a variety of mechanisms, including prolonged closure of calcium channels, alteration of cellular metabolism, activation or inactivation of specific genes, and prolonged alteration in the numbers of excitatory or inhibitory receptors. Although usually only a single small molecule neurotransmitter is released by each type of neuron (Dale's law), the same neuron may release one or more neuropeptide modulators at the same time. The latter can be released from within the brain or from other parts of the body to act on neurons distant from the release site.¹³ In terms of anesthesia, many neuroregulators are known to be of great importance, whereas the significance of others may not be appreciated at this time.

In terms of chronic pain, little is known about the roles of neuromodulators involved in windup and sensitization. However, it is becoming more widely accepted that the pathological processing of nociceptive input in the brain and spinal cord involves more than simple changes in "wiring" of neurons. Recent evidence suggests an important role for the glia. Glia cells are traditionally thought of as serving only a supporting role as the glue

that holds nervous structures in their correct orientation. However, microglia are now recognized to have immune system roles and the ability to secrete modulating substances, such as tumor necrosis factor, interleukins, and nitric oxide, that can alter neighboring cell physiology.^{14,15} Future treatment strategies for chronic pain syndromes will likely address the role of immune cells like microglia (the resident CNS macrophages) in overall nervous system function and alteration.¹⁶

Transmission at the Neuromuscular Junction

The motor nerve axon terminates opposite the muscle cell at the presynaptic terminal membrane. Facing it is a second membrane: the postjunctional membrane. The two are separated by the subneural synaptic space. The area where the nerve meets the muscle is termed the *motor end plate* (Fig. 6.13).

The postjunctional membrane is preferentially permeable to sodium and potassium ions. The interior of the muscle cell is negatively charged, whereas the exterior, facing the nerve, is positively charged. This polarity is caused by an excess of sodium ions outside and potassium ions inside. The electromotive difference in potential between sides is approximately 90 mV. When a nerve impulse reaches the end of the axon, it initiates the release of ACh from its bound form in the synaptic vesicles. It diffuses across the synapse and is reversibly bound on the nicotinic cholinergic receptors of the postjunctional membrane. This changes the allosteric configuration of proteins in the membrane and its ion permeability. Sodium ions flow inward and potassium

Fig. 6.13. The anatomy of the motor end plate and the sequence of events from the nerve action potential to the contraction of a muscle fiber. EPP, end-plate potential. From Gilman et al.⁴³

outward, resulting in a decrease in electronegativity within the postjunctional membrane termed *depolarization*. From -90 to -45 mV, nothing occurs. This range is termed the *end plate potential*. Beyond the threshold potential, -45 mV, electrical depolarization spreads to the muscle around the end plate and is termed the *action potential*. This reaches a value of up to $+30$ mV.

Depolarization requires 0.2 to 0.4 ms, during which ACh is hydrolyzed to acetic acid and choline by ACh esterase present in the postjunctional membrane. As ACh is hydrolyzed, membrane permeability is restored to its normal state by sodium-potassium ATPase and the ions return to their respective resting sides (repolarization). Muscle contraction is delayed 2 to 3 ms; hence, repolarization is already complete when contraction occurs. Excess choline is taken up by the presynaptic nerve terminal and, through action of choline-*O*-acetyltransferase, acetic acid and choline recombine to re-form ACh. During rest, small quantities, or quanta, of ACh are continuously released from the nerve terminal, diffuse across the synaptic cleft, and bind to postsynaptic ACh receptors, causing small end-plate potentials. These miniature end-plate potentials do not cause muscle contraction, but are necessary for normal neuromuscular junction physiology. In contrast, when a nerve action potential arrives at the terminal, large quantities of ACh are released and motor end-plate depolarization and muscle contraction occur. The amount of ACh released with an action potential is about 10 times the amount required for muscle contraction. Extra ACh provides a safety margin in neuromuscular transmission and explains why more than 70% to 80% of postsynaptic junctional receptors need to be blocked before twitch tension is noticeably reduced. Most muscle fibers have one neuromuscular junction per fiber, although some muscles (e.g., extraocular muscles) may have more than one.

The three types of nicotinic cholinergic receptors at the neuromuscular junction are (a) junctional postsynaptic receptors located at the end plate that are responsible for neuromuscular transmission, (b) extrajunctional (i.e., extrasynaptic) postsynaptic receptors that do not normally participate in neuromuscular transmission but that may proliferate if the muscle is damaged or denervated, and (c) prejunctinal receptors that modulate neurotransmitter mobilization from the nerve terminal. The adult postsynaptic junctional nicotinic receptor is composed of five subunits (two alpha subunits, and one each of beta, gamma, and delta) that are arranged to form an ion channel through the cellular membrane. When two ACh molecules bind to both alpha subunits, the channel opens and calcium and sodium enter, while potassium exits the cell.

Postsynaptic extrajunctional receptors, which are located on the muscle membrane away from the synaptic cleft, are present in low numbers in normal individuals but proliferate following denervation or muscle damage. When present in high numbers, extrajunctional receptors play an important role in the development of the exaggerated, and sometimes dangerous, response seen after administration of a depolarizing neuromuscular junction blocker.

Presynaptic junctional receptors are located on motor nerve terminals and modulate the mobilization and availability of neu-

rotransmitters. Antagonism of presynaptic receptors does not appear to inhibit the release of ACh directly but may reduce synthesis or vesicular transport within the nerve terminal. Depletion of ACh stores following repeated or tetanic nerve stimulation noticeably reduces twitch tension. The role of the presynaptic receptor in the development of neuromuscular junction blockade is not completely understood.

Evaluation of Neurological Function During Anesthesia

Although the primary effect of anesthetics and anesthetic adjuncts is to reversibly alter CNS function, detailed studies of their neurophysiological effects have received comparatively limited attention. Traditionally, CNS activity has been evaluated subjectively by using classic signs of anesthesia (Guedel's stages of ether anesthesia) because interpretation of standard EEG recordings has required extensive training.

Electroencephalography

Historically, the electric activity of the CNS has been used in diagnostics of CNS disorders, especially seizures. The EEG has not gained widespread popularity as a clinical tool for evaluation of analgesia and anesthesia. Standard EEG tracings, using a Grass polygraph or other raw signal recorder, have required a degree of subjective interpretation. However, computer analyses of standard EEG tracings are now widely used to evaluate the effects of anesthetic adjuncts on neurological function.

The diagnostic EEG is usually used as a quantitative measure for spontaneous brain electrical activity. For intraoperative monitoring, amplitude, frequency, and bilateral symmetry over the two hemispheres are observed. When nutrient delivery to the brain is reduced, neurons sacrifice function before losing the ability to maintain their structure. The decrease in function can be detected as a change in the distribution of the EEG frequencies from higher to lower frequencies. Severe ischemia or very deep levels of anesthesia with some anesthetics produces irregular EEG signals and a phenomena termed *burst suppression* characterized as periods of electrical silence alternating with periods of activity. Eventually, with extreme anesthetic depression, the EEG will become completely silent (isoelectric) as neuron electrical activity ceases. Changes are reversible if anesthetic depression is lessened.

Hypothermia, hypotension, and hypercarbia can each alter the EEG and must be accounted for when interpreted clinically. Hypothermia will slow human EEG frequency in temperature-related fashion. Intermittent burst suppression will begin around 26°C , and isoelectricity will follow. Similarly, cerebral perfusion pressure below 50 mm Hg results in EEG slowing. It is important to note that significant changes in systemic blood pressure may not be accompanied by changes in EEG activity until a threshold level of hypoperfusion is reached.

Alternative methods for earlier detection of cerebral insult or increasing anesthetic depression use monitor-created stimuli, such as sound (brain-stem auditory evoked responses), light (visual), or noxious electrical pulses (somatosensory). These evoke

a CNS response that can be detected with proper EEG processing and can be indicative of the status of the nervous system during anesthesia and surgery. Additionally, the evoked somatosensory potentials can be applied to distant regions of the body and used to assess total nervous system function, such as in monitoring of spinal cord function during spinal surgery. Evoked potentials are usually averaged to remove the cyclical changes in background EEG. The resulting EEG changes are temporally associated with the stimulus and latency and amplitude can be compared with normal or baseline values. Motor evoked potentials can be used to measure peripheral motor nerve function by measuring nerve or muscle responses.

The development of spectral analysis and computer-assisted analysis of EEG recordings enabled a quantitative comparison of the effects of various anesthetic agents and dosages over time.^{17–23} Spectral edge analysis of the EEG has been correlated with anesthetic depth.²⁴ This system converts signals recorded in sequential epochs into numerical values for display of EEG amplitude and frequency distribution. Shifts in the 80% power spectral edge enable investigators to determine shifts objectively in electric frequencies as influenced by drugs.^{17–22,25} Some investigators have used 95% spectral edge for analysis.²³ The spectral edge frequency is defined as that frequency below which a certain percentage (80% or 95%) of the total power (amplitude²) is located. Concurrent analysis of airway, blood, or tissue drug concentrations, anesthetic depth, and spectral edge frequency provides a method of gauging the correlation of neurological responses to anesthetics and analgesics.^{21,22}

In addition to the recording of raw EEGs, the mean frequencies and amplitudes for delta, theta, alpha, beta₁, and beta₂ frequency bands can be determined. These frequency bands correspond to below 3.9, 4.0 to 7.9, 8.0 to 12.9, 13.0 to 23.9, and 24.0 to 31.75 Hz, respectively. The summation for all activity is recorded at frequencies up to 31.75 Hz. The response curve for each frequency and the duration of drug effect can be determined at each dosage of anesthetic to assess actions on overall CNS activity. Details of the use of computerized spectral analysis of the EEG to assess anesthetic depression have been published.^{17–27}

Bispectral Index Monitor

The bispectral index (BIS) monitor is a commercially available human monitor designed to enable anesthetists to conveniently measure an EEG-derived index of hypnotic level. The monitor records EEG activity from a pair of recording electrodes. The EEG signal is automatically processed, and a statistically derived index (the bispectrum) is reported. Electromyographic activity occurs with a frequency that overlaps with the EEG and can be problematic, especially in conscious animals or at light planes of anesthesia. Newer BIS monitors report the higher electromyographic frequencies and notify users of potential false elevation in the BIS number. Deep levels of anesthesia or neurological injury can result in EEG burst suppression. The BIS monitor reports a suppression ratio as well as displaying a continuous EEG waveform, enabling users to detect erroneous BIS values caused by isoelectric EEG activity.

In humans, BIS monitoring has been used as an indicator of

hypnosis level. The BIS value best correlates to a patient's likelihood of response to verbal or physical stimulation. When delivering gas anesthetics to a patient, the BIS value should not be used as a "MAC meter." The BIS value is a processed signal, and changes are delayed 30 to 60 s from the change in EEG and physical status following an acute stimulus like a skin incision or a loud sound. This delay makes it difficult to use the BIS as an indication of CNS response to stimuli or changes in neurological status. The advantage of BIS evaluation lies in its approximation of the level of sedation. When coupled with the knowledge of the time of drug administration, the occurrence of surgical stimulation, and underlying patient physiology, the safety and quality of altered mentation can be crudely assessed.

In humans, a BIS index above 80 indicates a high probability of response to a command. For sedative agents, the likelihood of response drops dramatically to a very low probability as the BIS index nears 50. The index may also correlate with the incidence of recall, but since the index was statistically derived for movement, the values for recall and movement are different. Appropriate BIS values during anesthesia in veterinary patients are more difficult to determine. Since the index is derived using response to commands as the pharmacodynamic effect, veterinary publications reporting correlation of BIS values to MAC multiples are more difficult to interpret. Several studies have been performed to evaluate the usefulness of BIS in dogs.^{28,29} In general, BIS was found to be useful in measuring depth of anesthesia, and values have been correlated with MAC multiples. Some species, such as cats, have unusually low BIS values when unstimulated, such as when being prepared for surgery, resulting in apparently poor correlation to depth, but noxious stimulation appears to raise values and result in a useful correlation.^{30–32} Usefulness of BIS in swine is of interest because of their use as laboratory models. Early reports of BIS use indicated poor correlation with anesthetic depth; however, subsequent work using swine with individually measured MAC values had improved correlation with BIS and anesthetic depth.^{33,34} Other species have been examined using BIS as an index of anesthetic depth.^{35,36}

Functional Magnetic Resonance Imaging

Functional magnetic resonance imaging (fMRI) was developed in the early 1990s as a technique to localize brain activity. Its main advantages are its noninvasiveness and the spatial and temporal resolution it provides. fMRI uses the correlation between neuronal activity and regional CBF.³⁷ Currently, its use in animals has been limited to the research setting.

Introduction

Probably the most fundamental and important principle of physiology is *homeostasis*: the maintenance of constant conditions through dynamic equilibrium of the internal environment of the body. One of the many processes that maintain homeostasis is the regulation of *acid-base balance*, a term introduced by L. J. Henderson (1909). Central to all schemes of acid-base balance is the understanding that normal oxygen-dependent metabolism of food (carbohydrates, lipids, and proteins) results in the predictable production of work, heat, and waste. Indeed, normal metabolic processes are responsible for the production of thousands of millimoles of carbon dioxide (CO₂; volatile acid) and potentially hundreds of milliequivalents of nonvolatile hydrogen ions (fixed acid) daily. Individual differences in the amount of CO₂ and hydrogen ion (H⁺) produced are influenced by diet, cellular basal metabolic rate, and body temperature. Animals consuming high-protein diets, for example, produce CO₂ and excess quantities of H⁺ precursors, whereas animals consuming diets high in plant material produce CO₂ and excess quantities of bicarbonate ion (HCO₃⁻) precursors. The CO₂ that is produced is combined with water and is catalyzed by carbonic anhydrase (CA) to form carbonic acid (H₂CO₃). The formation of carbonic acid from CO₂ and water (H₂O) (Eq. 7.1) and the subsequent

generation of H⁺ and HCO₃⁻ (Eq. 7.2) serves as the focal point for almost all discussions of acid-base balance because (a) Henderson's studies highlighted that large quantities of CO₂ are produced by all metabolizing cells, (b) CO₂ is in equilibrium with H⁺ and HCO₃⁻ ion, and (c) in the 1950s the plasma CO₂ content was the only relevant acid-base quantity that could be conveniently determined.

Combining Eqs. 7.1 and 7.2 yields

Although current understanding and appreciation for the many processes responsible for acid-base homeostasis have expanded considerably since Henderson's introduction of the term *acid-base balance*, the central importance of H⁺ regulation to cell function and animal health cannot be overemphasized. This led A. B. Hastings (1961) to state: "Tiny though it is, I suppose no constituent of living matter has so much power to influence biological behavior."

Acid-base homeostasis ([H⁺] regulation) involves the integrated normal activity of the lungs, kidney, and liver (Fig. 7.1). The lung removes CO₂, the kidneys remove H⁺ as fixed acid, and the liver metabolizes protein, generating 1 mmol H⁺/kg body weight daily. Following is a review of basic principles of acid-base balance and their integration into both the traditional and independent-variable (Stewart) approach to understanding and interpreting acid-base abnormalities in animals. Other more specific texts should be consulted for a more comprehensive review of the subject.¹⁻⁸

Acids, Bases, pH, pK, and the Henderson-Hasselbalch Equation

Most formal definitions of acids or bases when applied to biological solutions universalize the Bronsted-Lowery concept, which classifies acids as proton donors and bases as proton acceptors. A more appropriate working definition, however, may be that acids are substances that increase H⁺ concentration ([H⁺]), a term used synonymously with *protons* in aqueous solutions. The strength of an acid and resultant acidity of a solution are determined by its activity coefficient, a factor influenced by temperature that determines the degree of dissociation. Since, by definition, a base is

Fig. 7.1. Integration of the gut, liver, lung, and kidney in acid-base balance. HCO_3^- , sodium bicarbonate ion.

an H^+ (proton) acceptor, each acid dissociates into H^+ and a potential H^+ acceptor or conjugate base. For example, H_2CO_3 in aqueous solution dissociates into H^+ and its conjugate base HCO_3^- . Substances that are strong acids have weak conjugate bases and vice versa. Interestingly, water, the most abundant solvent in the body, can function as both an acid (H_3O^+ ; proton donor) or a base (H_2O ; proton acceptor) depending on local conditions ($\text{H}^+ + \text{H}_2\text{O} \leftrightarrow \text{H}_3\text{O}^+$). At normal pH (7.40) and temperature (37° to 38°C), water is the most abundant base in the body.

In acid-base physiology, the formation of acids and therefore H^+ production are emphasized because the end product of oral intake, tissue metabolism, and many pathophysiological disease processes is the production and release of hydrogen ion. Sorensen (1909) developed the concept of pH ($-\log_{10}[\text{H}^+]$) in order to simplify the notation necessary to describe the large changes of $[\text{H}^+]$ observed in nature and chemical experiments. This notation, although cumbersome mathematically and somewhat misleading because of nonlinearity, converts $[\text{H}^+]$ to pH by the formula (Fig. 7.2)

$$\text{pH} = -\log_{10} [\text{H}^+] = \log_{10} (1/[\text{H}^+]) \quad (7.4)$$

Regardless of the relatively narrow range (20 to 150 nEq/L) over which changes in $[\text{H}^+]$ occur in biological fluids, the concept of pH persists and is routinely reported on most pH and blood-gas machines. Conversion formulas for pH to $[\text{H}^+]$ have been developed:

$$\text{pH} > 7.40 \quad [\text{H}^+] = (\text{pH}_m - 7.40) (40) (0.8) \quad (7.4a)$$

$$\text{pH} < 7.40 \quad [\text{H}^+] = (7.40 - \text{pH}_m) (40) (1.25) \quad (7.4b)$$

Fig. 7.2. Relationship between $[\text{H}^+]$ and pH. Note that the relationship is exponential and not linear.

where pH_m is the measured pH. The development of the pH concept by Sorensen combined with the theory of acid-base balance proposed by Henderson (1909) and the introduction of methods to measure pH in blood by Hasselbalch (1912) led to the development of the Henderson-Hasselbalch equation and the characterization of acid-base disturbances as being either respiratory or nonrespiratory (metabolic) in origin. Application of the law of mass action to body fluids produces many potential equilibrium equations that could be used to explain acid-base balance. The reasons why the carbonic acid equilibrium equation (Eqs. 7.1 and 7.2) was chosen to describe acid-base balance are (a) historical (method of assay development) factors; (b) the finding that, other than water, HCO_3^- is the major base in the extracellular fluid and H_2CO_3 the major acid; and (c) that the carbonic acid equation incorporates both volatile and nonvolatile substances. The law of mass action states that the rate (velocity) of a reaction is proportional to the concentration of the reactants and the dissociation constant (K) for the reaction. The rate of dissociation (r) for an acid can be characterized by

Using the dissociation constant K_1 ,

$$r_1 = K_1 [\text{HA}] \quad (7.6)$$

Similarly,

and

$$r_2 = K_2 [\text{H}^+] [\text{A}^-] \quad (7.8)$$

which at equilibrium results in $r_1 = r_2$, or

$$K_2/K_1 = K_a = [\text{H}^+][\text{A}^-]/[\text{HA}] \quad (7.9)$$

where K_a is the dissociation constant for the acid HA. Applying this law to carbonic acid, Henderson derived

$$[H^+] = K_a[CO_2]/HCO_3^- \quad (7.10)$$

Henderson used the concentration of dissolved molecular CO_2 instead of H_2CO_3 because H_2CO_3 could not be measured. Hasselbalch then introduced PCO_2 into Henderson's equation and put the equation into logarithmic form, producing the now universally applied Henderson-Hasselbalch equation:

$$pH = pK_a + \log_{10} \left\{ \frac{[HCO_3^-]}{[s \times PCO_2]} \right\} \quad (7.11)$$

where pH is $-\log_{10} [H^+]$, pK_a is $-\log_{10} K_a$, and s is the solubility of CO_2 . This equation is frequently rewritten for explanatory purposes as

$$pH = pK_a + \log \left\{ \frac{[\text{base}]}{[\text{acid}]} \right\} = \frac{\text{kidney}}{\text{lung}} \quad (7.12)$$

Henderson deliberately applied the law of mass action to the equilibrium of carbonic acid. The Henderson-Hasselbalch equation indicates the amount of H^+ (protons) available to react with bases. Since acids and bases are charged particles, the application of this equation to biological fluids assumes that

1. Mass is conserved: The concentration of all substances can be accounted for as the sum of the concentrations of dissociated and undissociated forms.
2. All dissociation constants for all incompletely dissociated substances (weak acids or bases) are satisfied.
3. Electroneutrality is preserved: All positive charges must equal all negative charges.

These assumptions have particular relevance to the application of acid-base principles and to the interpretation of acid-base imbalance and are the basis for always integrating electrolyte (Na^+ , K^+ , Cl^- , etc.) abnormalities into the evaluation of acid-base balance.

Body Buffering Systems

The body uses three principal mechanisms to minimize or buffer changes in H^+ .^{6,7} *Chemical buffers* act within seconds to resist or reduce changes in $[H^+]$ and are the first line of defense against changes in pH. The *respiratory system* responds within minutes to resist changes in $[H^+]$ by regulating the partial pressure of CO_2 (physiological buffering) and eliminating excess CO_2 molecules caused by an increase in H^+ production (chemical buffering).

Finally, H^+ that is produced by nonrespiratory mechanisms (metabolic or nonrespiratory acidosis) is excreted by the *kidney* in the urine over a period of hours or days (Fig. 7.3).

Chemical Buffers

These are compounds that minimize changes in the $[H^+]$ or the pH of a solution when an acid or base is added. A buffer solution consists of a weak acid and its conjugate base and is most effective

Fig. 7.3. Rate of response of the different buffering mechanisms in the body.

when the pH is within 1.0 pH units of its dissociation constant (pK_a) (Table 7.1). Alterations in blood, interstitial, and intracellular $[H^+]$ are immediately modified by chemical buffer systems. The ratio of the anion $[A^-]$ form of the buffer to its conjugate acid $[HA]$ is a function of its dissociation constant (pK_a) and the $[H^+]$. For weak acids, as $[H^+]$ increases, $[A^-]$ decreases and $[HA]$ increases by equal amounts, keeping the total amount of A_{tot} ($A_{tot} = HA + A^-$) the same. The principle chemical buffers for excess H^+ production are the bicarbonate (HCO_3^-/H_2CO_3), phosphate (HPO_4^-/H_2PO_4), and protein ($Prot^-/H Prot$) buffer systems. Bone can contribute calcium carbonate and calcium phosphate to the extracellular fluid, thereby increasing the buffering capacity. Indeed, bone may account for up to 40% of the buffering of an acute acid load. Functionally, anytime there is an increase in $[H^+]$ in the body, the anion form of the buffer (HCO_3^- , HPO_4^- , and $Prot^-$) accepts the excess proton, converting the buffer to its conjugate acid (H_2CO_3 , H_2PO_4 , and $H Prot$). Because the body can have only one $[H^+]$, the ratio of the acid to salt forms of the various buffer pairs in solution can always be

Table 7.1. pK_a values of important chemical buffers^a

Compound	pK_a
Lactic acid	3.9
3-Hydroxybutyric acid	4.7
Creatinine	5.0
Organic phosphates	6.0–7.5
Carbonic acid	6.1
Imidazole group of histidine	6.4–6.7
Oxygenated hemoglobin	6.7
Inorganic phosphates	6.8
α -Amino (amino terminal)	7.4–7.9
Deoxygenated hemoglobin	7.9
Ammonium	9.2
Bicarbonate	9.8

^aCompounds with pK_a values in the range of 6.4 to 8.4 are most useful as buffers in biological systems. The pK_a values for the imidazole group of histidine and for α -amino (amino terminal) groups are for those side groups in proteins. The pK_a range for organic phosphates refers to such intracellular compounds as ATP, ADP, and 2,3-DPG.

Table 7.2. Major body buffers

	pK_a	Compartment pH	Basis of Effectiveness	Weakness
ECF				
HCO_3^-	6.1	7.4	CO_2 removal by the lungs	Distance of pH from pK
ICF ^a			Quantity	Depends on lungs
Imidazole	Close to 7	7.0	Exceedingly large quantity	Changes charge on ICF proteins ^b
HCO_3^-	6.1	7.0	Relatively large quantity	Depends on lungs for CO_2 removal
Urine				
Inorganic phosphate	6.8	5–7	pK higher than urine pH	Little capacity to increase excretion rate

ECF, extracellular fluid; ICF, intracellular fluid; and HCO_3^- , sodium bicarbonate ion.

^aAlthough ICF creatine phosphate is not a buffer, during acidemia it is hydrolyzed, rendering it capable of H^+ binding.

^bThis change in charge on ICF proteins can have important effects on enzyme activities, transporters, and ICF volume.

predicted by the Henderson-Hasselbalch equation (isohydric principle), providing their concentration and their dissociation constant (pK_a) are known. With knowledge of the behavior of one buffer pair, one can predict the behavior of all the other buffer pairs in solution. The HCO_3^-/H_2CO_3 buffer pair is most frequently used to determine acid-base status in clinical practice because it is the most prominent chemical buffer in the extracellular fluid. Another important reason why the HCO_3^-/H_2CO_3 buffer pair is used to express acid-base status is that, in the presence of carbonic anhydrase, carbonic acid forms CO_2 , which is eliminated by alveolar ventilation. Thus, the body can be considered an “open” system.

Approximately 60% of the body’s chemical buffering capacity occurs by intracellular phosphates and proteins. Inorganic and organic (ATP, ADP, and 2,3-DPG) phosphates possess pK_a values that range from 6.0 to 7.5, making them ideal chemical buffers over a wide range of potential intracellular pH values. Inorganic phosphate (pK_a 6.8) is the major buffer in urine because renal tubular pH (6.0 to 7.0) includes the pK_a of the HPO_4^-/H_2PO_4 buffer pair.

Intracellular pH regulation depends on the activity of two cell membrane ion-transport systems: the Na^+-H^+ antiporter and the $Cl^-HCO_3^-$ antiporter (chloride pump), and intracellular proteins. Proteins are by far the most important intracellular buffers. Hemoglobin contributes approximately 80% of the nonbicarbonate buffering capacity of whole blood and with other intracellular proteins is responsible for three-fourths of the chemical buffering power of the body. The most important intracellular protein-dissociable group is the imidazole ring of histidine (pK_a 6.4 to 6.7). The α -amino groups of proteins (pK_a 7.4 to 7.9) play a secondary but important role in intracellular buffering. Plasma proteins, particularly albumin, also contain histidine and α -amino groups, and collectively are responsible for 20% of the nonbicarbonate buffering capacity of whole blood (Table 7.2).

Respiratory System

This offers an alternative route by which $[H^+]$ can be regulated by varying the partial pressure of carbon dioxide (PCO_2) (Fig. 7.1). Chemoreceptors throughout the body, but particularly those

located in the medulla and carotid body, monitor changes in $[H^+]$ and PCO_2 and adjust breathing (tidal volume and frequency) to maintain a normal $[H^+]$. The association of H^+ with HCO_3^- and the subsequent formation of CO_2 and H_2O is an example of chemical buffering (closed system), and the elimination of CO_2 by the lung (open system) constitutes a physiological buffering mechanism. Changes in blood CO_2 also have important consequences for hemoglobin affinity for oxygen and its buffering capacity. Increases in PCO_2 increase blood $[H^+]$ and decrease hemoglobin affinity for oxygen (Bohr effect). This change in the oxygen affinity of hemoglobin is advantageous in tissues, allowing hemoglobin to release more oxygen for metabolism. Unoxxygenated hemoglobin in turn can transport more CO_2 in the form of hemoglobin carbamino compounds (H^+ Prot) to the lungs (Haldane effect). It is important to realize that anytime there is a change in the PCO_2 , there is a relatively much greater change in $[H^+]$ than $[HCO_3^-]$, because $[HCO_3^-]$ is measured in milliequivalents per liter and $[H^+]$ in nanoequivalents per liter. Maintenance of $[H^+]$ within a narrow range is vital to normal tissue enzyme activity.

Renal System

The synthesis of new HCO_3^- and excretion of excess H^+ emphasize the role of the kidneys as both a chemical and physiological buffer system (Fig. 7.1). Although relatively slow (hours or days), compared with the lungs (minutes) and chemical buffering (seconds), the kidney serves as the principal means by which acids that are produced by metabolic processes (not owing to CO_2 production but rather fixed acids) are ultimately eliminated (Fig. 7.3). All hydrogen ions produced by metabolic processes are excreted in the urine in combination with weak anions (titratable acidity), primarily phosphate and ammonium salts. The term *titratable acidity* may be considered synonymous with *urinary phosphate concentration* but actually represents all weak acids, including creatinine and urate. Net acid excretion by the kidney includes the titratable acidity and ammonium minus the HCO_3^- eliminated in the urine. Ammonium (NH_4^+) is produced in the proximal tubule primarily from glutamine metabolism to α -ketoglutarate and NH_3 , a process that simultaneously gener-

Fig. 7.4. Reabsorption and regeneration of sodium bicarbonate ion (HCO_3^-) in the renal tubules. Bicarbonate reabsorption in the proximal tubule coincides with H^+ secretion. Bicarbonate regeneration in the renal tubules coincides with titration of phosphate by H^+ and ammonium formation.

ates HCO_3^- . Increases in H^+ production can increase the rate of ammonium salt excretion by fivefold during severe metabolic acidosis (Fig. 7.4).

It is important to note that potassium loss from cells can lead to intracellular H^+ or Na^+ accumulation in order to maintain electric neutrality. This effect in renal tubular cells can lead to increased H^+ excretion (aciduria) and HCO_3^- reabsorption (alkalemia and “paradoxical aciduria”). Renal tubular cell acidosis may also augment glutamine metabolism and NH_3 production, leading to enhanced NH_4^+ excretion. Alkalemia and paradoxical aciduria is known to occur in people, rats, and ruminants. Its importance in dogs and cats is questionable.

Temperature Effects on Acid-Base Balance

Increases and, more routinely, decreases in body temperature are frequently encountered in patients undergoing anesthesia and surgery. Increases in body temperature may be associated with stress, increases in skeletal muscle activity (inadequate relaxation), systemic disease, and/or infectious and genetic disorders (malignant hyperthermia). Decreases in body temperature are

Table 7.3. Effect of temperature on PO_2 , PCO_2 , and pH

Temp °C	PO_2	PCO_2	pH
20	27	19	7.65
25	37	24	7.58
30	51	30	7.50
35	70	37	7.43
36	75	38	7.41
37	80	40	7.40
38	85	42	7.39
39	91	44	7.37
40	97	45	7.36

much more common than increases during anesthesia and surgery. Hypothermia may be much more profound in smaller patients (<8 to 10 kg) because of their larger body surface area to body mass ratio and is exaggerated by cleaning solutions (water or alcohol), cold exposure (steel tables), illness (shock), drugs that cause vasodilation (phenothiazine, barbiturates, or isoflurane), and toxicity. Changes in body temperature affect the $[\text{H}^+]$ of all body fluids. Increases in body temperature decrease pH and vice versa such that blood pH changes by 0.015 to 0.02 units/°C. Changes in pH with body temperature are expected because of known temperature-induced changes on dissociation constants (pK_a) and the solubility of CO_2 in blood. For example, as body temperature decreases, the pK_a and blood solubility of CO_2 increase, producing an increase in pH and decrease in PCO_2 (Table 7.3). These temperature-dependent changes in both intracellular and extracellular pH are believed to be important in maintaining an OH^-/H^+ (relative alkalinity) ratio of 16:1 throughout the body. A constant relative alkalinity of 16:1 for OH^- and H^+ is known to be optimal for cellular enzyme systems to function normally. The most important of the dissociable groups responsible for maintenance of a constant ratio between $[\text{H}^+]$ and $[\text{OH}^-]$ is the imidazole ring of the histidine residues of hemoglobin. Indeed, the fractional dissociation of imidazole-histidine remains constant as temperature changes and varies with pH during isothermal conditions. This regulation of the functional imidazole-histidine dissociation to maintain acid-base balance is termed *alpha-stat regulation* in contrast to *pH stat regulation*, in which pH values are maintained constant (Table 7.4).^{7,9}

Both the alpha-stat and pH-stat concepts of acid-base balance have been used clinically when interpreting pH and blood gases

Table 7.4. Comparison of pH-stat and alpha-stat acid-base regulation

Concept	Purpose	Total CO_2	pH and PaCO_2 Maintenance	Intracellular State	α -Imidazole and Buffering	Enzyme Structure and Function
pH-stat	Constant pH	Increases	Normal corrected values	Acidotic (excess H^+)	Excess (+) charge, buffering decreased	Altered and activity decreased
Alpha-stat	Constant OH^-/H^+	Constant	Normal uncorrected values	Neutral ($\text{H}^+ = \text{OH}^-$)	Constant net charge, buffering constant	Normal and activity maximal

Table 7.5. Characteristics of primary acid-base disturbances

Disorder	pH	[H ⁺]	Primary Disturbance	Compensatory Response
Nonrespiratory acidosis	↓	↑	↓ [HCO ₃ ⁻]	↓ PCO ₂
Nonrespiratory alkalosis	↑	↓	↑ [HCO ₃ ⁻]	↑ PCO ₂
Respiratory acidosis	↓	↑	↑ [PCO ₂]	↑ [HCO ₃ ⁻]
Respiratory alkalosis	↑	↓	↓ [PCO ₂]	↓ [HCO ₃ ⁻]

Nonrespiratory is used in preference to metabolic. HCO₃⁻, sodium bicarbonate ion.

in patients with body temperatures higher or lower than normal.^{7,9} Proponents of the pH-stat hypothesis argue that it is important to maintain a constant pH of 7.40 and PCO₂ of 40 mm Hg at any temperature, whereas proponents of the alpha-stat strategy attempt to keep a constant ratio of [H⁺] to [OH⁻] of 1:16. Proponents of the pH-stat strategy realize that if the pH and PCO₂ were kept constant at pH of 7.40 and PCO₂ of 40 mm Hg during hypothermia, the patient would be acidotic, but they argue that pH-stat-oriented therapy reduces morbidity. Proponents of alpha-stat-oriented therapy argue similarly and point out that blood flow to vital organs, particularly cerebral blood flow, becomes pressure dependent with pH-stat management. More research is required to resolve all of the controversies regarding the potential benefits of either strategy. From a practical standpoint, however, pH and PCO₂ need not be corrected for temperature. Measuring a blood sample taken from a hypothermic patient at 37° or 38°C (the temperature at which most blood-gas machines are calibrated) enables appropriate therapeutic decisions and eliminates the need to know the patient's precise body temperature for interpretation of acid-base abnormalities.

Clinical Acid-Base Terminology

Descriptions of acid-base balance and acid-base abnormalities have been based on familiarity with the Bronsted-Lowery definition of an acid and base, the Henderson-Hasselbalch equation, and standard medical terms describing body fluids or fluid compartments. The terms *acidosis* and *alkalosis*, for example, are used to describe the abnormal or pathological (-osis) accumulation of acid [H⁺] or alkali [OH⁻] in the body.⁵ The terms *acidemia* and *alkalemia* are used to describe whether the blood pH is acid or alkaline, respectively. The Henderson-Hasselbalch equation characterizes all acid-base disturbances as being either respiratory or metabolic because of the body's production and elimination of volatile (dissolved CO₂; H₂CO₃) and nonvolatile or fixed (e.g., lactic and phosphoric) acids, respectively. Therefore, only four primary acid-base abnormalities are possible: respiratory acidosis, metabolic acidosis, respiratory alkalosis, and metabolic alkalosis (Table 7.5). Clinically, the terms *respiratory* and *metabolic* have been used to imply the involvement of the lung and kidney in acid-base regulation:

$$\text{pH} = \text{HCO}_3^- / \text{PaCO}_2 = \frac{\text{kidney function (fixed acids)}}{\text{lung function (volatile acids)}} \quad (7.14)$$

The term *nonrespiratory* frequently replaces *metabolic* in many discussions of acid-base imbalance because the term *metabolic* is not totally descriptive and is somewhat misleading (because it implies that all fixed acids are produced by cellular metabolism). The term *nonrespiratory* incorporates all mechanisms responsible for acid-base imbalance other than the production of CO₂ and carbonic acid (H₂CO₃). These mechanisms include alterations in the concentrations of strong (fully dissociated) ions and strong ion difference (SID), nonvolatile plasma buffers (primarily serum proteins; A_{tot}), and the ionic strength (dissociation constants; pK_a) of the solution (Fig. 7.5). The four factors used to describe changes in [H⁺] caused by respiratory and nonrespiratory imbalances are collectively referred to as *independent variables* (PCO₂, SID, A_{tot}, and pK_a) because each of them is regulated or changed independently of the others.¹⁰⁻¹² It should be noted, however, that changes in temperature can affect all the independent variables, a consideration that has special importance during surgery and anesthesia.

Primary abnormalities in acid-base balance can arise from disturbances in any one or several of the independent variables. Simple acid-base abnormalities are said to occur only when one independent variable is responsible for the acid-base disturbance. Mixed acid-base abnormalities are caused by disturbances in two or more of the independent variables. Mixed acid-base abnormalities may be additive (respiratory and nonrespiratory acidosis) or offsetting (respiratory alkalosis and metabolic acidosis) with regard to their ability to influence [H⁺] measured as pH. Offsetting mixed acid-base abnormalities occur when two primary acid-base abnormalities produce opposite effects on plasma [H⁺]. Patients with offsetting mixed acid-base abnormalities have both acidosis and alkalosis but do not necessarily demonstrate acidemia or alkalemia, because blood pH may be normal. These are some observations that should lead to suspicions of a mixed acid-base disturbance when evaluating blood-gas results:^{2,13,14}

1. The presence of a normal pH with abnormal PCO₂ and/or [HCO₃⁻]
2. A pH change in a direction opposite that predicted for the known primary disorder
3. PCO₂ and [HCO₃⁻] changing in opposite directions

Mixed acid-base disorders can be classified based on the origin of the primary disturbances as mixed respiratory disturbances, mixed nonrespiratory and respiratory disturbances, mixed nonres-

Fig. 7.5. Influence of independent variables on acid-base balance. The dependent variables (H^+ and OH^-) are enclosed by the dashed line. SID, strong ion difference.

piratory disturbances, and triple disorders. They also can be classified based on their effect on a patient’s pH in additive combinations, offsetting combinations, and triple disorders (Table 7.6).² In additive combinations, both primary disorders tend to change pH in the same direction (e.g., respiratory acidosis and nonrespiratory acidosis), whereas, in offsetting combinations, the primary disorders tend to change the pH in opposite directions (e.g., respiratory alkalosis and nonrespiratory acidosis). The final pH reflects the dominant of the two offsetting disorders in offsetting combinations.² Detailed reviews of mixed acid-base disorders in domestic animals have been presented elsewhere.^{2,13–15}

Secondary or compensatory (adaptive) acid-base changes frequently occur in response to most primary acid-base abnormalities and aid in buffering or minimizing changes in plasma $[H^+]$. Respiratory acid-base abnormalities, for example, are generally compensated for by controlled, oppositely directed changes in nonrespiratory function. In simple acid-base abnormalities such as primary respiratory acidosis caused by hypoventilation, the kidney compensates by producing nonrespiratory alkalosis.

Respiratory compensation in metabolic acid-base disorders is obtained by changing alveolar ventilation and therefore changing CO_2 excretion by the lungs. Nonrespiratory acidosis is characterized by an increase in $[H^+]$, a decrease in blood $[HCO_3^-]$ and pH, and a decrease in PCO_2 , caused by secondary hyperventilation; whereas nonrespiratory alkalosis is characterized by a decrease in $[H^+]$, increase in blood $[HCO_3^-]$ and pH, and an increase in PCO_2 , owing to compensatory hypoventilation.

In respiratory acid-base disorders, the compensation occurs in two phases. The first phase consists of titration by nonbicarbonate buffers, and the second phase reflects renal compensation of the acid-base disorder, by increasing or decreasing HCO_3^- and Cl^- excretion in the urine. Respiratory acidosis is characterized by increased PCO_2 , increased $[H^+]$, decreased pH, and a compensatory increase in blood $[HCO_3^-]$. CO_2 accumulation is caused by alveolar hypoventilation. Renal compensation occurs by titration of nonbicarbonate buffers, increase in net acid and Cl^- excretion, and increase in HCO_3^- reabsorption by the kidneys.^{6,14} Respiratory alkalosis is characterized by decreased PCO_2 , decreased $[H^+]$, increased pH, and a compensatory decrease in blood $[HCO_3^-]$. The initial compensation in respiratory alkalosis is caused by release of H^+ from nonbicarbonate buffers within cells. The second phase is mediated by a compensatory decrease in net acid excretion by the kidneys.¹⁴

When analyzing secondary changes in a given acid-base disorder, it is important to remember the following:

1. With the exception of chronic respiratory alkalosis, compensation does not return the pH to normal.
2. Overcompensation does not occur.
3. Sufficient time must elapse for compensation to reach a steady state, at which time the expected compensation can be estimated using the formulas in Table 7.7.

Table 7.6. Classification of mixed acid-base disorders

Classification	Effect on the pH
Mixed respiratory disorders	
Acute and chronic respiratory acidosis	Additive
Acute and chronic respiratory alkalosis	Additive
Mixed respiratory and nonrespiratory disorders	
Respiratory acidosis and nonrespiratory acidosis	Additive
Respiratory acidosis and nonrespiratory alkalosis	Offsetting
Respiratory alkalosis and nonrespiratory acidosis	Offsetting
Respiratory alkalosis and nonrespiratory alkalosis	Additive
Mixed nonrespiratory disorders	
Nonrespiratory acidosis and nonrespiratory alkalosis	Offsetting
Normal plus high anion gap nonrespiratory acidosis	Additive
Mixed high anion gap nonrespiratory acidosis	Additive
Mixed normal anion gap nonrespiratory acidosis	Additive
Triple disorders	
Nonrespiratory acidosis, nonrespiratory alkalosis, and respiratory acidosis	Final pH is function of relative dominance of acidifying and alkalinizing processes
Nonrespiratory acidosis, nonrespiratory alkalosis, and respiratory alkalosis	

Table 7.7. Expected compensatory responses in primary acid-base disorders

Disorder	Primary Change	Expected Range of Compensation
Nonrespiratory acidosis	↓ [HCO ₃ ⁻]	PCO ₂ = last 2 digits of pH × 100 ΔPCO ₂ = 1 – 1.13 (Δ[HCO ₃ ⁻]) PCO ₂ = [HCO ₃ ⁻] + 15 PCO ₂ = 0.7 [HCO ₃ ⁻] ± 3 (dogs)
Nonrespiratory alkalosis	↑ [HCO ₃ ⁻]	PCO ₂ : variable increase PCO ₂ = increases of 0.6 mm Hg for each new 1 mEq/L increase in [HCO ₃ ⁻] PCO ₂ = 0.7 [HCO ₃ ⁻] ± 3 (dogs)
Respiratory acidosis		
Acute	↑ PCO ₂	Acute [HCO ₃ ⁻] increases 1 mEq/L and pH decreases 0.05 units for every 10 mm Hg increase in PCO ₂ [HCO ₃ ⁻] = 0.15 PCO ₂ ± 2 (dogs)
Chronic	↑ PCO ₂	[HCO ₃ ⁻] increases 3.5 mEq/L and pH decreases 0.07 units for every 10 mm Hg increase in PCO ₂ [HCO ₃ ⁻] = 0.35 PCO ₂ ± 2 (dogs)
Respiratory alkalosis		
Acute	↓ PCO ₂	[HCO ₃ ⁻] falls 2 mEq/L and pH increases 0.1 units for each 10 mm Hg fall in PCO ₂ [HCO ₃ ⁻] = 0.25 PCO ₂ ± 2 (dogs)
Chronic	↓ PCO ₂	[HCO ₃ ⁻] falls 5 mEq/L and pH increases 0.15 units for each 10 mm Hg fall in PCO ₂ [HCO ₃ ⁻] = 0.55 PCO ₂ ± 2 (dogs)

HCO₃⁻, sodium bicarbonate ion.

Care should be exercised when dealing with cats because they may not be able to compensate for nonrespiratory acidosis as well as dogs.

The question that often arises when analyzing simple acid-base abnormalities that demonstrate both respiratory acidosis and nonrespiratory alkalosis is, “Which is the primary problem and is there a secondary and/or compensatory event?” The answer is not always obvious, although simple primary acid-base abnormalities change pH in the direction of the primary disorder. For example, a patient with respiratory acidosis and compensatory nonrespiratory alkalosis would have a pH that tended to be acidotic (e.g., a pH of 7.31). Mixed respiratory and nonrespiratory acid-base abnormalities are much more difficult to decipher, and like simple acid-base abnormalities must be carefully evaluated in the context of a patient’s signs, symptoms, and other available diagnostic information.

Because nonrespiratory acidosis is so frequently associated with disease processes in animals, indices of acid-base balance have evolved that enable the nonrespiratory component of acid-base abnormalities to be evaluated quantitatively. The *standard bicarbonate* is the concentration of bicarbonate in plasma after the whole blood sample has been equilibrated to a PCO₂ of 40 mm Hg at 38°C. This index quantifies the nonrespiratory component of any acid-base abnormality, because differences in the standard bicarbonate from normal (approximately 25 mEq/L) cannot be caused by changes in PCO₂, which is held constant at 40 mm Hg at 38°C. Similarly, the base excess (BE) quantitates the number of milliequivalents per liter of acid or base required to titrate 1 L of blood to pH 7.40 while the PCO₂ is held constant at 40 mm Hg at 38°C. Both the standard bicarbonate and BE (or

deficit) can be determined from nomograms. The BE has a normal value of zero (±3) and is changed only by nonvolatile acids, thereby indicating nonrespiratory acidosis. The numerical magnitude of the BE is a guide to therapy:

$$\text{Base (Na}^+\text{HCO}_3^-) \text{ needed} = (0.3) \times (\text{BE}) \times (\text{body weight [kg]}) \quad (7.15)$$

where 0.3 = % body weight that is extracellular water.

Anion Gap

The anion gap (AG) is a useful tool to assess mixed acid-base disorders.^{10,11,14} Chemically, there is no AG because electroneutrality must be maintained and the “anion gap” actually is the difference between the unmeasured anions (UA⁻) and unmeasured cations (UC⁺). Following the electroneutrality law,

$$([\text{Na}^+] + [\text{K}^+] + [\text{UC}^+]) - ([\text{Cl}^-] + [\text{HCO}_3^-] + [\text{UA}^-]) = 0 \quad (7.16)$$

or, when applied clinically,

$$\text{AG} = ([\text{Na}^+] + [\text{K}^+]) - ([\text{Cl}^-] + [\text{HCO}_3^-]) = [\text{UA}^-] - [\text{UC}^+] \quad (7.17)$$

Based on Equation 7.16, every time there is a decrease in [HCO₃⁻], either [Cl⁻] or [UA⁻] must increase to maintain electroneutrality. When titrated HCO₃⁻ is replaced by Cl⁻ in nonrespiratory acidosis, the difference ([UA⁻] – [UC⁺]; and consequently the AG) will remain the same (called *hyperchloremic* or *normal AG acidosis*). When titrated HCO₃⁻ is replaced by UA⁻, the difference ([UA⁻] – [UC⁺]; i.e., the AG) will increase

Table 7.8. Simple primary nonrespiratory acid-base disorders^a

Nonrespiratory Disorder	Na ⁺ Cl ⁻	AG	TCO ₂	Respiratory Compensation	Biochemical Profile
Alkaloses					
Hypoalbuminemia	N	N, ↓	↑	No	↓ Albumin
Hypochloremia	↑	N	↑	No	↓ [Cl ⁻] corrected
Concentration	↑	N	↑	Yes	↑ [Na ⁺]
Acidoses					
Hyperalbuminemia	N	N, ↑	↓	No	↑ Albumin
Hyperphosphatemia	N	N, ↑	↓	No	↑ Inorganic phosphate
Hyperchloremia	↓	N	↓	Yes	↑ [Cl ⁻] corrected
Dilution	↓	N	↓	Yes	↓ [Na ⁺]
Organic	N	↑	↓	Yes	Specific assays required

^aNa⁺ - Cl⁻ difference between sodium and chloride concentration; AG, anion gap; TCO₂, total CO₂; ↑, increase; N, normal; and ↓, decrease. See the text for limitations in using Na⁺ - Cl⁻ difference and AG.

From de Moraes and Muir.¹¹

while [Cl⁻] remains the same (called *normochloremic* or *high AG acidosis*).^{2,15}

Negatively charged proteins, phosphates, sulfates, and organic acids (e.g., lactate, β-hydroxybutyrate, acetoacetate, and citrate) constitute the UA⁻.¹⁶ Usually an increase in AG implies an accumulation of organic acids in the body.¹⁷ An increase in AG also occurs in alkalemia caused by an increase in the net negative charge on serum proteins or in situations where concomitant nonrespiratory alkalosis or respiratory alkalosis overrides a high-AG nonrespiratory acidosis.^{18,19} Hypoalbuminemia probably is the only important cause of a decrease in AG, and each decrease in albumin concentration by 1 g/dL generally produces a decrease of approximately 3 mEq/L in the AG.

The AG concept has some limitations. The summation of [Cl⁻] and [HCO₃⁻] is not acceptable based on principles of chemistry.²⁰ Each of these anions has a different activity coefficient partially because they are present in extracellular fluid at concentrations that differ by a factor of more than 5 (i.e., [Cl⁻] = 110 mEq/L vs. [HCO₃⁻] = 21 mEq/L).²⁰ Regardless, this simplification of the AG is helpful clinically (Table 7.8). The AG also can change because of excessive exposure of serum to air, resulting in changes of 6.5 ± 2.3 mEq/L after 2 h.²¹ These changes are more pronounced in patients with respiratory acidosis.²⁰

[Na⁺] - [Cl⁻] Difference

Plasma Cl⁻ and HCO₃⁻ concentrations have a tendency to change in the opposite direction in nonrespiratory alkalosis and hyperchloremic acidosis, whereas sodium concentration tends to remain normal in acid-base disturbances unless the primary disorder also affects water balance. The difference between sodium and chloride concentrations ([Na⁺] - [Cl⁻]) is therefore useful in the assessment of those nonrespiratory disturbances not associated with an increase in unmeasured anions. The [Na⁺] - [Cl⁻] is approximately 36 mEq/L. If [Na⁺] is normal, an increase in this value is caused by hypochloremia and is an indication of

Table 7.9. Relative changes in [Na⁺]₀ and [Cl⁻]₀ as an index of disorders in hydration or acid-base balance or both

- Proportionate change in [Na⁺]₀ and [Cl⁻]₀ are always due to the disturbances of hydration alone.
 - Dehydration
[Na⁺]₀ ↑ and [Cl⁻]₀ ↑
 - Overhydration
[Na⁺]₀ ↓ and [Cl⁻]₀ ↓
- Changes in [Cl⁻]₀ without any change in [Na⁺]₀ is always due to disturbances of acid-base alone.
 - Respiratory acidosis or nonrespiratory alkalosis
[Na⁺]₀ and [Cl⁻]₀ ↓
 - Respiratory alkalosis or hyperchloremic acidosis
[Na⁺]₀ and [Cl⁻]₀ ↑
- Disproportionate changes in [Na⁺]₀ and [Cl⁻]₀ are due to disturbances in both hydration and acid-base balance.
 - Dehydration plus respiratory acidosis or nonrespiratory alkalosis
[Na⁺]₀ ↑ and [Cl⁻]₀
 - Dehydration plus respiratory alkalosis or nonrespiratory acidosis
[Na⁺]₀ ↑ and [Cl⁻]₀ ↑↑
 - Overhydration plus respiratory alkalosis or hyperchloremic acidosis
[Na⁺]₀ ↓ and [Cl⁻]₀
 - Overhydration plus respiratory acidosis or nonrespiratory alkalosis
[Na⁺]₀ ↓ and [Cl⁻]₀ ↓↓

Modified from Emmett and Seldin.³⁰

metabolic alkalosis, whereas a decrease in the [Na⁺] - [Cl⁻] gradient is an indication of hyperchloremic acidosis.⁸ This difference, used in association with the AG, can be useful in identifying the presence of a mixed metabolic process (Table 7.9).

Strong Ion Difference

A new theory of acid-base regulation was proposed in the early 1990s.⁸ According to this theory, $[\text{HCO}_3^-]$ and pH ($[\text{H}^+]$) depend on PCO_2 , the total concentration of plasma weak nonvolatile acids ($[\text{A}_{\text{tot}}]$, composed mostly of albumin and inorganic phosphates), and the difference between the strong cations and the strong anions (called the *strong ion difference* or SID) (Fig. 7.5).^{4,8} As was previously pointed out, strong ions are substances that are completely dissociated in plasma at body pH. The most important strong ions in plasma are Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , lactate, β -hydroxybutyrate, acetoacetate, and sulfate. The influence of strong ions on pH and $[\text{HCO}_3^-]$ can always be expressed in terms of the SID. An increase in SID correlates with nonrespiratory alkalosis, whereas a decrease in SID correlates with nonrespiratory acidosis. Body homeostatic mechanisms indirectly regulate $[\text{H}^+]$ (and pH) and $[\text{HCO}_3^-]$ by changing PCO_2 (by changes in alveolar ventilation relative to CO_2 elimination rate) and SID (by differential reabsorption of Na^+ and Cl^- in the kidneys). Although changes in $[\text{A}_{\text{tot}}]$ will change $[\text{HCO}_3^-]$ and $[\text{H}^+]$, control of albumin production and inorganic phosphate concentration is not primarily directed at acid-base homeostasis.

Simple acid-base disturbances occur when an abnormality in one of the principal determinants of $[\text{H}^+]$ (e.g., PCO_2 , SID, or $[\text{A}_{\text{tot}}]$) is present.^{3,11,12} A simple acid-base disturbance includes both the primary process and the compensatory response: That is, if a sustained primary disturbance occurs in PCO_2 , a compensatory change of regulated magnitude normally occurs in the SID and vice versa. If the primary disturbance results from a change in $[\text{A}_{\text{tot}}]$, however, renal or ventilatory compensation does not occur.³

Clinical Disturbances

One method of classifying acid-base disturbances provides a mechanistic view of the causative disturbances and integrates serum electrolytes and albumin concentration into the interpretation of acid-base balance.⁷ Based on the preceding discussion, the following conclusions can be made: (a) acid-base homeostasis in body-fluid compartments is established based on the regulation of independent variables, including PCO_2 , SID, and $[\text{A}_{\text{tot}}]$; (b) acid-base disturbances are primarily caused by changes in one or more of the independent variables; (c) acid-base status is best determined by analysis of the independent variables; and (d) the fundamental basis for therapeutic success or failure depends on interventions that adjust the independent variables.^{3,22–25}

Disorders of PCO_2

Primary respiratory disturbances result from increases (respiratory acidosis) or decreases (respiratory alkalosis) in PCO_2 . CO_2 tension can be changed by alveolar ventilation, which has a profound effect on $[\text{HCO}_3^-]$ and $[\text{H}^+]$. Approximately 50% of daily variability of $[\text{HCO}_3^-]$ in normal dogs can be attributed to changes in PCO_2 alone. Because arterial PCO_2 (PaCO_2) is inversely related to alveolar ventilation, measurement of PaCO_2 provides clinicians with direct information about the adequacy of

alveolar ventilation. Respiratory acidosis is therefore caused by and synonymous with hypoventilation, whereas respiratory alkalosis is caused by and synonymous with hyperventilation. The principal disorders associated with respiratory acidosis are airway obstruction, respiratory-center depression (e.g., drugs or neurological disorders), cardiopulmonary arrest (PaCO_2 may be below normal during cardiopulmonary resuscitation), neuromuscular diseases, diaphragmatic hernia, chest wall trauma, and inadequate mechanical ventilation. Therapy for respiratory acidosis should be directed toward the elimination of the underlying cause of alveolar hypoventilation. Ventilatory assistance should be provided when necessary. Respiratory acidosis is not an indication for bicarbonate therapy. Administration of sodium bicarbonate (NaHCO_3) will decrease $[\text{H}^+]$ and decrease ventilatory drive, thus worsening hypoxemia and hypercapnia. The underlying cause of hypercapnia in patients with chronic pulmonary disease cannot usually be removed, but appropriate treatment of the underlying disease should be attempted.

The principal causes of respiratory alkalosis are hypoxia, low cardiac output, severe anemia, pulmonary disease (stimulation of peripheral reflexes, e.g., pneumonia), hyperventilation mediated by the central nervous system (e.g., drugs, central nervous system inflammation or tumor, liver disease, fear, or pain), and overzealous mechanical ventilation. Hypocapnia itself is not a major threat to the well-being of patients with respiratory alkalosis. The arterial pH in chronic primary respiratory alkalosis is usually normal or slightly alkalemic owing to efficient renal compensation in this setting. Therapy for the underlying disease responsible for hypocapnia should be the primary focus in patients with respiratory alkalosis.

Increases in Alveolar-Arterial Oxygen Difference

The alveolar-arterial oxygen difference [P(A-a)O_2 gradient] may be useful in differentiating intrinsic pulmonary disease from extrapulmonary disease in animals with hypoxemia. The (A-a) gradient estimates the difference between the PO_2 in the alveoli (PAO_2) and the arterial blood (PaO_2). It can be calculated clinically as $(\text{A-a}) \text{ gradient} = (150 - 1.25 \cdot \text{PaCO}_2) - \text{PaO}_2$. In normal animals at sea level, the P(A-a)O_2 gradient should be less than 15 mm Hg, although values up to 25 mm Hg have been considered normal.

Hypoxia can be caused by hypoventilation, decreased partial pressure of inspired O_2 (PiO_2), diffusion impairment, ventilation-perfusion mismatch, and right-to-left shunts. The P(A-a)O_2 gradient will be normal in patients with either hypoventilation or decreased PiO_2 (e.g., residence at high altitude) because they still have normal lung function. Patients with hypoventilation have an increase in PCO_2 , whereas patients breathing air with a low PiO_2 have a below-normal PCO_2 (hyperventilating). In contrast, the P(A-a)O_2 gradient is increased in patients with diffusion impairment (rarely recognized in veterinary medicine), ventilation-perfusion mismatch, and right-to-left shunt. Administration of 100% oxygen will usually improve hypoxemia in patients with ventilation-perfusion mismatch, but not in patients with significant right-to-left shunt.

Table 7.10. Disorders in strong ion difference

Free-water abnormalities	
Increase in $[\text{Na}^+]$	→ Concentration alkalosis
Decrease in $[\text{Na}^+]$	→ Dilution acidosis
Chloride abnormalities	
Decrease in $[\text{Cl}^-]$ corrected	→ Hypochloremic alkalosis
Increase in $[\text{Cl}^-]$ corrected	→ Hyperchloremic acidosis
Unmeasured strong anion abnormalities	
Increase in $[\text{XA}^-]$	→ Organic acidosis

$[\text{XA}^-]$, unidentified strong anions.

Disorders in $[\text{A}_{\text{tot}}]$

Albumin and inorganic phosphate are nonvolatile weak acids and collectively are the major contributors to $[\text{A}_{\text{tot}}]$ (Fig. 7.5).²⁴ Consequently, changes in their concentrations will change $[\text{H}^+]$. Hypoalbuminemia will tend to decrease $[\text{A}_{\text{tot}}]$ and cause a non-respiratory alkalosis. Although rare, an increase in albumin concentration can cause nonrespiratory acidosis, owing to an increase in $[\text{A}_{\text{tot}}]$. Phosphate is the second most important component of $[\text{A}_{\text{tot}}]$ and is normally present in plasma at a low concentration. Severe hyperphosphatemia can cause a large increase in $[\text{A}_{\text{tot}}]$, which can result in nonrespiratory acidosis. The treatment for hyperphosphatemic acidosis, hyperalbuminemic acidosis, and hypoalbuminemic alkalosis should be directed at the underlying cause. The administration of sodium bicarbonate shifts phosphorus into cells and can be used as adjuvant therapy in patients with hyperphosphatemic acidosis.²⁵

Disorders in Strong Ion Difference

Changes in SID usually are recognized by changes in $[\text{HCO}_3^-]$ or BE.²⁶ A decrease in SID is associated with nonrespiratory acidosis, whereas an increase in SID is associated with nonrespiratory alkalosis. There are three general mechanisms by which SID can change (Table 7.10): (a) changing the free-water content of plasma, (b) changing the Cl^- concentration, and (c) increasing the concentration of unidentified strong anions (XA^-).

Free-Water Abnormalities

Changing the water content of the various body-fluid compartments will dilute or concentrate both strong anions and cations. Consequently, SID will change by the same proportion. Changes in free water can be identified by evaluating the $[\text{Na}^+]$. An increase in SID caused by increases in $[\text{Na}^+]$ results in concentration alkalosis, whereas a decrease in SID caused by decreases in $[\text{Na}^+]$ results in dilution acidosis. It has been suggested that changes in extracellular fluid (ECF) volume alone lead to acid-base disturbances. However, change in ECF volume by itself does not change SID, PCO_2 , or $[\text{A}_{\text{tot}}]$ and therefore cannot change acid-base status.⁴ The so-called contraction alkalosis believed to be caused by a decrease in ECF volume is in reality caused by a primary decrease in $[\text{Cl}^-]$.^{10,27} The principal causes of concentration alkalosis and dilution acidosis are listed in Table 7.11.

Table 7.11. Principal causes of free-water abnormalities

Concentration alkalosis ($\uparrow [\text{Na}^+]$)
Pure-water deficit
Primary hypodipsia
Diabetes Insipidus
Fever
Inadequate access to water
High environmental temperature
Hypotonic fluid loss
Vomiting
Peritonitis
Pancreatitis
Nonoliguric renal failure
Postobstructive diuresis
Sodium gain
Salt poisoning
Hypertonic fluid administration (e.g., hypertonic saline, sodium bicarbonate)
Hyperaldosteronism
Hyperadrenocorticism
Dilution acidosis ($\downarrow [\text{Na}^+]$)
Severe liver disease
Nephrotic syndrome
Advanced renal failure
Congestive heart failure
Psychogenic polydipsia
Excessive sweating in horses
Hypotonic fluid administration (e.g., 0.45% sodium chloride solution)
Vomiting
Diarrhea
Uroabdomen
Hypoadrenocorticism
Diuretic administration

Adapted from de Moraes and Muir.¹¹

Therapy for dilution acidosis and concentration alkalosis should be directed at treating the underlying cause responsible for changing $[\text{Na}^+]$. If necessary, $[\text{Na}^+]$ and osmolality should be corrected.¹ Nonrespiratory acidosis should be treated only in patients with more severe acidemia ($\text{pH} < 7.2$).

Isonatremic Chloride Abnormalities

If there is no change in the water content of plasma, plasma $[\text{Na}^+]$ will be normal. Other strong cations (e.g., K^+) are regulated for purposes other than acid-base balance, and their concentration never changes sufficiently to affect SID substantially.⁴ Consequently, SID changes only as a result of changes in strong anions when water content is normal. If $[\text{Na}^+]$ remains constant, changes in $[\text{Cl}^-]$ can substantially increase or decrease SID.^{21,22,28} Evaluation of $[\text{Cl}^-]$ must be considered in conjunction with measurement of $[\text{Na}^+]$ because $[\text{Cl}^-]$ can change for reasons other than a change in water balance.^{21,28} Patient $[\text{Cl}^-]$ is therefore “corrected” for changes in $[\text{Na}^+]$, applying a formula

developed for use in people and adapted for use in small and large animals:^{11,27,29}

$$[\text{Cl}^-] \text{ corrected} = [\text{Cl}^-] \times [\text{Na}^+] \text{ normal}/[\text{Na}^+] \quad (7.18)$$

where $[\text{Cl}^-]$ and $[\text{Na}^+]$ are the patient Cl^- and Na^+ concentrations. The normal $[\text{Na}^+]$ is the normal Na^+ concentration for the species being evaluated. Suggested values for $[\text{Na}^+]$ in dogs are 146 and 147 mEq/L, whereas for cats they range from 150 to 156 mEq/L.^{11,28} In large animals, normal $[\text{Na}^+]$ is approximately 136 mEq/L in horses and 144 mEq/L in cattle.²⁴ Normal $[\text{Cl}^-]$ is approximately 107 to 113 mEq/L for dogs, 117 to 123 mEq/L for cats, 97 to 103 mEq/L for horses, and 101 to 107 mEq/L for cattle.^{10,24,28} These values may vary for different laboratories and different analyzers. An increase or decrease in corrected $[\text{Cl}^-]$ indicates that Cl^- is responsible at least in part for the changes in SID. An increase in corrected $[\text{Cl}^-]$ (i.e., an increase in $[\text{Cl}^-]$ relative to $[\text{Na}^+]$) results in a hyperchloremic nonrespiratory acidosis, whereas a decrease in corrected $[\text{Cl}^-]$ (i.e., a decrease in $[\text{Cl}^-]$ relative to $[\text{Na}^+]$) results in hypochloremic nonrespiratory alkalosis. A $[\text{Cl}^-]$ corrected to normal in the presence of abnormal observed $[\text{Cl}^-]$ indicates that SID changes are caused by dilution acidosis or concentration alkalosis.

The principal causes of hyperchloremic acidosis and hypochloremic alkalosis are listed in Table 7.12. Treatment of hyperchloremic acidosis should be directed at correction of the underlying disease. Administration of NaHCO_3 , when needed, will tend to correct hyperchloremic acidosis because this solution has an SID greater than plasma.

Chloride-responsive hypochloremic alkalosis can be caused by excessive loss of Cl^- relative to Na^+ or by administration of substances containing more Na^+ than Cl^- compared with ECF (e.g., NaHCO_3). The former can occur following the administration of diuretics that cause Cl^- wasting (e.g., furosemide) or when the lost fluid has a low or negative SID, as in the case of vomiting of stomach contents. Chloride administration is essential in the treatment of chloride-responsive hypochloremic alkalosis. Renal Cl^- conservation is ordinarily enhanced in hypochloremic states and renal Cl^- reabsorption does not return to normal until plasma Cl^- concentration is restored to normal or near normal.²² In cases where expansion of extracellular volume is desired, intravenous infusion of 0.9% NaCl is the treatment of choice. This solution has an SID of 0 and will decrease plasma SID.⁴ If hypokalemia is present, KCl should be added to the fluid. When volume expansion is not necessary, Cl^- can be administered using salts without Na^+ (e.g., ammonium chloride, potassium chloride, calcium chloride, and magnesium chloride). These salts will correct the alkalosis because Cl^- is given together with cations that are regulated within narrow limits for purposes unrelated to acid-base balance.⁴ Chloride-resistant hypochloremic alkalosis can be caused in animals by hyperadrenocorticism and primary hyperaldosteronism. In these diseases, increased mineralocorticoid activity causes sodium retention and urinary chloride loss, both of which will increase SID. Because of the increased chloruresis, administration of chloride will not correct the metabolic alkalosis. Fortunately, metabolic alkalosis in these patients is usually very mild.

Table 7.12. Principal chloride disorders

Hypochloremic alkalosis ^a ($\downarrow [\text{Cl}^-]$ corrected)
Excessive loss of chloride relative to sodium
Vomiting of stomach contents
Gastric reflux in horses with ileus
Abomasum torsion (ruminants)
Vagal indigestion with internal vomiting (ruminants)
Therapy with thiazides or loop diuretics
Hyperadrenocorticism
Excessive gain of sodium relative to chloride
Sodium bicarbonate therapy
Hyperchloremic acidosis ^b ($\uparrow [\text{Cl}^-]$ corrected)
Excessive loss of sodium relative to chloride
Diarrhea
Excessive gain of chloride relative to sodium
Fluid therapy (e.g., 0.9% NaCl, KCl supplemental fluids)
Salt poisoning
Total parenteral nutrition
Ammonium chloride or potassium chloride therapy
Chloride retention
Renal failure
Renal tubular acidosis
Hypoadrenocorticism
Diabetes mellitus
Drug induced (e.g., acetazolamide, spironolactone)

^aChronic respiratory acidosis will cause a compensatory decrease in corrected $[\text{Cl}^-]$.

^bChronic respiratory alkalosis will cause a compensatory increase in corrected $[\text{Cl}^-]$.

Adapted from de Morais and Muir.¹¹

Isonatremic Organic Acid Abnormalities

Accumulation of metabolically produced organic anions (e.g., lactate, acetoacetate, citrate, or β -hydroxybutyrate) or addition of exogenous organic anions (e.g., salicylate, glycolate from ethylene glycol poisoning, and formate from methanol poisoning) will cause nonrespiratory acidosis because these strong anions decrease SID.²² Addition of some inorganic strong anions (e.g., SO_4^{2-} during renal failure) will resemble organic acidosis because these substances decrease SID without changing electrolytes.^{1,11} The most frequently encountered causes of organic acidosis are listed in Table 7.13.

Treatment of organic acidosis should be directed toward the primary disorder and stabilization of the patient.¹ Sodium bicarbonate should be used cautiously because metabolism of accumulated organic anions will normalize SID and increase $[\text{HCO}_3^-]$. The initial goal in patients with severe organic acidosis is to raise systemic pH to 7.2.

Estimation of Strong Anion Concentration

Organic acidosis increases the AG, whereas hyperchloremic acidosis does not. The AG is used clinically to estimate the concen-

Table 7.13. Principal disorders of the unidentified strong anions in organic acidosis ($\uparrow[XA^-]$)

Disorder	Strong Anions Decreasing Strong Ion Difference
Uremic acidosis	SO_4^{2-} and other anions of renal failure
Diabetic ketoacidosis, ketosis, pregnancy toxemia	Acetoacetate, β -hydroxybutyrate
Lactic acidosis	Lactate
Salicylate intoxication	Salicylate
Ethylene glycol toxicity	Glycolate
Methanol toxicity	Formate

$[XA^-]$, unidentified strong anions.

tration of “unmeasured anions” (UA^-). Unfortunately, UA^- includes the strong anions (XA^-) and weak (variable charges of albumin and phosphates) unmeasured anions. The AG is therefore influenced by the concentration of plasma proteins, and changes in albumin concentration significantly change AG.⁴ Hyperphosphatemia may also increase the AG. The AG will change secondarily to changes in PCO_2 , SID, or $[A_{tot}]$.³ Thus, changes in AG do not always reflect a stoichiometric change in UA^- even in the presence of organic acidosis. Two mathematical models have been developed for estimation of XA^- in humans.^{16,22,26} One of these models has been used in evaluating acid-base disorders in veterinary medicine.^{10,11,28} Both models, however, still need to be validated in domestic animals. The history (e.g., ingestion of ethylene glycol); the clinical condition (e.g., shock); increases in serum creatinine concentration, blood urea nitrogen, or serum glucose; and the presence of ketonuria may help in establishing a diagnosis of organic acidosis. The measurement of plasma lactate concentration may be attempted in patients with suspected lactic acidosis.

Evaluations of Acid-Base Balance

A stepwise approach should be followed in all animals with suspected acid-base disorders.^{1,29} After obtaining the samples, the first step is to determine the pH and the nature of the primary disorder from the blood-gas analysis results. The possibility of a mixed respiratory and nonrespiratory acid-base disorder should be assessed by calculating the expected compensation (Table 7.7). If a nonrespiratory acid-base disorder is present, it should be determined whether it is caused by a change in $[A_{tot}]$, SID, XA^- , or a combination of these factors. Unfortunately, evaluation of changes in SID caused by increases in $[XA^-]$ is not straightforward. An increase in $[XA^-]$ may be suspected in acidotic patients with diseases known to be associated with organic acidosis (e.g., renal failure and diabetic ketoacidosis). Measurement of lactate concentration enables one of the many XA^- to be quantified. When blood-gas results are not available, the bio-

Table 7.14. Simplified estimation of change in base excess associated with strong ion difference and $[A_{tot}]$

Free-water abnormalities: $0.3([Na^+] - 140) = \uparrow$
Chloride abnormalities: $102 - [Cl^-]_{corr} = \uparrow$
Protein abnormalities: $3(6.5 - [P_{tot}]) = \uparrow$
Unidentified anions make up the balance = \uparrow
Total is the observed (reported) base excess = \uparrow

$[Cl^-]_{corr} = [Cl^-]_{obs} \cdot 140/[Na^+]$.
For [Alb] instead of $[P_{tot}]$, use $3.7(4.5 - [Alb])$.

chemical profile may help in determining the nonrespiratory abnormalities present (Tables 7.8 and 7.14).^{12,29}

Two quantitative clinical approaches for assessment of nonrespiratory acid-base disturbances have been proposed, one based on the use of BE and the other based on a mathematical relationship to estimate SID. BE has been used to assess changes in the nonrespiratory component because *SID* is synonymous with *buffer base*. BE is a measurement of the deviation of buffer base (and therefore SID) from normal values. It should be pointed out, however, that Siggaard-Andersen studied blood, not plasma, and protein was not considered an acid-base variable. The BE has been used clinically for decades to assess the nonrespiratory acid-base status in humans.^{3,4} Formulas to estimate changes in BE due to changes in SID and $[A_{tot}]$ are presented in Table 7.14. These formulas are helpful in understanding complex acid-base disorders in domestic animals.^{11,24,29} In the 1990s, a new mathematical approach was developed to evaluate nonrespiratory acid-base disorders.¹⁵ The XA^- obtained by using this mathematical model is not constrained by the limitations mentioned earlier for the AG and UA^- . Despite being very promising for assessment of nonrespiratory acid-base disorders, this model and the BE model were developed by using protein behavior of human albumin. However, calculation of SID_{eff} in this model is not simple and may be clinically impractical.¹⁵

Body-Fluid and Electrolyte Composition

At birth, total body water is more than 75% of body weight. Maturation changes result in reductions of total body-water content to 60%–66% of adult body weight.^{1–5} Lower water content can be anticipated to exist in older or obese patients. Total body water is comprised of intracellular and extracellular compartments. The intracellular fluid volume increases slightly with age, and in mature animals it is equivalent to approximately 40% of body weight. The volume of the extracellular fluid compartment decreases with maturation and accounts for 20% of the weight of adult animals.² The extracellular fluid compartment is further divided into the interstitial, plasma or intravascular, and transcellular fluid compartments. The water volume in the interstitial compartment accounts for 15% of a mature animal's weight, whereas plasma water volume approximates 5%. Plasma consists of water, electrolytes, proteins, nutritive substances, and metabolites. Plasma water volume constitutes 5% of the body weight and approximately 50% of the total blood volume (Table 8.1). The transcellular fluid compartment consists of joint and cerebrospinal fluid (CSF) in addition to water located within the eye and pleural, peritoneal, and pericardial spaces and approximates 1.0% to 3.0% of body weight.

Constituents of the various fluid compartments are listed in Table 8.2. Chemical substances that dissociate in solution to form electrically charged particles or ions are *electrolytes*. Their concentrations in solution are generally expressed in millimoles per liter (mmol/L) or as milliequivalents per liter (mEq/L). Sodium is the most important extracellular cation, whereas chloride and bicarbonate are the primary extracellular anions. Together, these ions form more than 90% of the total solute within the extracel-

lular fluid compartment.^{6–8} Plasma proteins, which at a vascular pH of 7.4 have a net negative charge, play a key role in the maintenance of intravascular fluid volume. The primary intracellular ions are potassium, magnesium, and phosphate. Cytoplasmic proteins play a role in the maintenance of intracellular electric neutrality. Even though the cell membrane is freely permeable to sodium and potassium, the sodium-potassium pump maintains a concentration gradient for each cation across the cell membrane. Thus, sodium salts serve as an osmotic skeleton for the extracellular fluid volume while potassium salts serve the same function in the intracellular space. In addition to maintaining electric neutrality, ionic concentration differences on either side of the semipermeable cell membrane perform a key role in the normal physiological function of excitable cells.

Movement of body water throughout, and between, compartments occurs by *osmosis*, which is the process by which the net movement of water occurs due to concentration gradients across a semipermeable membrane. The pressure required to prevent water movement across semipermeable membranes is defined as the *osmotic pressure*, which depends on the number of nondiffusible, nondifferentiable particles such as ions or molecules in solution, and not their mass. To express the concentration of these particles in terms of their numbers, the unit called the *osmole* (osm) is used: 1 osm is equivalent to 1 g mol of nondiffusible and nonionizable substance. *Osmolality* is the osmolal concentration of a solution when the concentration is expressed in osmoles per kilogram (osm/kg) of water. In contrast, *osmolarity* is the concentration of a solution when expressed in osmoles per liter (osm/L) of water. Both terms are often used interchangeably in respect to discussions of fluid balance and therapy: 1 milliosmole (mOsm) per liter exerts an osmotic pressure of 19.3 mm Hg.

Total body water is determined by the number of osmotically active agents in both compartments.⁹ Water distribution across the intracellular and extracellular compartments depends on osmotic equilibrium between the two compartments. More than 80% of the osmolality of the extracellular fluid compartment is determined by sodium and its associated anions.¹⁰ As a result, sodium regulation plays a major role in extracellular fluid osmolality and extracellular fluid volume. The various cardiovascular, renal, and neurohormonal mechanisms that function in an integrated fashion to maintain and preserve sodium and water homeostasis are discussed elsewhere.^{11,12} Of the intracellular fluid compartment's osmolality, 50% is determined by potassium, whereas the remainder is exerted by other intracellular constituents. Disturbance in osmolality of either compartment results in

a rapid shift in water balance in order that equilibrium between the two compartments is reestablished. For example, increases in extracellular osmolality, owing to either pure water loss or the gain of osmotically active agents, result in water movement from the intracellular compartment into the extracellular fluid space until an osmotic equilibrium is reached. Plasma electrolyte and osmolality values for the various domestic species are listed in Table 8.3.

Within the extracellular fluid space, plasma water communicates directly with water in the interstitial space at the level of the capillary beds. The direction and magnitude of water movement between the interstitial and intravascular spaces are determined by the algebraic sum of hydrostatic and osmotic forces in each compartment as originally described by Starling.^{13,14} The capillary walls are freely permeable to sodium, chloride, and glucose. As a result, these substances are osmotically inactive across capillary membranes. However, plasma proteins are limited in their ability to cross capillary membranes. Blood or plasma volume ultimately is maintained by the colloid osmotic pressure or plasma oncotic pressure exerted by plasma proteins. Colloid osmotic pressure is approximately 23 mm Hg and results in a plasma osmolarity of 1.5 mOsm/L greater than that found in the interstitial or intracellular fluid spaces.⁷ Despite that, the net forces in the

capillary beds lead to a net filtration of a small amount of fluid into the interstitial space. This loss is balanced by fluid return to the intravascular space through the lymphatic system.^{9,13}

Alterations in volume or composition of either the extracellular or intracellular fluid compartments are readily assessed if a number of basic principles are followed. It is important to remember that the osmolalities of both compartments are at equilibrium except for a brief period (minutes) after a change in one of the compartments. Fluids are defined as isotonic, hypotonic, or hypertonic based on their effect on erythrocyte size or volume. *Isotonic solutions* exert no volume changes on erythrocytes, whereas *hypotonic solutions* increase erythrocyte size and *hypertonic solutions* decrease erythrocyte size. Administration of isotonic solutions to the intravascular space does not alter the osmolality of the extracellular fluid. As a result, there is no net osmotic effect, and only the volume of the extracellular fluid compartment is expanded. Parenteral administration of hypotonic solutions, however, reduces extracellular fluid osmolality and results in the osmotic movement of water into the intracellular compartment. Similarly, hypertonic solutions increase the osmolality of extracellular fluids, which causes a fluid shift out of the intracellular compartment.

Secondly, the number of osmotically active agents in either compartment remains constant unless one of the substances moves from one to the other compartment or is added or lost from either of the compartments. In this instance, sodium or potassium imbalances or acid-base or metabolic disorders can induce compositional changes that affect fluid balance between compartments.

Composition of Parenteral Solutions

Crystalloid Preparations

The term *crystalloid* refers to any solution of crystalline solids that are dissolved in water, such as sodium-based electrolyte solutions or solutions of dextrose in water. If the electrolyte composition of the prepared solution approximates that of the extracellular fluid, then the parenteral fluid is referred to as a *balanced electrolyte solution*. Multiple or balanced electrolyte solutions are formulated based on the concept that the amount of water and electrolytes that a patient retains depends on intact regulatory mechanisms in the body, not on the amount of water and electrolytes received. Commercial preparations are available as inexpensive sterile nonpyrogenic isotonic, hypotonic, or hypertonic solutions. The composition of each solution varies according to its intended purpose. Parenteral fluids provide water, electrolytes, and, in some instances, alkalinizing agents or a source of calories or both. Solutions that are polyelectrolytic have value in maintaining or replenishing electrolytes. Those preparations that contain lactate, acetate, or gluconate produce an alkalinizing effect when the anion is metabolized to carbon dioxide and water.

Maintenance Solutions

Daily water loss includes the insensible loss through evaporation from the respiratory system and skin, as well as sensible losses in which there is an associated obligatory loss of electrolytes. For

^aFactors used to convert SI units to conventional units are listed in Table 8.6.

many domestic species and birds, the daily maintenance water requirement ranges from 40 to 60 mL/kg/day, whereas, in calves, it ranges from 80 to 100 mL/kg/day.^{15–20} The daily requirement for nonlactating dairy cows and lactating cows has been estimated at 29 L/day and 56 L/day, respectively.²¹ The net daily loss of sodium in small animals ranges from 35 to 50 mmol/L (35 to 50 mEq/L), whereas daily potassium losses are 20 to 30 mmol/L (20 to 30 mEq/L).¹⁵

Maintenance solutions are designed to meet the water and electrolyte requirements of patients that are not taking in adequate amounts sufficient to meet their daily requirements. To meet these specific requirements, maintenance solutions have lower sodium and chloride concentrations and an increased potassium concentration when compared with extracellular fluid. If the concentration of potassium in the parenteral solution is less than 20 mmol/L (20 mEq/L), then the maintenance fluid may be supplemented with additional potassium.

Infusion rates up to 15 mL/kg/h are safe as long as the potassium concentration in the parenteral solution is less than 30 mmol/L (30 mEq/L).²² Hypotonic preparations, or solutions that contain dextrose, provide free water. Isotonic salt solutions provide osmolar water instead of free water. In the case of solutions containing dextrose, free water is not available to all body compartments until the dextrose has been metabolized. Maintenance fluids are generally administered over a 24-h period. These solutions should not be used in situations where large volumes are to be rapidly infused, because this could result in significant electrolyte abnormalities in the extracellular fluid.

Replacement Solutions

The composition of isotonic, balanced electrolyte solutions such as lactated Ringer's USP closely approximates the electrolyte composition of extracellular fluid. These solutions may be administered rapidly in large volumes to reexpand the extracellular fluid volume without inducing changes in its electrolytic composition. Since they are isotonic, their use does not induce fluid shifts between the intracellular and extracellular compartments. Balanced electrolyte solutions will rapidly equilibrate across the intravascular and interstitial fluid compartments. As a result, only 20% to 25% of the administered volume remains within the intravascular space after 1 h.¹⁰ This must be considered when using replacement fluids to replenish intravascular volume losses. To replace the vascular deficit, it is necessary to administer a volume equivalent to at least three- to fourfold the volume of blood lost.²³ Many of the preparations presently available contain lactate, acetate, or gluconate, which serve as alkalizing agents. Acid-base considerations in situations in which patients require acute care are discussed in Chapter 7.

Replacement solutions are often used as maintenance fluids. In this situation, normal renal function should be present to ensure that electrolytes in excess of daily requirements are eliminated. Long-term management of a patient's maintenance requirements with a replacement solution may cause hypokalemia. In this instance, replacement solutions should be supplemented with potassium chloride to provide a final potassium concentration of 20 mmol/L (20 mEq/L). Replacement fluids that have been supplemented with potassium chloride should not be used in clinical situations where large volumes may be rapidly infused.

Other Parenteral Solutions

Isotonic and Hypotonic Saline Isotonic saline, which is prepared as a 0.9% solution that contains 154 mmol/L (154 mEq/L) each of sodium and chloride ions and has an osmolarity of 308 mOsm/L, is often referred to as normal or physiological saline. However, only the sodium-ion concentration of the preparation matches that of extracellular fluid. The use of 0.9% sodium chloride solutions has been advocated for maintenance and replacement purposes. Isotonic saline does not meet the patient's free-water and electrolyte needs for maintenance purposes. It may be used for rapid expansion of the extracellular fluid volume despite the possibility of inducing a hyperchloremic acidosis in patients.^{24–26} Similar to other crystalloid solutions, intravenously administered saline solutions rapidly distribute throughout the extracellular fluid space. However, their composition does not match that of extracellular fluid, and excessive use of isotonic saline for replacement purposes could lead to the unnecessary dilution of other extracellular electrolytes and buffers. Isotonic saline may also be used to correct hyponatremia or a metabolic alkalemia.

Hypotonic saline solutions are available in a number of strengths. Commercial preparations of 0.45% saline are hypotonic (osmolarity, 154 mOsm/L) and may be used as a hydrating solution. Hypotonic saline preparations may be used for maintenance purposes, particularly when they are supplemented with dextrose, potassium chloride, or both. When 2.5% dextrose is added to 0.45% saline, the resultant solution is isotonic. Upon metabolism of the dextrose, free water is made available for distribution across all fluid compartments.

Hypertonic Saline Traditionally, solutions of 3% and 5% saline have been used to treat patients who have severe hyponatremia where rapid sodium replacement is considered necessary. More recently, hypertonic saline solutions have been used successfully to manage severe shock, particularly hemorrhagic shock.^{27–33} In situations in which a patient is moribund or critically ill, the infusion of small volumes of hypertonic saline enables the clinician to obtain the time required to institute other lifesaving measures. Hypertonic saline solutions of 7.5% have been used for this purpose. The osmolarity of 7.5% saline is 2400 mOsm/L. To prepare 7.5% saline, it is necessary to purchase 5% saline in 500-mL bags and 23.4% saline in 30-mL bottles (American Reagent Labs, Shirley, NY; Lyphomed Canada, Markham, Canada). Remove 120 mL of 5% saline from the 500-mL bag and inject 60 mL of the 23.4% saline solution into the bag to make a 7.5% solution.²⁷

The mechanisms by which hypertonic saline exerts its physiological effects are still subject to some debate.^{33–38} Overall changes attributed to hypertonic saline in the past included improved cardiac output and aortic blood pressure, reduced peripheral vascular resistance, an increase in plasma volume with hemodilution, and an increase in interstitial fluid volumes. These overall improvements in cardiovascular function and tissue perfusion were attributed to the direct and indirect effects of the infused hypertonic saline solution.^{16,30,31,35,36,39–41} It had also been postulated that the sodium administered in the hypertonic solution stimulates pulmonary osmoreceptors or chemoreceptors,

thus activating a pulmonary vagal reflex. However, it has been pointed out that pulmonary reflexes have not been induced by using hypertonic saline in any species other than dogs anesthetized with pentobarbital.³³ Selective activation of sympathetic pathways was also thought to occur, resulting in vasoconstriction of capacitance vessels, leading to improved cardiac filling along with selective precapillary vasoconstriction in skin and muscle, thus redistributing blood volume within the vascular space.³⁶

It is now apparent that hypertonic saline exerts its beneficial effects through plasma volume expansion coupled with a transient decrease in afterload. Vasodilation occurs in some vascular beds because of the direct hyperosmotic effect of the solution. This reduces total peripheral resistance and enhances perfusion of vital organs.^{30,36,39} Upon administration, hypertonic saline equilibrates rapidly throughout the extracellular fluid space. Because of the increase in extracellular fluid osmolality caused by the hypertonic solution, water moves out of the intracellular fluid compartment. As a result, the extracellular fluid compartment volume is expanded. Solutions of 7.5% saline, when infused intravenously into dogs, have been demonstrated to increase plasma volume 2 to 4 mL for 1 mL of solution administered.³⁰ The maximum vascular volume expansion occurs within 30 min of the administration of the hypertonic saline solution. These fluid shifts produce an intracellular water debt and an eventual decrease in total body water because of the obligatory water loss associated with natriuresis.^{35,42}

The intravenous administration of 4 to 8 mL/kg in dogs or 1 to 4 mL/kg in cats of 7.5% saline over 3 to 5 min results in a rapid restoration of hemodynamic parameters with subsequent improvements in tissue perfusion.^{15,28,34,43,44} It has been suggested that in dogs an infusion rate of 2 mL/kg/min be used to reduce the possibility of inducing acute hypotension.³⁹ In conscious horses, 5 mL/kg of 7.5% saline was infused at rates of 80 mL/min with no adverse effects noted.⁴⁵ In ruminants, it has been suggested that the rate of administration of 4 to 5 mL/kg of hypertonic saline not exceed 1 mL/kg/min.^{33,46} Since relatively small volumes are infused, clinicians need not worry about fluid overload or the development of interstitial edema in patients. However, hypertonic saline solutions should not be used in situations where cardiac dysrhythmias exist, if hemorrhage is not controlled, or if a patient is hypernatremic, has coagulation disorders, or is significantly dehydrated.^{27,40,47}

The hemodynamic effects of 7.5% hypertonic saline are not sustained.^{28,30,40–42,48} The duration of effect in cats was found to be approximately 60 min in one study, whereas another study found improved hemodynamic function over a period of 180 min.⁴⁹ This concern has led to a number of studies that have demonstrated the feasibility of prolonging the beneficial effects of hypertonic saline by adding hyperoncotic preparations such as dextran 70 to the mixture.^{35,41,42,50–56} Regardless of the eventual outcome of these and similar studies, it is advisable to use hypertonic saline solutions in the initial resuscitative management of moribund patients and to follow this initial treatment with more traditional therapeutic measures. When hypertonic saline is administered over a prolonged period, serum sodium and osmolality should be monitored.

Dextrose Solutions These are commercially available in a wide range of concentrations ranging from 2.5% to 50% dextrose in water; 5% dextrose in water contains 50 g of dextrose monohydrate per 1 L of water and exerts an osmolarity of 252 mOsm/L. Dextrose solutions provide a source of free water for total body distribution once the carbohydrate is metabolized. An additional 0.6 mL of water is made available for each gram of dextrose that is metabolized. The volume of water administered eventually distributes across all fluid compartments, so dextrose solutions are not effective for use as plasma volume expanders. However, they are effective in replenishing primary total body-water deficits (e.g., dehydration).

The 5% dextrose solutions contain 171 calories per liter, which does not meet the energy requirements of domestic animal species. Hypertonic dextrose solutions are generally used for caloric supplementation of parenteral maintenance fluids.⁵⁷ Long-term infusions of 5% dextrose or the infusion of hypertonic dextrose solutions may cause thrombophlebitis. Care should be taken to ensure that the hypertonic preparations in particular are infused via the caudal or cranial vena cava.⁵⁷ The administration rate of dextrose solutions should be less than 0.5 g/kg/h so as not to induce glucosuria.²²

Alkalinizing Agents

Sodium Bicarbonate This solution is a hypertonic (1500 mOsm/L) preparation of sodium bicarbonate (NaHCO_3) in sterile water for injection. Solutions contain 5.0%, 7.5%, or 8.4% sodium bicarbonate in 50-mL ampules or vials and 500-mL bottles. The solution is administered intravenously, either in another parenteral solution or undiluted in emergencies. An isotonic solution results when a 50-mL vial of 7.5% sodium bicarbonate is added to 200 mL of sterile water for injection; with a 50-mL vial of 8.4% solution, 224 mL of sterile water is required. Alternatively, three 50-mL ampules of 8.4% solution may be added to 1 L of 5% dextrose.

Sodium bicarbonate is indicated in the treatment of metabolic acidosis. It is also indicated in barbiturate intoxication in order to facilitate dissociation of barbiturate-protein complex. Overcorrection of the bicarbonate deficit produces metabolic alkalosis with a rise in blood pH. From a clinical standpoint, alkalosis is seldom encountered. However, administration of sodium bicarbonate is generally contraindicated in patients losing chloride through vomiting or in those with hypokalemia. Sodium bicarbonate administration produces sodium retention and should be used with caution in patients with congestive heart failure or other conditions causing edema. Doses of up to 2 mEq/kg in cats induce minimal changes in the electrolyte status of the animal. Sodium bicarbonate doses in excess of 4 mEq/kg can induce hyperosmolality, hypernatremia and hypokalemia.⁵⁸

The dose of sodium bicarbonate is determined by the base deficit of blood and the clinical symptoms of the patient. Quantitative estimation of the bicarbonate dose may be calculated from this formula:

$$\text{base deficit} \times 0.3 \times \text{body weight (kg)} = \text{mEq of NaHCO}_3$$

The factor $0.3 \times$ body weight is an approximation of the acute volume of distribution of infused HCO_3^- and approximates the

volume of the extracellular fluid compartment. Distribution to interstitial fluid requires approximately 30 min to be 98% complete. Although the factor 0.6 has been used in the formula, the use of $0.6 \times$ body weight assumes that the volume of HCO_3^- distribution is total body water. About 18 h are required for complete distribution. When the 0.6 factor is used, the dose of HCO_3^- may be too high and, if given, must be administered slowly. The amount of HCO_3^- needed to correct the base deficit in metabolic acidosis varies widely depending on the cause of the acidosis and variations in distribution of HCO_3^- into intracellular spaces. Overtreatment should be avoided. Acid-base measurements should be made frequently, because changes with anesthesia and disease processes are dynamic. Usually half the calculated dose is administered, and a second base-deficit determination made. Should alkalosis result from sodium bicarbonate administration, the use of bicarbonate should be discontinued, and the patient should be treated according to the degree of alkalosis. Sodium chloride injection (0.9%) intravenously is usually sufficient to correct plasma chloride. If the alkalosis is severe enough to be accompanied by hyperirritability or tetany, ammonium chloride (NH_4Cl) may be given intravenously as a 1:6 molar solution (167 mEq/L). Calcium gluconate may also be useful in controlling tetany.

To correct for the acidity inherent in acid citrate dextrose (ACD)-preserved blood, the contents of 1 ampule added to 250 mL of sterile water for injection may be given for every 4 units (1600 mL) of blood administered.

Intravenous sodium bicarbonate administration leads to increased CO_2 levels in blood and CSF. Because plasma HCO_3^- enters the CSF slowly, a paradoxical acidosis in the brain may result. General depression of the central nervous system, including the medullary centers, may develop, reducing respiratory drive. Patients thus must be ventilated adequately to prevent these adverse side effects. When given in large quantities, sodium bicarbonate has been shown to cause hyperosmolality of blood. Experimental and clinical observations indicate that increases in plasma osmolality to levels exceeding 350 mOsm are potentially fatal. Detrimental effects of alkalemia include an increase in the affinity of hemoglobin for oxygen with an unfavorable effect on oxygen release. Routine measurement of plasma osmolality, in addition to acid-base determinations, is recommended prior to administration of additional doses of an alkalinizing agent. Another detrimental effect associated with the use of sodium bicarbonate is prolongation of thrombin clotting and prothrombin times.

Tromethamine Tromethamine (THAM) is a slightly hypertonic (380 mOsm/L) 0.3 M solution with the pH adjusted to 8.6 with acetic acid. This organic amine buffer is used for correction of severe systemic respiratory or metabolic acidosis, such as that which occurs during shock, cardiac arrest, or massive transfusions of ACD-preserved blood.⁵⁹ Given intravenously, it acts as an amine proton acceptor, attracting hydrogen ions to form salts that are then excreted by the kidneys. The buffering capacity of THAM is equivalent to that of sodium bicarbonate, yet it does not cause hypernatremia or hypercapnia.^{59,60}

THAM also acts as an osmotic diuretic, increasing urine flow, urine pH, and excretion of electrolytes, fixed acids, and carbon dioxide. Approximately 30% of THAM at a pH of 7.4 is not ionized. As a result, THAM is an effective intracellular and extracellular buffer.⁶¹

The intravenous dose may be estimated from the buffer base deficit:

$$\text{THAM (mL, of 0.3 M) required} = \text{body weight (kg)} \times \text{base deficit (mEq/L)} \times 1.1$$

In treatment of cardiac arrest, THAM should be given at the same time that other standard resuscitative measures, including cardiac massage, are being applied. Intravenous doses of 3.5 to 6 mL/kg have been administered in these circumstances. Additional amounts may be required to control the systemic acidosis that persists after the cardiac arrest is reversed. The intravenous lethal dose of THAM in dogs is 500 mg/kg when given at 50 mg/kg/min.

The use of THAM is contraindicated in patients with anuria or uremia. Large doses may depress respiration, owing to pH change and CO₂ reduction with subsequent increase in blood lactate. Rapid infusion may produce electrocardiogram (ECG) changes similar to those of hyperkalemia. Hypoglycemia may also occur. For these reasons, blood pH, PCO₂, bicarbonate, glucose, and electrolyte levels should be determined during administration of large quantities of this drug. Although significant clinical coagulation abnormalities do not appear to be a problem when THAM is used in dogs with normal coagulation indices, care should be taken as coagulation time is increased.

Colloid Preparations

Colloids are a suspension of large molecular weight particles. If the average molecular weight of the particles in solutions exceeds 50,000, they will tend to remain within the vascular compartment. This increases intravascular colloid osmotic pressure, which not only limits further water movement out of the intravascular space but may also cause water movement from the interstitial space to the intravascular space. Colloid preparations are thus effective when used to expand vascular volume. To ensure that an effective vascular volume is maintained, colloids are also used in acute hypoproteinemic states where plasma albumin levels are less than 15 g/L (1.5 g/dL) or total serum protein levels are less than 35 g/L (3.5 g/dL). Natural colloids include plasma, albumin preparations, and whole blood. Artificial colloids include dextran, gelatin, and hydroxyethyl starch preparations. The effectiveness of the artificial colloids is determined by their physiochemical characteristics, such as average molecular weight, colloid content, and biodegradability. Artificial colloids exert a vascular effect similar to that of plasma. When using artificial colloids, the clinician's therapeutic goal is to maintain plasma oncotic pressure above 17 mm Hg.¹⁰ They are more expensive than plasma, but under certain circumstances, such as during intraoperative procedures in large animals, they may be more readily available.

Plasma

Plasma proteins play a predominant role in establishing plasma oncotic pressure, which is ultimately responsible for maintaining

vascular volume at the level of the capillary beds. The albumin fraction of total serum protein ranges from 35% to 50% (Table 8.3), and albumin accounts for 75% of the plasma oncotic pressure exerted by plasma proteins. Reductions in serum albumin levels to 15 g/L (1.5 g/dL), or total serum protein levels to 35 g/L (3.5 g/dL) or lower, result in a net water loss from the vascular compartment to the interstitial space. If untreated, vascular volume diminishes and interstitial edema occurs.

Plasma is harvested from whole blood and either used as fresh plasma for the treatment of coagulopathies or stored at -70°C as fresh-frozen plasma.⁶² There is evidence to suggest that canine plasma may be stored for up to 30 days at 2°C with no significant effect on hemostatic parameters.⁶³ Each gram of albumin will retain approximately 17 to 18 mL of water within the vascular space. In the perioperative period, plasma is used to treat vascular volume deficits or hypoproteinemia. Plasma must be gradually warmed to 37°C prior to being administered. Plasma should not be thawed using temperatures higher than 37°C. A blood administration set with an in-line 18-micron micropore filter should be used when plasma is to be infused. It has been recommended that, for dogs, the recipient should receive 28 to 33 mL/kg of plasma to administer 1 g/kg of albumin when the protein concentration of plasma of the donor is 30 to 35 g/L (3.5 g/dL).⁶² Alternatively, one may estimate the amount of donor plasma required:⁶⁴

$$\text{amount donor plasma required (mL)} = \left[\frac{\text{desired TP} - \text{actual TP}}{\text{donor plasma TP}} \right] \times \text{Recipient Plasma Volume (mL)}$$

Care should be taken to ensure that there are no allergic reactions to the transfusion or that the patient is not volume overloaded.

Whole Blood

Patients who are severely anemic or who have had a significant decrease in their packed cell volume (PCV) from normal (Table 8.3) are candidates for whole blood transfusion or the administration of packed red cells if plasma protein levels are within normal limits. In the perioperative period, acute blood loss exceeding 10% to 15% of the patient's blood volume should be replaced with whole blood. Chronic reductions in hematocrit to 15% in healthy nonexercising animals does not necessarily result in clinical signs of oxygen debt. However, when one considers the cardiopulmonary effects of most anesthetic agents, it is advisable to maintain a hematocrit of at least 21% to 25% or a hemoglobin concentration of at least 70 g/L (7 g/dL) in surgical patients.^{64,65} This helps ensure that adequate oxygen is delivered to the peripheral tissues in the perioperative period.^{66,67}

Whole blood is collected from donors in an anticoagulant such as ACD, citrate phosphate dextrose (CPD), citrate phosphate dextrose adenine (CPDA-1), sodium citrate, or heparin. Once collected, plasma may be harvested and stored separately, if desired. Whole blood and packed red cells are stored at 1° to 6°C.^{68,69} Details regarding the collection and storage of whole blood or blood components may be obtained elsewhere.^{68,69}

The duration of storage that is considered acceptable in terms of red cell viability depends on the anticoagulant used and the use of appropriate storage procedures.⁷⁰ Transfused red cell viability of previously stored blood should exceed 70% at 24 h after the transfusion. Nonviable transfused red cells are removed from the circulation within 24 h. Whole blood or packed cells that are properly stored in ACD may be used for up to 21 days after collection, whereas CPD and CPDA-1 maintain adequate red cell viability for up to 4 weeks.⁶⁸ Storage of red blood cells dramatically reduces DPG (2,3-diphosphoglycerate), which shifts the oxygen hemoglobin dissociation curve to the left in dogs.⁷⁰ In cats, the release of oxygen is independent of DPG.⁷¹ Left shifts of the oxygen hemoglobin dissociation curve decrease oxygen availability to peripheral tissues. In humans, DPG returns to 50% of normal levels within 24 h of transfusion. If oxygen delivery to peripheral tissues is of significant concern in the perioperative period, then the use of freshly collected blood or blood that has been stored for a minimum period in CPD or CPDA-1 should be considered.

The number and type of clinically significant blood groups with respect to transfusion reactions vary among the domestic animal species (Table 8.4). Normal red blood cell viability or circulation half-life also varies significantly among the various species (Table 8.5). Where possible, all donors should be typed and all potential transfusion recipients should be typed and cross-matched with the donor.^{62,68,69,72} Canine blood donors should be at least dog erythrocyte antigen 1.1 and 1.2 negative.⁶⁸ In cats, there are significant variations among breeds as to the predominant blood group, and naturally occurring isoagglutinins exist.^{68,72–74} As a result, it is recommended that all feline donors and recipients be typed, donors of each blood group be available, and a crossmatch be performed on the first transfusion.

If donors are not typed, then fresh blood collected from the donor and recipient should be crossmatched. This enables the clinician to determine whether the recipient has been previously sensitized or has naturally occurring isoantibodies to the donor's red blood cells. A minor crossmatch would indicate whether the donor has antibodies against the recipient's red blood cells. It should be noted that the crossmatch tests only for isoagglutinins. In cattle and horses, isohemolysins play a major role in transfusion reactions.^{69,75,76} As a result, the crossmatch in these species may not provide an adequate indication of the potential for a transfusion reaction, so alternative tests may be necessary.

Whole blood and packed red cells, like plasma, must be slowly rewarmed to 37°C prior to being transfused into the patient. Temperatures higher than 37°C should not be used to rewarm whole blood or blood products. Packed red cells may be diluted with 0.9% saline to facilitate the transfusion process by reducing the viscosity of the suspension. Under no circumstances should rewarmed whole blood, or red cells, be re-refrigerated if unused. Intravenous administration sets used for transfusion purposes should contain in-line filters with a pore size of 80 microns so that cellular debris and blood clots are not transfused into the patient. In cats, where blood is often collected into a syringe, syringe filters (Hemo-nate; Gesco International, San Antonio, TX) may be used to accomplish the same purpose. All blood transfu-

Canine	110–120
Caprine	125
Equine	140–150
Feline	75–80
Ovine	64–94
Porcine	75–95

sions should be administered through a separate intravenous access, and other therapeutic agents should not be administered to the patient via the blood administration set.

The volume of blood to be administered may be set empirically at 10 to 40 mL/kg in dogs and 5 to 20 mL/kg in cats or calculated.⁷⁷ In species where the blood volume approximates 7% of total body weight, the following formulas may be used to calculate the required volume of whole blood or packed red cells for transfusion purposes. If the hematocrit of the donor's blood is 40%, then administration of 1.75 mL/kg will raise the recipient's hematocrit by 1%. Similarly, if the hematocrit of the packed cell solution is 70%, then administration of 1.0 mL/kg will raise the recipient's hematocrit by 1%.⁷⁸ Alternatively, in small animals, the following formulas may be used:^{62,79}

For cats,

$$\text{mL blood required} = \text{BW}_{\text{kg}} \times 70 \left[\frac{\text{desired PCV} - \text{patient PCV}}{\text{donor PCV}} \right]$$

For dogs,

$$\text{mL blood required} = \text{BW}_{\text{kg}} \times 90 \left[\frac{\text{desired PCV} - \text{patient PCV}}{\text{donor PCV}} \right]$$

Whole blood, or suspensions of packed red cells, may be administered at rates of 5 to 10 mL/kg/h. In critical situations, where rapid restoration of blood volume is of concern, adminis-

tration rates of 22 mL/kg/h in dogs and 40 mL/kg/h in cats may be used.⁶⁹ Rates of 10 to 40 mL/kg/h in cattle and 20 to 30 mL/kg/h in horses have been suggested.^{69,80} Transfusions are best completed within 4 h to avoid bacterial contamination and functional loss of blood components. If more than 50 mL/kg of blood is administered, then consideration should be given to the administration of calcium chloride or gluconate to counteract the effects of the anticoagulant.⁶⁴

Patients must be continuously monitored for clinical signs that suggest an acute adverse reaction to the transfusion. Adverse reactions may be caused by prior bacterial contamination of the donor's blood, allergic or immunologic reactions to the transfusion itself, circulatory overload, or citrate-induced hypocalcemia.⁸¹ The nature of the observed clinical signs of acute transfusion reaction varies. In some species, hemolysis as opposed to agglutination occurs. Clinical signs may include tachycardia, dysrhythmias, hypotension, tachypnea, dyspnea, tremors, emesis, wheals, urticaria, transient fever, hemolysis, hemoglobinemias, and hemoglobinuria.^{64,69,72,79,81} It is important to remember that a number of these clinical signs may not occur in anesthetized patients. Therefore, any unexpected changes in the clinical status of an anesthetized patient that is receiving a transfusion must be critically evaluated. If a transfusion reaction is suspected, then the transfusion must be terminated and supportive therapy instituted.^{81,82} Sepsis, circulatory overload, and hypocalcemia are detected by careful monitoring of anesthetized patients and treated accordingly.

Dextran Solutions

Dextrans are low to average molecular weight polysaccharides that are produced as a result of bacterial enzymatic action on sucrose. Dextran 40 is a low molecular weight polysaccharide with an average molecular weight of 40,000 and a molecular weight range of 10,000 to 70,000. Dextran 70 and dextran 75, respectively, consist of glucose polymers with an average molecular weight of 70,000 and 75,000. Both preparations have a molecular weight range of 20,000 to 200,000, and as a result their clinical effects are similar. Polymers with a molecular weight less than 50,000 are eliminated from the circulation by glomerular filtration and renal excretion. Polysaccharides with a molecular weight greater than 50,000 are eventually stored in the reticuloendothelial system and subsequently metabolized.

Dextran solutions are used for plasma volume expansion when hematogenous products are not available. They are not a substitute for whole blood and possess no oxygen-carrying capacity. Therefore, to ensure that a patient's hematocrit is not reduced to critical levels, care should be exercised when dextran is used in the treatment of severe hemorrhage. Dextran may be used in situations where hypoproteinemia has been induced by the infusion of a large volume of a crystalloid solution and plasma is not available.

Dextran 70 and 75 are slightly hyperoncotic when compared with plasma, and they induce a water shift of approximately 20 to 25 mL/g from the interstitial fluid space into the vascular system. Dextran 70 and 75 increase the plasma volume by an amount that is slightly greater than the colloidal volume admin-

istered. The maximum increase in plasma volume occurs within 1 h of the termination of the infusion and lasts for up to 6 h. The duration of effect depends on the volume infused and rate of clearance from the vascular system.

Dextran 40 is used for vascular volume expansion. The 10% solution is significantly hyperoncotic when compared with plasma, so dextran 40 should be administered with an equal volume of a crystalloid solution to minimize fluid shifts from the interstitial space. The improvement in vascular volume that results from the administration of dextran 40 is equivalent to twice that of the volume infused. The peak volume effect occurs quickly but is brief, lasting only 2 to 3 h. Of the administered dose of dextran 40, 50% is excreted within 3 h, and 75% is excreted within 24 h. Low molecular weight dextran has been advocated for the treatment of impaired microcirculation or capillary sludging during low-flow states induced by hypovolemia or shock. The capability of dextran 40 to enhance blood flow in the microcirculation is attributed to (a) volume expansion and subsequent hemodilution, (b) maintenance of red cell electronegativity, (c) coating of red blood cells and platelets, (d) decreased blood fibrinogen levels, (e) subsequent reductions in blood viscosity, and (f) an increased suspension stability of blood. Dextran 40 has been associated with renal dysfunction, so the use of dextran 70 is preferable for volume expansion.

The primary concerns with respect to the use of dextran solutions relate to the potential for allergic reactions or interference with the normal hemostatic mechanisms of blood. The recommended dose for dextran 40, 70, or 75 is 10 to 20 mL/kg/day in dogs and 5 to 10 mL/kg/day in cats to reduce the possibility of adverse reactions. Infusion rates of 5 mL/kg/h may be used in noncritical situations. Administration rates of up to 20 mL/kg/h have been recommended in situations where the vascular volume must be quickly restored.⁸³ This rate of infusion induced minimal hemostatic abnormalities in clinically normal animals, but bleeding may be precipitated in dogs with deficiencies in hemostatic function.⁸³

Hydroxyethyl Starch

Hydroxyethyl starch is a synthetic polymer that is synthesized from a waxy starch composed primarily of amylopectin. Hydroxyethyl ether groups are introduced into the glucose units of the starch compound to retard degradation of the compound by serum amylase. *Hetastarch*, a commercially available preparation, is a sterile, nonpyrogenic solution of 6% hetastarch in 0.9% saline. The oncotic pressure of hetastarch is 30 mm Hg, and its osmolarity is 310 mOsm/L. The number average molecular weight of hetastarch is 70,000, and the molecular weight of the polymers ranges from 10,000 to 1,000,000. The smaller particles are eliminated through glomerular filtration and renal excretion. Approximately 40% is excreted in urine within 24 h in patients with normal renal function.⁸⁴ The larger molecules are slowly degraded by serum amylase until they are small enough to be excreted or taken up into the reticuloendothelial system. This results in a sustained ability of hetastarch to maintain vascular volume expansion as compared with dextran preparations.

Hetastarch may be used for the same purposes as dextran so-

lutions. The colloidal properties of hetastarch are similar to that of albumin. One gram of hetastarch causes a fluid shift into the vascular space of approximately 14 mL of water from the interstitial space.⁸⁴ The infusion of hetastarch expands plasma volume only slightly in excess of the volume infused. The volume expansion lasts less than 12 h in dogs and up to 24 h in horses.^{85,86} As a result, multiple doses may be required in patients with ongoing protein losses. Hetastarch should not be used in normovolemic patients because of the potential for volume overload. Other complications associated with the infusion of hetastarch solutions include anaphylactoid reactions and coagulopathies.^{15,84} A dose of 10 mL to 20 mL/kg/day of 6% hetastarch has been recommended for administration to dogs and 5 to 10 mL/kg/day in cats.^{15,87} Rudloff and Kirby have recommended specific infusion rates based on the underlying disease process being treated.⁴⁴ Rapid infusion of hetastarch in cats may induce moderate reactions such as nausea and vomiting.⁸⁸

Pentastarch is an isotonic, hyperoncotic solution of 10% pentastarch in 0.9% saline, with an osmolarity of 326 mOsm/L. The number average molecular weight of pentastarch is 35,000. Like hetastarch, pentastarch is indicated for plasma volume expansion when fresh-frozen plasma is not available. The infusion of 500 mL of pentastarch will expand the plasma volume by 700 mL. Pentastarch is more rapidly eliminated than is hetastarch and is less likely to cause coagulopathies. Based on clinical requirements, doses of 10 to 25 mL/kg/day in dogs and 5 to 10 mL/kg/day in cats for up to 3 days has been suggested.⁸⁷

Considerations for Fluid Therapy

Perioperative recognition and management of fluid and electrolyte disturbances are important components of the anesthetic management of surgical patients. Patients that are presented for anesthesia and surgical or diagnostic procedures vary in size, age, metabolic requirements, and physical condition, in addition to the nature of the ongoing disease process. Anesthesiologists must consider each patient's current fluid and electrolyte status in addition to changes that are anticipated to occur during the immediate perioperative period.

In all but the most critical emergencies, clinically significant fluid and electrolyte imbalances in patients should be identified, assessed, and corrected prior to the induction of anesthesia. Many anesthetic protocols require that patients be kept off food and water for varying time lengths in the preoperative period. The use of non per os (NPO) orders causes varying degrees of total body-water deficits, which should be taken into account by the anesthesiologist during the anesthetic procedure. Furthermore, anesthetic agents and many surgical procedures have a significant effect on the cardiovascular stability of patients. There is a net loss of vascular volume during the surgical procedure because of hemorrhage, redistribution, and sequestration of fluids into traumatized tissues at the surgical site. Increased water loss owing to evaporation from the surgical site as well as the respiratory system also becomes important in surgical patients. Postoperatively, fluid and electrolyte imbalances may continue to occur, requiring that the patient be continuously assessed and treated.

Preoperative Considerations

A thorough history should be obtained from the owner. This should provide the clinician with information relating to the type, volume, and duration of fluid losses that have been experienced by the patient. This information, in conjunction with a detailed physical examination, should enable the clinician to estimate the degree of dehydration and the type of electrolyte disturbance that might exist. The degree of dehydration can be estimated by assessing the patient's skin turgor and correlating that information with the other clinical findings. Age of the animal, its nutritional status, and individual variations make skin turgor difficult to assess. In small animals, skin turgor is tested by pinching a skinfold over the torso and twisting it while the animal is in lateral recumbency. Skin turgor is tested in large animals by pinching and twisting the skin of the upper eyelid or the neck. Skin turgor can also be used to determine the hydration status of avian patients.⁸⁹ Total body-water deficits in liters are calculated in terms of percentage of body weight measured in kilograms. A patient that is estimated to be 10% dehydrated has lost a volume of water in liters equivalent to 10% of the animal's weight.

Patients with a history of water loss but that have no obvious clinical signs associated with dehydration are generally assumed to be less than 5% dehydrated. Clinical signs do occur in neonatal calves that are 4% dehydrated.⁹⁰ The skin tent persists for less than 2 s in these animals. An animal is assumed to be 6% to 8% dehydrated if, on clinical examination, the eyes are mildly sunken in their orbits, the mucous membranes are sticky to dry, and the skin tent persists for more than 3 s. Clinical signs are very pronounced when an animal is 10% to 12% dehydrated. The eyes will be deeply sunken into the orbits, with as much as a 2- to 4-mm gap between the eyeball and bony orbit. The mucous membranes are dry and possibly cold to the touch. The skin tent and twist will persist indefinitely. Animals that are dehydrated more than 15% are generally moribund.

The initial clinical assessment is confirmed by collecting baseline samples from the patient for laboratory analysis. These data confirm the diagnosis and provide a reference point for subsequent therapeutic measures. The information also ensures that the clinician can later assess the patient's response to therapy. Analysis of whole blood, plasma, and serum samples enables the clinician to determine hematologic values, plasma osmolality, serum electrolyte concentrations, and serum glucose, urea, or creatinine values. The measured parameters are then evaluated in relation to the patient's current condition and to expected normal values of each (Table 8.3). Table 8.6 lists the conversion factors required to convert from SI to conventional units. Although serial measurements of body weight have been recommended as aids in determining a patient's response to therapy, these data should be interpreted with care.^{90,91}

Hematocrit and total protein values are commonly used to determine the degree of hemoconcentration or hemodilution in patients. Normally, hematocrit values vary widely in some species, whereas, in others, the spleen plays a major role in altering PCV.^{33,92} The hematocrit should not be permitted to decrease below 21% to 25% in anesthesia candidates. Normovolemic reductions in PCV to 25% in dogs result in optimal delivery of oxy-

Table 8.6. Conversion of system international units to conventional units.

Hemoglobin	g/L	0.1	g/dL
Albumin	g/L	0.1	g/dL

gen to peripheral tissues.^{65,67,93} Stable, healthy surgical patients will tolerate normovolemic reductions in hematocrit to 21% or hemoglobin levels of 70 g/L if cardiac output is maintained and arterial oxygenation is ensured in the perioperative period.⁹⁴ Further reductions in hematocrit increase the potential for inadequate oxygen delivery to the peripheral tissues of anesthetized patients. This is of particular importance to patients with hemodynamic instability or pulmonary disease. Polycythemia, on the other hand, increases blood viscosity and reduces capillary flow, which can reduce the oxygen-delivery capacity of blood with respect to peripheral tissues.⁶⁷ Patients, particularly large animal patients, with PCVs in excess of 50% should be treated with fluids to restore the hematocrit to more normal levels.⁹²

Total protein levels may represent a more effective index of plasma volume variations than does PCV. Serum protein levels should be maintained above 35 g/L (3.5 g/dL) and albumin levels above 15 g/L (1.5 g/dL) to ensure that there is not a net loss of water from the vascular compartment, resulting in interstitial edema. It has been recommended that, in large animals, fluid therapy is indicated if total serum protein exceeds 80 to 100 g/L (8 to 10 g/dL).⁹²

Measurement of serum electrolytes enables clinicians to calculate or measure plasma osmolality and determine whether there are significant life-threatening compositional changes within the extracellular fluid. Plasma osmolality may be calculated as follows:

SI units:

$$\text{mOsm/L} = 1.86 (\text{Na}^+ + \text{K}^+) + \text{glucose} + \text{BUN} + 9$$

Conventional units:

$$\text{mOsm/L} = 1.86 (\text{Na}^+ + \text{K}^+) + \left[\frac{\text{glucose}}{18} \right] + \left[\frac{\text{BUN}}{2.8} \right] + 9$$

Differences between measured and calculated plasma osmolality indicate the presence of unmeasured osmotically active sub-

stances in plasma. Determination of plasma osmolality may also aid in the assessment of the degree of dehydration of patients. The fluid deficit in liters may be calculated as follows:⁹⁵

$$\text{fluid deficit (L)} = (0.6) \text{BW}_{\text{kg}} \left[\frac{(\text{mOsm plasma} - 300)}{300} \right]$$

Urine should be collected and its specific gravity, osmolality, and pH determined. In addition, the sample should be tested for the presence of protein, red blood cells, and glucose.

Once a clinician has assessed a patient's fluid and electrolyte status, a plan for therapeutic intervention, if required, is initiated. Selection of the appropriate fluid for replacement purposes depends on the nature of the disease process and the composition of the fluid lost from the patient. The following criteria have been used in determining the appropriate therapeutic intervention: (a) volume deficit, (b) PCV and total serum protein concentrations, (c) plasma osmolality, (d) electrolyte concentrations, (e) acid-base status, (f) caloric requirements (water-soluble vitamins, carbohydrates, and amino acids), and (g) trace-element concentrations.⁹⁶ In those situations where it is necessary to correct fluid and electrolyte deficits prior to surgery, consideration is given to the replacement of previous and continuing losses as well as the provision of maintenance requirements if the animal is not currently ingesting food or water. It is preferable to replenish total body water and correct electrolyte deficits over a 24- to 48-h period. Patients may be stabilized over the first 4 to 6 h, with 50% of the estimated deficit being corrected during that period. Of the deficit, 75% may be corrected within 24 h, in addition to the replacement of concurrent losses and the administration of maintenance requirements. The remainder of the deficit, in conjunction with maintenance requirements, may be administered over the next 24 h. Continuing losses should be estimated and replaced, if necessary, over this period, as well.

In critically ill or moribund patients, vascular and interstitial volume deficits must be corrected as rapidly as is necessary to ensure survival. In the treatment of shock, initial fluid-administration rates of 50 to 90 mL/kg/h in dogs or 50 to 60 mL/kg/h in cats are recommended. Once the crisis has been averted, fluid-administration rates may be reduced to 10 to 12 mL/kg/h in dogs and 5 to 6 mL/kg/h in cats.⁹⁷ Lower administration rates in noncrisis situations help ensure adequate expansion of extracellular space before diuresis is induced. In large animal species, administration rates of 60 (equine), 80 (calves), and 40 mL/kg/h (cattle) may be used in the initial stages of shock therapy.^{46,98-100}

Fluid Administration

Fluids may be administered orally, subcutaneously, or directly into the vascular space by the intravenous or intraosseous routes. Oral administration of fluids is recommended unless an animal is in critical condition or has severe gastrointestinal disease. Isotonic, nonirritating maintenance solutions may be administered subcutaneously if time and the clinical condition of the patient permit. In critically ill patients, where a rapid response to therapy is desired, fluids and electrolytes should be administered directly into the intravascular compartment. Fluids that are ad-

ministered intravenously, particularly if administered rapidly or in large volumes, should be warmed to 37°C before being infused or transfused.

Venipuncture, for fluid-administration purposes, is best accomplished with intravenous butterfly sets or catheters. Butterfly infusion sets are not suitable for unsupervised fluid-therapy procedures because of the potential for extravascular infusion of fluids. Similarly, they should not be used routinely for perioperative venous access in surgical patients because they cannot be relied upon to remain intravascular. Short-term venous access for anesthetic procedures and fluid or drug administration is best accomplished with the use of over-the-needle-type catheters. Angiocath (Deseret Medical, Sandy, UT) intravenous catheters are available in sizes of 24-gauge \times 1.9 cm to 10-gauge \times 7.6 cm and are made of Teflon (polytetrafluoroethylene). Insite catheters are constructed of Vialon (Deseret Medical) to increase wall strength that facilitates their passage through the tough skin of domestic and exotic animal species with which veterinarians deal. Catheters made of Vialon have been associated with a 46% lower incidence of thrombophlebitis when compared with catheters made of Teflon.⁹⁷ Another product, the Streamline intravenous catheter (Menlo Care, Menlo Park, CA), is made of an elastomeric hydrogel that is hydratable and enlarges after being intravenously placed. One study has demonstrated an increase in flow through a 20-gauge catheter of 26% within 1 h of its intravenous placement.¹⁰¹ The 20-gauge catheter expanded in size to approximate an 18-gauge catheter.¹⁰¹ Such products may be of value in establishing an intravenous access quickly when larger catheters may not be easily placed. Through the needle-type intravenous catheters (I-Cath; Delmed, New Brunswick, NJ) are ideal for long-term fluid therapy, although similar catheter styles and lengths are available as over-the-needle catheter placement units (E-Z Cath; Deseret Medical). The length of these intravenous placement units ensures that they are less likely to become dislodged from the intravenous space. This is of concern particularly in large animal patients.

Selection of the venous access site depends on the species involved, the physical condition of the patient, the volume and type of fluid to be administered, the rate of fluid administration, and the accessibility of a peripheral or central vein. The jugular and saphenous veins may be catheterized in most species. The cephalic vein is commonly used in small animal patients, and the auricular vein may be used in some large animal species. The saphenous or jugular veins may be used in larger birds, whereas the cutaneous ulnar vein may be used in small avian patients.^{102,103} In situations where large volumes are to be infused quickly, the jugular vein is often the best choice. Catheterization of the jugular vein with a multiport catheter enables the clinician to administer fluids, monitor central venous pressure, and collect blood samples for laboratory analysis. There is a reduced chance of thrombophlebitis if dextrose or hypertonic solutions are infused into the jugular vein as opposed to infusions into smaller peripheral veins.

The rate at which fluids may be intravenously administered is determined by factors such as (a) viscosity of the fluid, (b) internal diameter of the catheter and intravenous administration sys-

tem, (c) length of the intravenous administration system, and (d) the height at which the fluid reservoir is hung above the patient.¹⁰⁴ Of these, the internal diameter of the catheter and the fluid-administration set is the most important factor in determining the maximum rate of flow through the system. In situations where rapid administration of fluid is required, the use of multiple large-bore catheters should be considered. A 20-gauge catheter will permit up to 75 mL/min to flow into the cephalic vein of a canine patient with a gravity feed of 1.75 m. However, if an 18-gauge catheter and a gravity feed of 1.0 to 1.75 m are used, the flow rate would increase to 114 mL/min.⁸² Similarly, increasing catheter size to a 16-gauge device increases flow to 160 to 210 mL/min.^{98,104} Flow through a 14-gauge catheter is 50% greater than that through a 16-gauge catheter.¹⁰⁵ Further flow increases of up to 21% may be obtained by using a blood administration set as opposed to a traditional intravenous fluid-administration set. In large animals, flow rates can be dramatically improved upon by modifying a Y Type TUR/Bladder Irrigation Set (Baxter, Toronto, Canada) to end in a standard luer lock connector. Fluid-administration rates can be increased further by using pressure-infusor sets, accommodating a 1-L fluid bag (Baxter) up to a 5-L fluid bag (Disposable Pressure Infusor; Biomedical Dynamics, Minneapolis, MN). More rapid rates of fluid administration may be achieved by using mechanized intravenous fluid pumps and multiple intravenous catheter sites.

The intraosseous space provides an alternative route for the parenteral administration of fluids and therapeutic agents into the vascular space. This method of fluid administration should be used whenever intravenous access cannot be established for the treatment of critically ill patients. Therapeutic agents and fluids that are administered into the intraosseous space rapidly reach the systemic circulation via the bone marrow.^{106,107} In small animals, the intraosseous space may be accessed through the tibial tuberosity, the trochanteric fossa of the femur, or the flat media surface of the proximal tibia just distal to the tibial tuberosity. In the avian species, the distal end of the ulna is cannulated, because pneumatic bone must be avoided. The details with respect to cannula placement, maintenance, and use of intraosseous administration techniques in small animals have been described.^{64,108–110}

Assessment

Once the fluid-therapy regimen is initiated, the clinician should continue to reevaluate the patient to determine its response to therapy. Serial measurements of weight and laboratory values in conjunction with frequent physical examinations enable the clinician to alter the therapeutic regimen according to the patient's changing status. Additional data are obtained in respect to the patient's status and response to therapy through monitoring systemic blood pressure, central venous pressure, volume of urine production, colloid oncotic pressures, and the ECG. These parameters are commonly monitored by the veterinarian in the perioperative period and are discussed in detail elsewhere (Chapter 19).

Intraoperative Considerations

The most common changes during the intraoperative period are alterations to the volume or composition of the extracellular

fluid. These alterations result from increased evaporative losses of free water, sequestration of plasma water in traumatized tissues (third spacing), and hemorrhage. Maintenance deficits in anesthetized patients occur in the preoperative period, owing to NPO orders, and continue throughout the intraoperative and recovery periods. Consideration should be given to the fact that intraoperative losses of free water by evaporation exceed values commonly estimated for routine maintenance purposes. The perioperative free-water deficit can be estimated to be at least 2.0 to 2.5 mL/kg for each hour that an animal is not eating or drinking. Ideally, free-water deficits should be replaced using a hypotonic solution, 5% dextrose in water, or a maintenance solution. However, replacement solutions, such as lactated Ringer's, are often used for this purpose to simplify the intraoperative fluid-therapy regimen.

Third-space losses occur through translocation of plasma and intracellular water into surgically traumatized tissues.⁹⁴ The degree to which the vascular volume is reduced is directly related to the extent of the surgical trauma to the patient. These losses lead to a hemoconcentration effect and in some instances may be estimated as follows:

$$\text{plasma deficit (mL)} = \left[\frac{\text{normal blood volume} \times \text{initial PCV}}{\text{measured PCV}} \right] - \text{normal blood volume}$$

Third-space losses are replaced with balanced electrolyte solutions at administration rates of up to 2 mL/kg/h for superficial procedures, 3 to 5 mL/kg/h for mildly traumatic procedures, 5 to 10 mL/kg/h for moderately traumatic surgeries, and up to 15 mL/kg/h for severely traumatic procedures. Rates up to 15 mL/kg/h have minimal impact on the PCV of healthy dogs. In avian species, intraoperative fluid-administration rates of 10 mL/kg/h for the first 2 h and 5 to 8 mL/kg/h for subsequent hours have been recommended.¹⁷ Third-space loss is replaced in addition to that volume of fluid being administered for maintenance purposes.

Acute, intraoperative losses of blood in excess of 15% of total blood volume in normal patients or 10% in critically ill patients should be replaced with whole blood or packed red cells. A hemoglobin-based, oxygen-carrying solution such as Oxyglobin (bovine hemoglobin glutamer 200) may be of value in instances where whole blood or packed red cells are not available. There is some debate as to the clinical utility of regular use of such solutions, and readers are directed to other sources for additional information.¹¹¹⁻¹¹⁶ The manufacturer's recommended dose of Oxyglobin in dogs is 30 mL/kg infused at a rate of 10 mL/kg/h. A lower infusion rate of 3 to 5 mL/kg/h should be used if the solution is administered to cats. The lower infusion rate in cats may prevent the development of pulmonary edema, pleural effusion, or both.¹¹⁵ Blood loss that does not exceed the limits previously mentioned may be replaced with balanced electrolyte or replacement solutions. As already mentioned, crystalloid solutions equilibrate across the extracellular fluid space, and it is necessary to administer a volume of fluid up to five times the volume of blood that has been lost from the vascular space.²³ As they occur, whole blood losses are replaced with the appropriate volume of colloid or balanced electrolyte solution.

Finally, consideration must also be given to the administration of fluids to maintain cardiovascular stability and organ perfusion, which might be altered by the direct hemodynamic effects of the anesthetic drugs used. The total volume of fluid administered to patients in the perioperative period should be adjusted to ensure that vital signs such as blood pressure and urine production are maintained above critical levels. It is important to remember that perioperative release of alcohol dehydrogenase can reduce the volume of urine produced. This will complicate the ability to assess or use urine production as a prognostic indicator of volume expansion.

The intraoperative administration of large volumes of replacement fluids can lead to hemodilution and the interstitial accumulation of fluids. Although some degree of hemodilution can be beneficial, the hematocrit should be maintained above 21% in healthy patients and at 25% at least in critically ill patients. Total serum protein levels should not be permitted to decrease to below 35 g/L (3.5 g/dL) or albumin to levels below 15 g/L (1.5 g/dL).⁶⁵ It has been suggested that hypertonic saline and dextran 70 solutions may be of value for the intraoperative management of hemorrhagic episodes in maintaining hemodynamic function and reducing the possibility of inducing a fluid volume overload.⁵⁰

Continual assessment of the patient is necessary to maintain cardiovascular stability postoperatively. If ongoing blood losses are not of concern, then the clinician's attention should be directed toward replacing continuing third-space losses and maintenance requirements of the patient. Care should be exercised when administering crystalloid solutions in the postoperative period. Overt fluid overloading may not be readily apparent in patients until 24 to 72 h after the surgical procedure. Postsurgical alterations in aldosterone and alcohol dehydrogenase activity result in reduced free-water clearance in the postoperative period. Once the neurohormonal responses to the surgical procedure abate, third-space fluid and the excess fluid in the interstitial space are mobilized and returned to the vascular space. This can cause a volume overload that might be detrimental to critically ill patients (e.g., those with pulmonary edema).⁴⁰

Electrolyte Disturbances

Compositional changes in the extracellular fluid during the perioperative period may be caused by previous or ongoing disease processes or they may be iatrogenic in origin. Clinically significant disturbances in electrolyte balance should be corrected in the preoperative period. Acute, life-threatening, intraoperative alterations in sodium, calcium, or magnesium concentrations are uncommon unless iatrogenically induced.

Sodium

This is the osmolar skeleton of the extracellular fluid. Sodium balance may be altered by depletion or retention of water, sodium, or both. Sodium regulation and diseases that result in sodium imbalances are discussed elsewhere.^{11,15,117}

Hyponatremia exists when the serum sodium concentration is less than 136 mmol/L (136 mEq/L). Clinical signs relating to neurological dysfunction occur when the sodium concentration is

less than 120 mmol/L (120 mEq/L) and become marked when serum sodium is less than 110 mmol/L (110 mEq/L). Clinical signs include anorexia, lethargy, weakness, vomiting, muscle cramping, myoclonus, seizures, tachycardia, shock, and coma. In complicated cases, the ECG may reveal a widened QRS complex with an elevated ST segment. A nonrespiratory dilutional acidosis may also develop. Ventricular tachycardia or fibrillation can occur when serum sodium levels are below 100 mmol/L (100 mEq/L). Severe hyponatremia may be corrected with the careful administration of 3% saline over 24 h. It has been recommended that the amount of sodium to be administered during this period be calculated as follows:¹⁵

$$\text{mmol Na}^+ = 0.2 \text{ BW}_{\text{kg}} (\text{normal } [\text{Na}^+] - \text{patient's } [\text{Na}^+])$$

In less severe situations, free-water restriction, correction of the underlying cause, and intravenous administration of 0.9% saline may be considered.

Hypernatremia occurs most commonly owing to water loss in excess of the sodium loss in small animal patients. Those animals that do not have free access to water are prone to develop hypernatremia if they have increased water losses such as would occur from heat prostration, burns, and so forth. Salt poisoning occurs commonly in cattle and swine.¹¹⁷ Serum sodium concentrations above 156 mmol/L (156 mEq/L) in dogs and 160 mmol/L (160 mEq/L) in cats and large animal species constitute hypernatremia. Severe hypernatremia may lead to nonrespiratory concentration alkalosis. Clinical signs include lethargy, confusion, muscle weakness, myoclonus, seizures, and coma. The severity of the clinical signs depends on the rate of onset and the degree of the hypernatremia. Treatment depends on the initial cause of the hypernatremia and the chronicity of the electrolyte imbalance. Significant sodium imbalances should be medically managed and corrected prior to any anesthetic or surgical procedure. Details regarding the medical management of hypernatremic states are readily available from a number of sources.^{11,15,118}

Calcium

This ion plays a major role in the physiology of neuromuscular function, cell membrane permeability, muscle contraction, and hemostasis. With respect to total body content, up to 99% of calcium is located within bone. Total serum calcium consists of an ionized portion, a protein-bound portion, and a portion that is complexed to divalent anions such as phosphate and bicarbonate. Close to 50% of total serum calcium is bound to proteins, primarily albumin. Although the ionized portion (40%) is the physiologically active fraction, it is rarely measured. Serum ionized calcium levels are pH dependent, with alkalemia reducing and acidemia increasing ionized serum calcium levels. In dogs, formulas have been developed to adjust calcium measurements to account for alterations in serum protein or albumin concentrations.¹¹⁹ In cats, at least one study has recommended that similar adjustments not be made.¹²⁰

Symptomatic hypocalcemia can be caused by hypoparathyroidism and eclampsia in small animals or parturient paresis in large animal species. Intraoperative hypocalcemia, induced by

the administration of large volumes of citrated whole blood, reduces ventricular function and systemic blood pressure.¹²¹ Hypocalcemia exists when serum calcium levels are below 1.75 mmol/L (7 mg/dL) in small animals and below 2.0 mmol/L (8 mg/dL) in large animal species. Hypoalbuminemia may induce hypocalcemia of 1.75 to 2.0 mmol/L (7 to 8 mg/dL) in small animals. Serum calcium concentrations below 1.62 mmol/L (6.5 mg/dL) are generally the result of a metabolic disorder. Small animals with hypocalcemia may show clinical signs of restlessness, muscle fasciculations, tetany, or convulsions. The ECG may show prolonged QT and ST segments because of prolonged myocardial action potentials. Recently calved, mature cattle with parturient paresis often have serum calcium levels less than 1.25 mmol/L (5 mg/dL). These cows become recumbent when serum calcium levels are less than 1.5 mmol/L (6 mg/dL). Serum calcium levels less than 1.0 mmol/L (4 mg/dL) are fatal.

Acute, intraoperative, hypocalcemic episodes that are iatrogenic in origin may be treated with 10% calcium chloride or calcium gluconate: 10% calcium chloride contains 1.4 mEq/mL of calcium, whereas calcium gluconate contains 0.45 mEq/mL of calcium. The dose to be administered depends on the severity of the situation and ranges from 5 to 15 mg/kg administered over 1 h. If more than 50 mL/kg of whole blood or packed red cells is administered, then calcium supplementation should be considered in order to counteract the effects of the anticoagulant. Up to 6 mL of calcium chloride/gluconate per unit of blood may be administered via a separate intravenous route. The ECG should be observed for evidence of toxicity during the infusion, and additional laboratory data should be assessed prior to administering subsequent calcium salts.

Hypercalcemia can result from hyperparathyroidism or malignancies in small animals, whereas in large animals it is often iatrogenic in origin—in many instances the result of excessive dietary supplementation. Hypercalcemia has been reported to occur in horses with chronic renal failure.¹¹⁷ Hemoconcentration that results in increased serum albumin levels may increase serum calcium levels to 3.2 mmol/L (13 mg/dL). Serum calcium concentrations above 3 mmol/L (12 mg/dL) in dogs and 2.74 mmol/L (11 mg/dL) in cats are indicative of hypercalcemia. Clinical signs include anorexia, vomiting, and gastrointestinal dysfunction. Generalized locomotor weakness may also be evident. Bradycardia, with a prolonged PR interval and a shortened ST segment, may be observed. Rapid increases in serum calcium levels in excess of 3.74 mmol/L (15 mg/dL) may lead to vagal stimulation and severe bradycardia, whereas severe, but less acute, increases may lead to ventricular dysrhythmias.^{122,123}

Potassium

This is the primary intracellular cation, and at least 90% of the total body potassium content is located within the intracellular compartment. Extracellular fluid potassium content represents approximately 2% of the total body content. As a result, serum potassium levels may not accurately represent the extent or severity of a potassium disorder, particularly in chronic disease processes. Potassium is highly labile, and serum levels are significantly altered in the presence of acidemia, alkalemia, or extra-

cellular fluid osmolality changes or by alterations in serum insulin, glucagon, or catecholamine concentrations. Changes in extracellular fluid pH cause rapid and significant alterations in the potassium concentration of extracellular fluid. Acute reductions in PaCO₂ of 10 mm Hg have been shown to increase plasma pH by 0.1 unit and decrease plasma potassium by 0.4 mmol/L (0.4 mEq/L) in dogs.¹²⁴ Similarly, in cats, serum potassium concentrations change on an order of 0.6 to 0.7 mmol/L (0.6 to 0.7 mEq/L) per 0.1 unit change in pH.⁵⁸ Intraoperative ventilatory or metabolic acid-base disturbances are common, particularly in critically ill patients. Anesthesiologists must monitor patients for, and respond to, significant alterations in plasma potassium levels before they become life-threatening.

Hypokalemia results from reductions in dietary intake or increased losses through the urinary or gastrointestinal systems. Increased losses through the urinary system can be caused by osmotic diuresis, chronic steroid therapy, or the use of loop or thiazide diuretics. Alkalemia will reduce serum potassium levels as extracellular potassium moves intracellularly in exchange for hydrogen ions. The degree to which clinical signs become apparent depends on the rapidity of the electrolyte alteration and the chronicity of the disease process. An acute reduction in serum potassium levels to less than 3.0 mmol/L (3 mEq/L) results in clinical signs that may include reduced gastrointestinal motility and generalized muscle weakness. Rapid reductions in extracellular potassium levels disrupt the normal intracellular to extracellular potassium ratio and hyperpolarize myocardial cells. The ECG demonstrates evidence of prolonged repolarization times, with prolonged PR, QRS, and QT intervals, depression of the ST segment, and a flattened or inverted T wave. Severe cardiac manifestations of hypokalemia may include sinus bradycardia, heart block, paroxysmal atrial tachycardia, and atrioventricular dissociation.¹¹⁸ Clinical signs may not be apparent until the potassium concentration approaches 2.5 mmol/L (2.5 mEq/L) in chronic conditions.

Patients in which serum potassium levels have been acutely reduced to below 3.0 mmol/L (3 mEq/L) should have their serum potassium levels corrected, if at all possible, before inducing anesthesia. Moderate to severe reductions in serum potassium levels (2.5 mEq/L) may require the intravenous administration of potassium chloride. It is important that the clinician assess the patient's cardiac and renal function and that the fluid volume and acid-base status of the patient be determined. Volume deficits and acid-base disturbances should be corrected early to ensure adequate renal perfusion and to enable the clinician to determine the plasma potassium levels in a more normalized situation with respect to the patient's acid-base status. Potassium chloride may be infused at a rate of 0.5 mmol/kg/h (0.5 mEq/kg/h) to a maximum daily dose of 2 to 3 mmol/kg (2 to 3 mEq/kg).¹¹⁸ Patient status must be monitored continually during this period. In addition to serial potassium determinations, the patient should be monitored with an ECG so that early signs of potassium toxicity can be detected.

In situations where the potassium imbalance is caused by a chronic disease process, anesthesia and surgery should be delayed, if possible, and the imbalance corrected and medically managed over 3 to 5 days. In this situation, the goal is to replenish the total body potassium deficit without inducing clinical

signs of potassium toxicity. This may be accomplished through the oral administration of potassium supplements or the parenteral administration of a maintenance solution in which the potassium level has been adjusted to at least 20 to 30 mmol/L (20 to 30 mEq/L). Again, it is imperative to assess the patient's status continually and alter the therapeutic regimen accordingly.

If the surgical procedure cannot be delayed, then it may be prudent not to correct serum potassium levels that have been reduced to values between 2.5 to 3.0 mmol/L (2.5 to 3.0 mEq/L) by a chronic process. Rapid corrections of plasma potassium levels in this instance may acutely disturb the intracellular to extracellular potassium ratio and induce alterations in cell membrane stability. In humans, chronic reductions of serum potassium levels to 2.6 mmol/L (2.6 mEq/L) were not associated with, or predictive of, intraoperative dysrhythmias. Instead, intraoperative dysrhythmias were better correlated with the incidence of preoperative dysrhythmias.¹²⁵

Hyperkalemia is not as common in large animals as in small animals, but it does occur with acidemia and equine hyperkalemic periodic paralysis. In small animals, increases in plasma potassium levels in excess of 6.5 mmol/L (6.5 mEq/L) may be iatrogenic or result from renal failure, urethral obstruction, hypoadrenocorticoidism, or acidemia. Postoperatively, increased plasma potassium levels may occur owing to increased tissue catabolism or acidemia. Neonates, Akitas, and English springer spaniels are known to have a high potassium content (20 mEq/L) within their red blood cells, and hemolysis may cause hyperkalemia.¹²⁶ In most instances, there is no total body excess of potassium, and the increase in potassium content is limited to the extracellular fluid compartment.

Increases in extracellular fluid potassium concentrations decrease the magnitude of cell membrane polarization, which subsequently enhances membrane excitability. Clinical signs become apparent once the plasma potassium concentration exceeds 6.5 mmol/L (6.5 mEq/L). Myocardial contractility decreases and bradycardia develops. As the plasma potassium concentration approaches 8 mmol/L (8 mEq/L), the ECG will show peaked T waves and a decrease in the P-wave amplitude. Plasma potassium concentrations above 8 mmol/L (8 mEq/L) have a significant effect on myocardial activity. The PR interval is prolonged, and the P wave may be absent. As the potassium level increases, the QRS complex widens until it assumes a sine-wave appearance, and atrioventricular dissociation occurs. Eventually, asystole or ventricular fibrillation ensues. Patients with a plasma potassium concentration above 6.5 mmol/L (6.5 mEq/L) should not be anesthetized unless the patient's life is immediately threatened by some other process.

Severe potassium-induced cardiotoxicity may be initially antagonized by the intravenous administration of 10% calcium chloride or gluconate at a dose of 0.2 to 0.3 mEq/kg. If the dysrhythmias persist, the dosage may be repeated in 5 min. Additional doses of calcium salts after this point are unlikely to be of benefit. Calcium will help restore cell membrane potentials, and although its effect will last only for 10 to 20 min, this will provide time to institute other therapeutic measures. Rapid decreases in plasma potassium concentration may also be achieved by instituting controlled ventilation and reversing respiratory acidosis rapidly.⁹⁴

Fluid volume deficits and acid-base disturbances should be assessed and corrected: 5% dextrose or 0.9% saline may be used to correct the fluid deficit, promote diuresis, and functionally dilute the extracellular potassium. Dextrose solutions not only provide free water for volume-replacement purposes but enhance the cellular uptake of potassium as part of the normal mechanisms of glucose metabolism. In situations where plasma potassium levels are significantly increased, glucose may be administered at a dose of 0.5 to 1.0 g/kg to enhance the intracellular movement of potassium. The effect of this therapeutic measure should last for a few hours. The effect of glucose on serum potassium concentration may be facilitated by administering 0.5 unit/kg of regular insulin combined with dextrose at a ratio of 2 g of dextrose per unit of administered insulin.¹¹⁸ Correction of acidemia will result in an intracellular shift of potassium in exchange for hydrogen ions. Considerations for therapeutic measures in acid-base disturbances are discussed in Chapter 7. Patients should be continually assessed and care taken to ensure that the therapeutic measures undertaken do not cause hypokalemia or other functional disturbances.

Chapter 9

Anticholinergics and Sedatives

Kip A. Lemke

Introduction

Anticholinergics

Atropine

Glycopyrrolate

Sedatives

Phenothiazines and Butyrophenones

α_2 -Agonists

α_2 -Antagonists

Benzodiazepine Agonists

Benzodiazepine Antagonists

Introduction

Anticholinergics and sedatives are two of the most widely used—and misused—classes of anesthetic adjuncts in veterinary medicine. Anticholinergics are used perioperatively to manage bradycardia and atrioventricular (AV) block associated with surgical manipulation (oculovagal and viscerovagal reflexes) or with the administration of other anesthetic adjunctive drugs (e.g., α_2 -agonists or opioids). Occasionally, they are also used to control excessive oral and airway secretions. Anticholinergics are often combined with sedatives and opioids as part of a preanesthetic combination. Intraoperatively, anticholinergics are used primarily to manage sinus bradycardia and other vagally mediated arrhythmias. Sedatives are used perioperatively to induce sedation, provide restraint, and reduce the amount of injectable and inhalational anesthetics required to induce and maintain anesthesia. Some sedatives suppress or prevent vomiting (phenothiazines and butyrophenones), others provide muscle relaxation (benzodiazepines), and still others provide analgesia and muscle relaxation (α_2 -agonists). Sedatives can also be used to promote a smooth recovery from anesthesia, and some sedatives (α_2 -agonists, opioids, and benzodiazepines) have specific antagonists that can be administered after short diagnostic and minor surgical procedures.

Anticholinergics and sedatives should not be administered perioperatively on an indiscriminate basis. Rather, the risks and benefits associated with administration of different drugs should be assessed, and the safest drugs chosen for each patient. Most injectable and inhalational anesthetics that are used currently do not cause the dramatic autonomic responses (salivation and bradycardia) that occurred with some older anesthetics (ether). Further, the tachycardia induced by anticholinergic administration may be contraindicated in some patients with cardiovascular disease (e.g., hypertrophic cardiomyopathy). Therefore, anticholinergics should be administered only when there is a clear in-

dication for their use (prevention or treatment of bradycardia). Similarly, most sedatives have significant cardiovascular side effects. The phenothiazines can contribute to the development of significant intraoperative hypotension. The α_2 -agonists consistently cause bradycardia and a decrease in cardiac output. Alternatively, the benzodiazepines are relatively free of cardiovascular side effects, but may not be reliable sedatives in some patients. The following patient-related factors should be considered when selecting anticholinergics and sedatives for perioperative use: age, species, temperament, concurrent disease, medications, and previous response to anesthetic drugs. Several procedure-related factors also play a practical role in drug selection. These include the type of procedure (inpatient or outpatient, diagnostic or surgical, and elective or emergency), as well as the duration of the procedure. Availability and clinical experience with the use of anticholinergics and sedatives in different species must also be considered.

Anticholinergics

Anticholinergics are often called parasympatholytic drugs because they block the effects of the parasympathetic nervous system on other body systems—especially the cardiovascular and gastrointestinal systems. Atropine and glycopyrrolate are the anticholinergics used most commonly in veterinary medicine. These two drugs do not block nicotinic cholinergic receptors and are more accurately classified as antimuscarinics. There are three major types of muscarinic receptors: M_1 , M_2 , and M_3 (Table 9.1). M_1 receptors are located on neurons in the central nervous system (CNS) and on autonomic ganglia. M_2 receptors are located in the sinoatrial (SA) and AV nodes and in the atrial myocardium. M_3 receptors are located in secretory glands, vascular endothelium, and smooth muscle. The cellular response to activation of these muscarinic receptors is mediated by several different molecular mechanisms (Table 9.1). Anticholinergics can also produce indirect sympathomimetic and parasympathomimetic effects. Presynaptic muscarinic receptors (heteroreceptors) located on sympathetic nerve terminals normally inhibit release of norepinephrine, and blockade of these receptors by muscarinic antagonists facilitates release of norepinephrine. Similarly, presynaptic muscarinic receptors (autoreceptors) located on parasympathetic nerve terminals normally inhibit release of acetylcholine, and blockade of these receptors by muscarinic antagonists facilitates release of acetylcholine.

Atropine and glycopyrrolate are relatively nonselective mus-

Table 9.1. Anatomical location, cellular response, and physiological response associated with different muscarinic receptor subtypes

Receptor (G Protein)	Anatomical Location	Cellular Response	Physiological Response
M ₁ (G _{q/11})	Neurons and autonomic ganglia	Activate PLC and increase IP ₃ , DAG, and cytosolic calcium	Depolarization of neurons and autonomic ganglia
M ₂ (G _{i/o})	Sinoatrial node, atrioventricular node, and atrial myocardium	Increase potassium conductance Inhibit AC and decrease cAMP Decrease calcium conductance	Decreased sinus rate, conduction velocity, and contractile force
M ₃ (G _{q/11})	Secretory glands, smooth muscle, and vascular endothelium	Activate PLC and increase IP ₃ , DAG, and cytosolic calcium Generation of nitric oxide	Increased secretion and smooth muscle activity, and vasodilation

AC, adenylate cyclase; cAMP, cyclic adenosine monophosphate; DAG, diacylglycerol; IP₃, inositol triphosphate; PLC, phospholipase C.

Table 9.2. Comparative effects of atropine and glycopyrrolate

	Sedation	Decrease in Oral Secretions	Increase in Heart Rate	Decrease in Gastrointestinal Motility	Ocular Effects	Increase in Gastric pH
Atropine	+	+	+++	++	++	0
Glycopyrrolate	0	++	+++	++	0	+

0, none; +, mild; ++, moderate; +++, marked.

Modified from Stoelting.³²⁴

carinic antagonists, but despite this lack of selectivity the effectiveness of muscarinic blockade varies considerably from tissue to tissue (Table 9.2). Salivary and bronchial glands are the most sensitive to muscarinic blockade. Cardiac tissues and smooth muscle are intermediate in sensitivity, and gastric parietal cells are the least sensitive to muscarinic blockade. Cardioselective muscarinic (M₂) antagonists that prevent bradycardia and have limited effects on gastrointestinal smooth muscle activity have become available.^{1,2}

Perioperatively anticholinergics are usually administered to prevent or treat severe bradycardia caused by surgical manipulation (vagal reflexes) or by administration of other anesthetic drugs (e.g., α_2 -agonists and opioids). The incidence and severity of bradyarrhythmias can be reduced by preoperative administration of atropine or glycopyrrolate, but significant arrhythmias can still occur, and anticholinergic administration should never be used as a substitute for diligent patient monitoring. Anticholinergic administration routinely causes sinus tachycardia, which is problematic for many patients with cardiovascular disease. Tachycardia associated with administration of anticholinergics leads to an increase in myocardial work and a decrease in myocardial perfusion. Further, coadministration of anticholinergics and ketamine has been associated with the development of myocardial infarcts in, and the death of, young cats undergoing routine surgical procedures.³ Anticholinergic administration also has dramatic effects on gastrointestinal function. At therapeutic doses, nonselective muscarinic antagonists like atropine and glycopyrrolate reduce lower esophageal sphincter tone and have little effect on gastric pH.⁴ These two factors increase the incidence

of gastroesophageal reflux and esophagitis in anesthetized dogs.⁵ Perioperative administration of anticholinergics also reduces intestinal motility and can lead to gastrointestinal complications postoperatively.⁶

Atropine

This agent is a racemic mixture of the l (–) and d (+) isomers of hyoscyamine. The l (–) isomer is at least 100 times more potent than the d (+) isomer. Chemically, atropine consists of two components (tropic acid and an organic base) that are bound by an ester linkage (Fig. 9.1). Atropine has approximately the same affinity for all three major types of muscarinic receptors. Relative to other synthetic muscarinic antagonists, atropine is very selective for muscarinic receptors and has little effect on nicotinic receptors.

Pharmacokinetics and Pharmacodynamics

Atropine is rapidly absorbed after intramuscular (IM) administration. Onset of cardiovascular effects occurs within 5 min, and peak effects occur within 10 to 20 min. After intravenous (IV) administration at a dose of 0.03 mg/kg, onset of cardiovascular effects occurs within 1 min, peak effects occur within 5 min, and heart rate increases by 30% to 40% for approximately 30 min (Fig. 9.2).¹ The effects of atropine on other body systems subside within a few hours, but ocular effects can persist for 1 to 2 days. Atropine is rapidly cleared from the blood after parenteral administration. Some of the drug is hydrolyzed to inactive metabolites (tropine and tropic acid), and some of it is excreted unchanged in the urine. Rabbits and some other species (cats and

Fig. 9.1. Chemical structures of muscarinic antagonists
With permission from Stoelting.³²⁴

rats) have a plasma enzyme (atropine esterase) that accelerates metabolism and clearance of the drug.⁷

At therapeutic doses, atropine administration produces limited effects on the CNS. A mild sedative effect may be observed, and the incidence of vomiting mediated by the vestibular system may be reduced. Blockade of the pupillary constrictor muscle and the ciliary muscle produces long-lasting mydriasis and cycloplegia, respectively. Lacrimal secretions are also reduced, which may contribute to corneal drying during anesthesia unless artificial tears are applied concurrently.⁸⁻¹⁰ Atropine should be used with discretion in animals with acute glaucoma and increased intraocular pressure because its mydriatic effect may impede drainage from the anterior chamber.

Atropine administration produces very dramatic effects on heart rate and rhythm.¹¹⁻¹³ The SA and AV nodes and the atrial

myocardium all receive vagal parasympathetic input. Muscarinic receptors are located both presynaptically and postsynaptically in the SA and AV nodes. The typical response to IV or IM administration of therapeutic doses (0.02 to 0.04 mg/kg) of atropine is blockade of postsynaptic muscarinic receptors that leads to an increase in sinus rate, an acceleration of AV nodal conduction, and an increase in atrial contractility. At lower doses, a transient decrease in sinus rate and slowing of AV nodal conduction (AV blockade) can occur.^{11,12} This response appears to be due to blockade of presynaptic muscarinic receptors that normally inhibit acetylcholine release.¹⁴ Once postsynaptic muscarinic blockade is established, this paradoxical increase in vagal tone usually resolves.

Airway smooth muscle and secretory glands also receive parasympathetic input from the vagus nerves. Blockade of M₃ receptors by therapeutic doses of atropine decreases airway secretions and increases airway diameter and anatomical dead space. In the past, atropine was given before administration of noxious inhaled anesthetics (ether) to reduce airway secretions and the potential for laryngospasm. Modern inhaled anesthetics do not cause the same degree of airway irritation, and routine preoperative administration of atropine for this reason is difficult to justify.

Atropine administration also produces very dramatic effects on the gastrointestinal system. Blockade of M₁ and M₃ receptors in the gastrointestinal tract reduces secretory activity and motility. In dogs, administration of atropine reduces smooth muscle contractile activity, and administration of selective M₂ antagonists has limited effects on intestinal motility.¹ Atropine is not usually administered perioperatively to large animals. Although it can be given to horses intraoperatively to manage severe bradycardia associated with administration of α_2 -agonists, gastrointestinal motility is reduced and colic can occur postoperatively.^{6,15}

Clinical Uses

Atropine can be given subcutaneously (SC), IM, or IV, but the IM and IV routes are preferred because uptake from subcutaneous sites can be erratic in patients with altered hydration and peripheral

Fig. 9.2. Effect of intravenous administration of atropine (6 to 60 µg/kg) on heart rate in dogs. With permission from Hendrix and Robinson.¹

circulation. Doses for dogs and cats range from 0.02 to 0.04 mg/kg. Atropine is also effective when given endotracheally or endobronchially to dogs for cardiopulmonary resuscitation.¹⁶ Doses for ruminants and swine range from 0.04 to 0.08 mg/kg, but salivation may not be completely obtunded in these species. Atropine is not usually given perioperatively to horses because of its gastrointestinal side effects. Atropine can also be used to control muscarinic side effects when anticholinesterases (e.g., edrophonium) are administered to reverse neuromuscular blockade produced by nondepolarizing muscle relaxants (e.g., atracurium).

Glycopyrrolate

This is a synthetic quaternary ammonium muscarinic antagonist. Like atropine, the drug consists of two components (mandelic acid and an organic base) bound together by an ester linkage (Fig. 9.1). Glycopyrrolate is four times as potent as atropine and has approximately the same affinity for all three major types of muscarinic receptors. The drug's polar structure (quaternary amine) limits diffusion across lipid membranes and into the CNS and fetal circulation.¹⁷

Pharmacokinetics and Pharmacodynamics

Absorption, metabolism, and elimination of glycopyrrolate are similar to that of atropine. Absorption is rapid after IM administration. Onset of cardiovascular effects occurs within 5 min, peak effects occur within 20 min, and heart rate remains elevated for approximately 1 h.¹⁸ Glycopyrrolate is rapidly cleared from the blood after parenteral administration, and most of the drug is excreted unchanged in the urine.

At therapeutic doses, glycopyrrolate produces few, if any, effects on the CNS. Unlike atropine administration, sedation is not observed, and recovery times are not prolonged. Administration of glycopyrrolate to conscious dogs with normal intraocular pressure does not alter pupil diameter and intraocular pressure, and intraoperative administration of glycopyrrolate to dogs with glaucoma and increased intraocular pressure appears to be safe.¹⁹ Similarly, pupil diameter and light reflexes are unaffected when conscious horses are administered glycopyrrolate IV.²⁰

Glycopyrrolate administration produces effects on the heart that are comparable to those of atropine.¹² Studies in people suggest that glycopyrrolate produces less tachycardia than atropine, but the two drugs produce similar increases in heart rate when administered IV to sedated or anesthetized dogs.^{12,21} The typical response to IV or IM administration of therapeutic doses (5 to 10 µg/kg) of glycopyrrolate is an increase in sinus rate, acceleration of AV nodal conduction, and an increase in atrial contractility. At lower doses, a transient decrease in sinus rate and slowing of AV nodal conduction can occur.¹² Glycopyrrolate can also be given intraoperatively to correct bradycardia in both small and large animals. Dogs weighing less than 10 kg require a higher dose of glycopyrrolate (10 µg/kg IV) to correct bradycardia, and those over 10 kg require a lower dose (5 µg/kg IV).²² Glycopyrrolate is given to horses at a lower dose (2.5 to 5.0 µg/kg IV) to correct bradycardia and to increase cardiac output and blood pressure (Fig. 9.3), but the potential for postoperative gastrointestinal complications (colic) must be considered.^{23,24}

Fig. 9.3. Effect of intravenous administration of glycopyrrolate (2.5 to 7.5 µg/kg) on heart rate (HR), cardiac output (CO), and mean arterial blood pressure (MAP) in horses anesthetized with halothane and xylazine. With permission from Teixeira Neto et al.²⁴

Like atropine, glycopyrrolate produces dramatic effects on the gastrointestinal system. Intestinal motility is reduced for at least 30 min in anesthetized dogs.²¹ In conscious horses, gastrointestinal motility is reduced for 2.4 and 6.4 h after IV administration of glycopyrrolate at doses of 2.5 and 5.0 µg/kg, respectively.²⁰ Further, when these doses were given intraoperatively to 17 horses undergoing routine surgical procedures, only one horse developed signs of colic postoperatively.²³ Although well-controlled comparative studies are lacking, glycopyrrolate appears to be a safer choice than atropine for the treatment of intraoperative bradycardia in horses.

Clinical Uses

Glycopyrrolate is used perioperatively to prevent severe bradycardia caused by surgical manipulation (vagal reflexes) or by administration of other anesthetic drugs (α_2 -agonists and opioids). Glycopyrrolate can be given subcutaneously (SC), IM, or IV, but the IM and IV routes are preferred because uptake from SC sites can be erratic in patients with altered hydration and peripheral circulation. Doses for dogs and cats range from 5 to 10 $\mu\text{g}/\text{kg}$. Intravenous doses for horses range from 2.5 to 5.0 $\mu\text{g}/\text{kg}$, but gastrointestinal side effects can occur. Like atropine, glycopyrrolate can be used to control muscarinic side effects when anticholinesterases (e.g., edrophonium) are given to reverse neuromuscular blockade produced by nondepolarizing muscle relaxants (e.g., atracurium).

Sedatives

Behavioral responses to different classes of sedatives vary considerably among species. The phenothiazines and α_2 -agonists are effective sedatives in dogs and cats but are not reliable sedatives in swine. Conversely, the benzodiazepines are effective sedatives in ferrets, rabbits, swine, and birds but are not reliable sedatives in cats and young dogs. Dose requirements also vary considerably among species. For example, the α_2 -agonists are effective sedatives in horses and cattle, but the xylazine dose requirement for horses is approximately ten times that for cattle. Because of this variability, accurate classification of these drugs as tranquilizers, sedatives, or hypnotics is problematic. Therefore, the drugs discussed in this chapter are simply referred to as sedatives, with the knowledge that their effects will vary with species and with dose.

In North America, only a limited number of sedatives are approved for use in animals. All of these sedatives are classified as phenothiazines (acepromazine), butyrophenones (azaperone), or α_2 -agonists (xylazine, medetomidine, detomidine, and romifidine). Despite the widespread use of benzodiazepines (diazepam and midazolam) as sedatives, muscle relaxants, and anticonvulsants in veterinary medicine, none are approved and marketed for use in animals. In the United States, the benzodiazepine zolazepam is available in combination with a dissociative anesthetic (tiletamine) and is approved for use in cats and dogs as an anesthetic. Only acepromazine and xylazine are approved for use in cats, dogs, and horses. Medetomidine is approved for use in

dogs, detomidine and romifidine are approved for use in horses, and azaperone is approved for use in swine. In Canada, acepromazine and xylazine are also approved for use in ruminants.

Selection of sedatives for different species and for animals with different behavioral and medical problems can be difficult without a thorough understanding of the physiological effects of the different classes of sedatives. In cats and dogs, administration of acepromazine or an α_2 -agonist is associated with significant cardiovascular side effects (hypotension or bradycardia, respectively). Therefore, these sedatives are probably best reserved for use in young healthy animals. If a sedative is needed for pediatric, geriatric, or sick patients, administration of diazepam or midazolam should be considered. In horses, acepromazine and the α_2 -agonists are the only reliable sedatives, and doses must be carefully individualized for each patient. Although midazolam is not widely used in animals, it is an excellent sedative for swine and some exotic species (rabbits, ferrets, and birds).

Phenothiazines and Butyrophenones

Phenothiazines and, to a lesser extent, butyrophenones produce a wide variety of behavioral, autonomic, and endocrine effects. The behavioral effects of these drugs are mediated primarily by blockade of dopamine receptors in the basal ganglia and limbic system. At therapeutic doses, phenothiazines and butyrophenones inhibit conditioned avoidance behavior and decrease spontaneous motor activity. At higher doses, extrapyramidal effects (tremor, rigidity, and catalepsy) can occur. These sedatives also have significant binding affinity for autonomic (adrenergic and muscarinic) and other types of receptors (Tables 9.3 and 9.4). For example, phenothiazines bind with greater affinity to α_1 recep-

Table 9.3. Relative receptor-binding affinities of phenothiazines and butyrophenones

	D ₁	D ₂	α_1	5-HT ₂	M ₃	H ₁

Table 9.4. Adverse effects of phenothiazines and butyrophenones

	Pharmacological Effects	Mechanism
Central nervous system	Catalepsy, tremor, and rigidity Seizure activity	Dopaminergic blockade Electroencephalographic slowing and synchronization
Autonomic nervous system	Decreased blood pressure and hematocrit Decreased glandular secretions	α -Adrenergic blockade Muscarinic blockade
Endocrine system	Galactorrhea, abnormal cycles, and altered libido	Dopaminergic blockade and increased prolactin secretion

tors than to dopaminergic receptors. Blockade of α_1 receptors is responsible for the hypotension that is typically associated with perioperative use of these drugs. Blockade of these receptors may also be responsible for the ability of phenothiazines and butyrophenones to protect against the development of malignant hyperthermia in susceptible animals anesthetized with halothane.²⁵ Dopamine receptors in the hypothalamus are responsible for tonic inhibition of prolactin secretion. Blockade of these receptors increases prolactin secretion and is responsible for most of the endocrine effects associated with administration of these drugs. Blockade of dopamine receptors in the chemoreceptor trigger zone of the medulla produces an antiemetic effect, and depletion of catecholamines in the thermoregulatory center of the hypothalamus leads to a loss of thermoregulatory control. Phenothiazines and butyrophenones also produce slowing and synchronization of the electroencephalogram, which can facilitate the development of seizures in predisposed animals.²⁶

Dopamine is largely an inhibitory neurotransmitter and is responsible for regulation of behavior, fine motor control, and prolactin secretion. Dopamine receptors are G-protein-coupled receptors and are divided into two major families of receptors: Dopamine 1 (D_1) receptors are located postsynaptically, and dopamine 2 (D_2) receptors are located both presynaptically and postsynaptically. Activation of the D_1 family of receptors increases adenylate cyclase activity and intracellular levels of cyclic adenosine monophosphate (cAMP). Activation of the D_2 family of receptors decreases adenylate cyclase activity and intracellular levels of cAMP, and can also activate other presynaptic signal transduction pathways (decrease calcium conductance) and postsynaptic signal transduction pathways (increase potassium conductance). Most behavioral effects are mediated by the D_2 family of receptors.

Acepromazine

This is one of the most widely used sedatives in veterinary medicine. The chemical name of acepromazine is 2-acetyl-10-(3-dimethylaminopropyl) phenothiazine (Fig. 9.4). The drug is more potent than other phenothiazine derivatives and produces sedation at relatively low doses. Acepromazine administration produces some muscle relaxation but has no analgesic effect. In North America, the drug is sold as acepromazine maleate and is approved for use in both small and large animals.

Pharmacokinetics and Pharmacodynamics Onset of sedation after parenteral administration of acepromazine to cats, dogs, and horses is relatively slow, and sedation persists for several hours. In dogs given acepromazine and an opioid IM, onset of sedation is observed within 15 min, peak effects are observed within 30 min, and sedation lasts for 2 to 3 h.^{27,28} In horses given acepromazine IV, peak effects are observed within 30 min and sedation lasts for 1 to 2 h.^{29,30} The pharmacokinetics of IV administration of acepromazine have been determined in horses at relatively high doses. At a dose of 0.3 mg/kg, acepromazine is widely distributed ($V_d = 6.6$ L/kg), is extensively protein bound (>99%), and has an elimination half-life of 3 h.²⁹ At a dose of 0.15 mg/kg, acepromazine has a smaller volume of distribution ($V_d = 4.5$

Fig. 9.4. Chemical structures of acepromazine and azaperone. With permission from Gross.³²⁵

L/kg) and shorter elimination half-life (1.6 h).³⁰ The drug is metabolized by the liver, and unconjugated and conjugated metabolites are excreted in the urine.³¹

Acepromazine administration decreases halothane and isoflurane requirements in several species. In dogs anesthetized with halothane, IM administration of acepromazine at doses of 0.02 and 0.2 mg/kg decreases the minimum alveolar concentration (MAC) by 34% and 44%, respectively.³² In a comparative study, IM administration of acepromazine (0.2 mg/kg) to dogs anesthetized with halothane or isoflurane decreased the MAC by 28% and 48%, respectively.³³ Administration of acepromazine (0.05 mg/kg IV) also decreases the MAC of halothane in ponies by 37% and the MAC of isoflurane in goats by 44%.^{34,35} Given the 30% to 40% reduction in halothane and isoflurane requirements that occurs when acepromazine is given perioperatively, patients should always be monitored closely and vaporizer settings reduced accordingly.³⁶

Acepromazine administration produces dramatic effects on the cardiovascular system in both conscious and anesthetized animals. In conscious dogs, stroke volume, cardiac output, and mean arterial pressure decrease 20% to 25% after IV administration of acepromazine (0.1 mg/kg), and mean arterial pressure is reduced for at least 2 h.^{37,38} In conscious cats, IM administration of acepromazine (0.1 mg/kg) decreases mean arterial pressure by 30% within 10 min of injection.³⁹ In dogs anesthetized with halothane, IV administration of acepromazine at doses of 0.05, 0.125, and 0.25 mg/kg decreases mean arterial pressure by 2.3%, 9.4%, and 16.8%, respectively.⁴⁰ Preanesthetic administration of acepromazine (0.1 mg/kg IM) also decreases mean arterial pressure by 24% in dogs anesthetized with isoflurane (Fig. 9.5).⁴¹ In conscious horses, administration of acepromazine (0.1 mg/kg IV) decreases mean aortic pressure by 20% to 30% and decreases cardiac output by 10% to 15%.⁴² In horses anesthetized with

Fig. 9.5. Effect of acepromazine (0.1 mg/kg intramuscularly) on mean arterial pressure in dogs anesthetized with isoflurane (2%). With permission from Bostrom et al.⁴¹

halothane, IV administration of acepromazine (0.03 mg/kg) decreases mean arterial pressure by 25%.⁴³ When acepromazine is given preoperatively to animals anesthetized with halothane, a modest decrease in arterial pressure occurs. However, when acepromazine is given to animals anesthetized with isoflurane, a dramatic decrease in arterial pressure occurs. Currently, the widespread practice of administering acepromazine preoperatively, maintaining anesthesia with isoflurane, and failing to monitor arterial pressure contributes to the high incidence of intraoperative hypotension in small animals.

Heart rate does not change appreciably in conscious dogs and horses administered acepromazine (0.1 mg/kg IV).^{37,42} Increases in heart rate and sinus tachycardia can occur in some patients. At very high doses (1 mg/kg), bradycardia and SA block can occur in dogs given acepromazine, but these arrhythmias are not usually observed at lower doses.⁴⁴ Heart rate decreases after administration of acepromazine in dogs anesthetized with halothane but does not change in horses anesthetized with halothane.^{43,45} Premedication with acepromazine also increases the dose of epinephrine required to induce ventricular arrhythmias in dogs anesthetized with halothane.^{46,47} Blockade of myocardial α_1 receptors by acepromazine may prevent the development of ventricular arrhythmias in anesthetized animals—provided that adequate diastolic pressure is maintained.⁴⁸

Administration of acepromazine to conscious or anesthetized animals has little effect on pulmonary function. In conscious dogs and horses, respiratory rate decreases, but arterial pH, partial pressure of carbon dioxide (PCO₂), partial pressure of oxy-

gen (PO₂), and hemoglobin saturation do not change after IV administration of acepromazine.^{42,44} In horses anesthetized with halothane, respiratory rate and arterial blood-gas values do not change after IV administration of acepromazine.⁴³

Acepromazine administration produces significant gastrointestinal and urogenital effects. In dogs, administration of acepromazine 15 min before administration of morphine, hydromorphone, or oxymorphone lowers the incidence of vomiting from 45% to 18%.⁴⁹ However, administration of acepromazine alone or in combination with an opioid reduces lower esophageal sphincter tone, delays gastric emptying, and may increase the incidence of gastric reflux.^{50–52} In horses, acepromazine administration delays gastric emptying and reduces intestinal motility.^{53,54} Glomerular filtration is maintained in dogs premedicated with acepromazine and anesthetized with isoflurane.⁴¹ Acepromazine also decreases urethral pressure by 20% in cats already anesthetized with halothane.⁵⁵

Acepromazine administration can produce significant hematologic side effects in animals. In dogs and horses, hematocrit decreases by 20% to 30% within 30 min of acepromazine administration and remains well below baseline values for at least 2 h.^{29,30,56} Acepromazine administration also inhibits platelet aggregation but does not appear to alter hemostasis in normal dogs.⁵⁷ Bradycardia and hypotension can occur in boxers and other breeds of dogs after acepromazine administration. These animals usually respond to fluid loading with isotonic crystalloids and administration of an anticholinergic to correct the bradycardia. Acepromazine administration produces penile protrusion in horses, and both the degree and duration of protrusion are dose dependent.²⁹ At a dose of 0.04 mg/kg, protrusion is 60% of the maximum length within 30 min and is below 30% after 90 min. At a dose of 0.4 mg/kg, protrusion is over 90% of the maximum length within 30 min and is still over 80% after 4 h. Although uncommon, prolonged prolapse or priapism can occur, and amputation may be required.⁵⁸ Low doses of acepromazine can be used safely in geldings but should be avoided in breeding stallions.

Clinical Uses Clinical uses of acepromazine are usually restricted to healthy animals. The drug is administered alone as a sedative for nonpainful diagnostic procedures or in combination with an opioid for painful diagnostic and minor surgical procedures. Acepromazine is also given alone and in combination with opioids as a preanesthetic to facilitate placement of IV catheters and to reduce the dose of injectable and inhalational anesthetics required to induce and maintain anesthesia. Small doses of acepromazine can also be given postoperatively to smooth recovery—provided that patients are hemodynamically stable and that pain has been managed effectively. Administration of acepromazine postoperatively to quiet patients in the absence of effective analgesic therapy makes accurate assessment of pain impossible and is inhumane. The drug is used in several species, including cats, dogs, and horses, but is not a reliable sedative in swine. Acepromazine can be given SC, IM, or IV, but the IM and IV routes are preferred because uptake from SC sites can be erratic in patients with altered peripheral circulation. Intramuscular

doses for cats and small dogs range from 0.05 to 0.2 mg/kg, and those for larger dogs range from 0.04 to 0.06 mg/kg. Intravenous doses for horses range from 0.02 to 0.04 mg/kg.

Azaperone

This agent is a butyrophenone derivative (Fig. 9.4). The chemical name of the drug is 4-fluoro-4-(4-[2-pyridyl]-1-piperazinyl) butyrophenone. In North America, azaperone is approved for use in swine to produce sedation and control aggression when groups of animals are mixed. The drug produces some muscle relaxation but has no analgesic effect. Like acepromazine, azaperone can be used alone or in combination with other drugs (e.g., opioids and ketamine).

Pharmacokinetics and Pharmacodynamics In pigs, sedation begins within 10 min after IM administration of azaperone at the label dose (2 mg/kg). Ideally, animals should be left undisturbed in a quiet environment for approximately 20 min. Peak sedation is reached within 15 min in young pigs and within 30 min in mature animals, and sedation persists for 2 to 3 h. Excitement has been observed in other species when azaperone is administered IV.⁵⁹ Limited pharmacokinetic data are available for azaperone, but the drug is metabolized by the liver and is rapidly cleared from tissues.

Azaperone administration produces dramatic effects on the cardiovascular system. Heart rate and cardiac output decrease by 20% to 40% in young pigs given azaperone IM at a dose of 2.5 mg/kg.⁶⁰ Arterial pressure decreases in pigs given azaperone IM at doses ranging from 0.3 to 3.5 mg/kg, and the pressure decrease is not dose dependent.⁶¹

As with acepromazine, azaperone administration has little effect on pulmonary function, but thermoregulation is impaired. Small increases in respiratory rate and decreases in arterial PCO₂ occur in pigs given azaperone IM at doses of 1 to 3.5 mg/kg.⁶¹ Rectal temperature decreases 1° to 2°C over 4 h after IM administration of azaperone at a dose of 5 mg/kg.⁶² Intramuscular administration of azaperone at a low dose (0.5 mg/kg) prevents serious fighting in breeding boars, but penile prolapse occurs in a small percentage of animals (<4%).⁶⁰

Clinical Uses Clinical uses of azaperone are usually restricted to healthy swine. The drug is used alone as a sedative for non-painful diagnostic procedures or in combination with an opioid for painful diagnostic and minor surgical procedures. Azaperone is also used alone and in combination with opioids as a preanesthetic to facilitate placement of IV catheters and to reduce the dose of injectable and inhalational anesthetics. Intramuscular administration of azaperone at a dose of 1 to 2 mg/kg produces a mild to moderate sedative effect in most swine. Azaperone is also given in combination with ketamine to immobilize or anesthetize animals for various diagnostic and surgical procedures. In swine, administration of azaperone (1 mg/kg IM) and ketamine (5 to 10 mg/kg IM) will immobilize most animals, and administration of azaperone and ketamine at twice these doses will anesthetize most animals. Injections should always be made with needles long enough to reach the target muscle groups. In small pigs,

1-inch needles are adequate, but longer needles must be used in mature animals. In Canada, animals given azaperone must not be slaughtered for food for at least 1 day.

α_2 -Agonists

α_2 -Agonists are the most widely used class of sedatives in veterinary medicine. In most species, these drugs induce reliable dose-dependent sedation, analgesia, and muscle relaxation that can be readily reversed by administration of selective antagonists.

Xylazine has been used in both small and large animals for over two decades, and detomidine has been used in horses for over a decade.^{63,64} In small animals, medetomidine has been used for several years in North America and in Europe.⁶⁵⁻⁶⁷ Romifidine has also been used in horses in North America and in Europe.⁶⁴ Selective antagonists (tolazoline, yohimbine, and atipamezole) are available for use in both small and large animals in several countries. α_2 -Agonists and their antagonists are also used to facilitate capture and handling of many exotic species.^{68,69}

The α_2 receptors are located in tissues throughout the body, and norepinephrine is the endogenous ligand for these receptors. The α_2 receptors exist presynaptically and postsynaptically in neuronal and nonneuronal tissues, and extrasynaptically in the vascular endothelium and in platelets. Within the nervous system, α_2 receptors are located presynaptically on noradrenergic neurons (autoreceptors) and on nonnoradrenergic neurons (heteroreceptors). The sedative and anxiolytic effects of α_2 -agonists are mediated by activation of supraspinal autoreceptors or postsynaptic receptors located in the pons (locus ceruleus), and the analgesic effects are mediated by activation of heteroreceptors located in the dorsal horn of the spinal cord.⁷⁰ Supraspinal α_2 receptors located in the pons also play a prominent role in descending modulation of nociceptive input.

Three distinct α_2 -receptor subtypes (A, B, and C) have been identified.⁷¹⁻⁷³ The cellular response to activation of these receptor subtypes is mediated by several different molecular mechanisms (Table 9.5). Physiological responses have been determined in transgenic or “knockout” animals, but specific cellular responses associated with each of the receptor subtypes have not been clearly defined. The α_{2A} receptors mediate sedation, supraspinal analgesia, and centrally mediated bradycardia and hypotension, whereas the α_{2B} receptors mediate the initial surge in vascular resistance and reflex bradycardia. The α_{2C} receptors mediate the hypothermia that accompanies administration of α_2 -agonists. Neurotransmitter release is modulated primarily by presynaptic α_{2A} receptors, and spinal analgesia appears to be mediated by both α_{2B} and α_{2C} receptors. Subtype selective agonists are not currently available, but α_{2A} selective agonists with fewer vascular side effects could potentially be developed.

In contrast to the physiological effects mediated by α_2 receptors, activation of α_1 receptors produces arousal, excitement, and increased locomotor activity in animals.^{74,75} These behaviors are also observed after administration of excessive doses of less selective α_2 -agonists and after accidental intracarotid injection. Excitement and muscle rigidity occur in dogs administered xylazine IM at high doses (4 to 8 mg/kg).⁷⁶ Similarly, excitement,

Table 9.5. Anatomical location, cellular response, and physiological response associated with different α_2 -receptor subtypes

Receptor (G Protein)	Anatomical Location	Cellular Response	Physiological Response
α_{2A} ($G_{i/o}$)	Cerebral cortex, locus caeruleus, and platelets	Inhibit AC activity and decrease cAMP Increase potassium conductance Decrease calcium conductance	Sedation and supraspinal analgesia Centrally mediated bradycardia and hypotension
α_{2B} ($G_{i/o}$)	Spinal cord (dorsal root ganglia) and vascular endothelium	Activate PLC and increase IP ₃ , DAG, and cytosolic calcium	Spinal analgesia Vasoconstriction and peripherally mediated reflex bradycardia
α_{2C} ($G_{i/o}$)	Spinal cord (dorsal root ganglia)		Spinal analgesia Hypothermia and modulation of dopaminergic activity

AC, adenylate cyclase; cAMP, cyclic adenosine monophosphate; DAG, diacylglycerol; IP₃, inositol triphosphate; PLC, phospholipase C.

seizures, and muscle rigidity occur in horses after intracarotid injection of xylazine.⁷⁷ This paradoxical response appears to be more common after administration of α_2 -agonists that have some affinity for α_1 receptors (xylazine), but can occur in animals given toxic doses of more selective agonists.⁷⁸ Activation of central α_1 receptors can also antagonize the sedative effects of selective α_2 -agonists.^{79,80} Receptor binding or selectivity ratios (α_2/α_1) for xylazine, detomidine, romifidine and medetomidine are 160:1, 260:1, 340:1, and 1620:1, respectively.^{81,82}

As with acepromazine, the clinical use of α_2 -agonists is usually restricted to healthy animals. α_2 -Agonists can be used alone or in combination with opioids to provide sedation for diagnostic and minor surgical procedures. α_2 -Agonists can also be used in combination with ketamine to provide anesthesia for brief surgical procedures. Perioperatively, α_2 -agonists are used at lower doses, alone or in combination with opioids, to produce sedation and analgesia required for catheter placement, to reduce the amount of injectable anesthetic (e.g., ketamine, thiopental, or propofol) required to induce anesthesia, and to reduce the amount of inhalational anesthetic (e.g., halothane or isoflurane) required to maintain anesthesia.⁶⁷ α_2 -Agonists also potentiate the effects of other analgesic drugs (opioids and local anesthetics) and attenuate the stress response associated with surgical trauma. Postoperatively, low doses of α_2 -agonists can be used to facilitate recovery from anesthesia in both small and large animals.

In small animals, the perioperative use of α_2 -agonists has been controversial.^{83,84} Certainly, the initial vasoconstriction and reflex bradycardia induced by administration of α_2 -agonists are problematic. However, at low doses, these cardiovascular effects are not as pronounced nor as long in duration and are well tolerated by healthy animals. Preoperatively, anticholinergics can be administered with α_2 -agonists to prevent bradycardia. α_2 -Agonists also dramatically reduce the amount of thiopental or propofol required to induce anesthesia, and the amount of isoflurane required to maintain anesthesia.^{85–87} Given that all of these anesthetics have a very narrow therapeutic range and produce dramatic effects on myocardial function, the reduction in dose achieved by administering α_2 -agonists preoperatively significantly reduces the adverse cardiovascular effects associated

with administration of most general anesthetics. Isoflurane administration also produces marked vasodilation and significant reductions in arterial pressure at concentrations normally required to induce and maintain anesthesia.⁸⁸ In dogs, concurrent administration of α_2 -agonists initially increases vascular tone and attenuates the vasodilation and reduction in arterial pressure induced by high concentrations of isoflurane.^{89,90} As a result, perioperative administration of α_2 -agonists attenuates the vasodilatory effects of isoflurane by enhancing vascular tone. In sharp contrast, administration of acepromazine exacerbates vasodilation and the reduction in arterial pressure induced by isoflurane (Fig. 9.5).⁴¹

Some patients may be refractory to the sedative effects of α_2 -agonists. Failure to achieve optimal sedation with α_2 -agonists is often due to preexisting stress, fear, excitement, and pain. All of these conditions increase endogenous catecholamine levels and can interfere with reductions in excitatory neurotransmitter release induced by administration of α_2 -agonists. Sedation is consistently achieved when xylazine or another α_2 -agonist is given to calm patients in quiet surroundings with minimal environmental stimuli. In most species, sedation is even more reliable when α_2 -agonists are administered in combination with opioids.

Concerns have been raised about the potential for α_2 -agonists to sensitize the myocardium to epinephrine-induced arrhythmias.⁴⁸ Initial studies reported that high doses of xylazine facilitate the development of reentrant ventricular arrhythmias (premature depolarizations and tachycardia) in dogs anesthetized with thiopental and halothane—two drugs that dramatically sensitize the myocardium to epinephrine.^{46,91} Subsequent studies in dogs anesthetized with halothane or isoflurane and administered lower doses of xylazine or medetomidine showed that α_2 -agonists do not facilitate the development of reentrant ventricular arrhythmias.^{47,92–94} Further, the decrease in sympathetic tone and increase in parasympathetic tone induced by the administration of selective α_2 -agonists appear to attenuate the development of epinephrine-induced arrhythmias in dogs.⁹⁵

In a 1998 survey of veterinarians in Ontario, an increase in the incidence of anesthetic complications was associated with the use of xylazine in small animals.⁹⁶ Failure to appreciate the dra-

matic reduction in anesthetic requirements produced by preoperative administration of xylazine and subsequent administration of a relative overdose of injectable or inhalational anesthetic may have contributed to the increased risk reported in this study. Given that patient monitoring standards were extremely lax a decade ago, failure to recognize and treat significant bradyarrhythmias could have been a factor, as well. More recent studies have found that administration of relatively low doses of medetomidine alone or in combination with opioids is associated with occasional bradyarrhythmias (sinus bradycardia and AV block) and a low incidence of severe anesthetic complications. Glycopyrrolate administration decreases the incidence and severity of bradyarrhythmias in healthy older (≥ 5 years old) dogs given medetomidine and butorphanol IM as preanesthetics, and only 1 of 88 dogs developed complications severe enough to require reversal with atipamezole.⁹⁷ Similarly, no anesthetic deaths and only 13 protocol modifications were recorded after repeated sedation of 136 geriatric cats (1862 procedures) and 541 geriatric dogs (6329 procedures) with medetomidine, butorphanol, and glycopyrrolate to facilitate radiation therapy.⁹⁸ Based on the latter studies, it appears that low doses of α_2 -agonists can be used safely in older dogs and cats, provided that cardiopulmonary function is evaluated carefully before drug administration and monitored closely afterward.

Xylazine

Although its mechanism of action was unknown at the time of its introduction into clinical practice, xylazine was the first α_2 -agonist to be used by veterinarians. The drug was synthesized in West Germany in 1962 for use as an antihypertensive in people but was found to have potent sedative effects in animals. The chemical name for xylazine is 2-(2,6-dimethylphenylamino)-4H-5,6-dihydro-1,3-thiazine hydrochloride (Fig. 9.6). Initially, the drug was used as a sedative in cattle and other ruminants in Europe. In the early 1970s, reports of xylazine's utility as an anesthetic adjunct began appearing in American and European veterinary literature.^{99–109} These reports documented the effectiveness of xylazine in eliminating muscular hypertonicity in dogs and cats given ketamine, and in producing rapid, predictable sedation, analgesia, and muscle relaxation in horses and cattle after IV administration. It was also evident that there was tremendous variation in the dose of xylazine required to produce equivalent levels of sedation and analgesia in different species. In 1981, the sedative and analgesic effects of xylazine were definitively linked to activation of central α_2 -adrenergic receptors.^{110,111}

Pharmacokinetics The pharmacokinetics of xylazine have been determined in cattle, horses, and dogs after its IV and IM injection at doses of 0.2, 0.6, and 1.4 mg/kg, respectively.¹¹² After IV administration, the elimination half-life is 36, 50, and 30 min in cattle, horses, and dogs, respectively. After IM administration, peak plasma concentrations are reached within 15 min, and the elimination half-life is 58 and 35 min in horses and dogs, respectively. In cattle given xylazine IM (0.35 mg/kg), the drug and its metabolites are undetectable in tissues after 3 days and in milk after 12 h.¹¹³ Despite the rapid clearance of xylazine from tissues

and milk, the United States Food and Drug Administration has refused to approve its use in food-producing animals.¹¹⁴ This refusal underscores the failure to address animal-welfare issues associated with performing surgical procedures in the absence of appropriate sedation and analgesia, and legitimate human-safety concerns associated with restraint and handling of unsedated animals. Xylazine is approved for use in ruminants in Canada and several other countries around the world.

Pharmacodynamics In most species, the onset of sedation and analgesia is rapid after parenteral administration of xylazine. In dogs, peak sedation and analgesia develop within 15 min and persist for 1 to 2 h after administration of xylazine (2.2 mg/kg IM).¹¹⁵ In horses, peak sedation and analgesia develop within 5 min, persist for the next 30 min, and then subside over the next 30 min after administration of xylazine (1.1 mg/kg IV).^{82,103,108,116} At a lower dose of xylazine (0.4 mg/kg IV), peak sedation develops

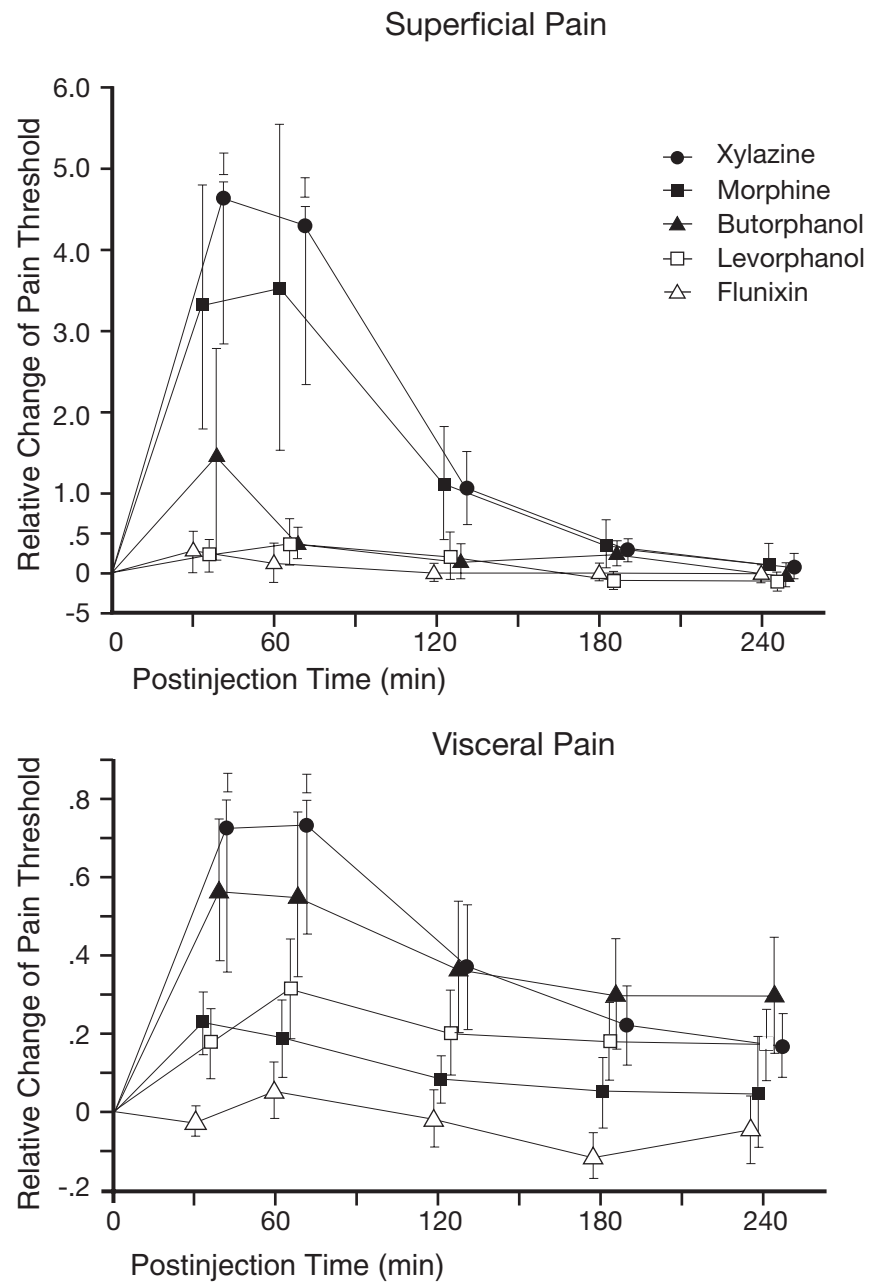

Fig. 9.7. Somatic and visceral analgesic effects of xylazine, morphine, butorphanol, levorphanol, or flunixin in ponies. With permission from Kalpravidh et al.¹¹⁹

with 10 min and then subsides over the next 20 min.¹¹⁷ Most clinical studies show that the sedative and analgesic effects of xylazine are comparable in duration and do not support the “conventional wisdom” that the analgesic effect is significantly shorter than the sedative effect. Further, xylazine has been reported to be more effective than either opioid agonists (meperidine, methadone, morphine, oxymorphone, or fentanyl), agonist-antagonists (pentazocine, butorphanol, or levorphanol), or nonsteroidal anti-inflammatories (flunixin) in relieving somatic and visceral pain in horses (Fig. 9.7).^{118,119}

Xylazine administration decreases injectable and inhalational anesthetic requirements dramatically in several species. Intramuscular administration of xylazine (2.2 mg/kg) decreases the dose of thiopental required to induce anesthesia in and cats and

dogs by 80%.^{120,121} Although this dose of xylazine is relatively high and not recommended, this study illustrates the striking reduction in thiopental requirements that can be achieved when large doses of α_2 -agonists are given as preanesthetics. Similarly, administration of xylazine (0.8 mg/kg IM) decreases the dose of propofol required to induce anesthesia in dogs by over 50%.^{86,122} Perioperative administration of xylazine also reduces halothane and isoflurane requirements in animals. In dogs, administration of xylazine (1.1 mg/kg IV) decreases the MAC of halothane by 38%, an effect that was reversed by administration of an α_2 -antagonist (tolazoline).¹²³ In horses, administration of xylazine (0.5 mg/kg IV) decreases the MAC of halothane and isoflurane by 20% and 25%, respectively (Fig. 9.8).^{124,125} Given the results of these studies, doses of injectable and inhalational anesthetics

Fig. 9.8. Effects of xylazine (0.5 mg/kg intravenously) on the minimum alveolar concentration (MAC) of halothane or isoflurane in horses. With permission from Bennett et al.¹²⁴

should be significantly reduced when xylazine is administered perioperatively to both small and large animals.

Intravenous administration of xylazine induces a brief period of hypertension and reflex bradycardia, followed by a longer-lasting decrease in cardiac output and arterial pressure. In most species, cardiac output decreases by 30% to 50% and arterial pressure by 20% to 30%.^{42,103,126,127} The initial hypertensive phase is caused by activation of peripheral postsynaptic α_2 receptors, which produces vascular smooth muscle contraction and vasoconstriction. In horses, administration of a low dose of xylazine (0.4 mg/kg IV), produces less dramatic changes in arterial pressure, heart rate, and cardiac output.¹¹⁷ Pretreatment with a calcium-channel blocker such as nifedipine dampens the initial increase in arterial pressure in dogs anesthetized with halothane.¹²⁸ In dogs, xylazine administration is associated with a decrease in splenic weight, which suggests a decrease in systemic vascular capacity.¹²⁹ Subsequent reductions in arterial pressure are due to decreases in sympathetic tone resulting from activation of central and peripheral (presynaptic autoreceptors) α_2 receptors. Xylazine administration also decreases heart rate by enhancing vagal tone and baroreceptor reflexes.¹³⁰ In contrast to the cardiovascular effects observed after IV injection, increases in arterial pressure and vascular resistance are not as dramatic after IM administration of xylazine in dogs and horses.^{109,126} In calves given xylazine IM, hemodynamic effects are characterized by a 20% to 30% decrease in heart rate and cardiac output, and a 10% decrease in arterial pressure—without an initial increase in pressure.¹³¹ These results suggest that IM administration of xylazine in calves does not cause transient vasoconstriction and an increase in arterial pressure to the same degree as it does in dogs and horses.

When xylazine is administered with ketamine, decreases in heart rate and cardiac output are partially offset. Ketamine administration increases heart rate and cardiac output, but arterial pressure, systemic vascular resistance, and myocardial oxygen con-

sumption increase, as well.^{127,132} Because of these acute cardiovascular changes, xylazine-ketamine combinations should be reserved for use in healthy patients and not be used in patients with myocardial disease or reduced cardiopulmonary reserve.^{127,132,133}

Sinus bradycardia and AV block are the arrhythmias that are encountered most commonly after xylazine administration.^{126,127} Development of these arrhythmias is a normal physiological response to the increase in vagal tone induced by xylazine. Several studies have also assessed the ability of xylazine, administered alone or in combination with other anesthetic drugs, to sensitize the myocardium to the development of epinephrine-induced arrhythmias.⁴⁸ This is usually accomplished by measuring the amount of epinephrine required to induce premature ventricular depolarizations, and this amount is called the *arrhythmogenic dose of epinephrine* (ADE). In an initial study using a more severe test (the epinephrine fibrillation threshold), premedication with xylazine decreased the dose of epinephrine required to induce fibrillation in dogs anesthetized with thiamylal and halothane, whereas premedication with acepromazine had the opposite effect.⁴⁶ In a later study, ketamine administration reportedly decreased the ADE more than did xylazine administration, and coadministration decreased the ADE more than either drug alone.¹³⁴ Studies using a saline-controlled ADE model to reduce experimental error associated with repeated epinephrine administration demonstrated no change in the ADE after IM administration of xylazine or medetomidine in dogs anesthetized with halothane or isoflurane.^{92,93} From these studies, it is clear that, if anesthetic-induced changes in the ADE (arrhythmogenicity) are a concern, selection of the inhalational anesthetic (halothane vs. isoflurane) is far more critical than selection of an α_2 -agonist as the preanesthetic.

Although respiratory rate decreases after administration of clinically recommended doses of xylazine, arterial pH, PO_2 , and PCO_2 remain virtually unchanged in cats, dogs, and horses.^{42,103,117,126,127,135} Decreases in respiration rate are ac-

accompanied by increases in tidal volume, which keep alveolar ventilation and arterial blood-gas values relatively constant.^{127,136} In horses suffering from recurrent obstructive pulmonary disease (heaves), xylazine administration decreases pulmonary resistance, increases dynamic compliance, and may have some therapeutic value.¹³⁷ In contrast, when a large dose of xylazine (1.0 mg/kg IV) is administered to healthy dogs, minute ventilation, physiological dead space, oxygen transport, venous PO₂ and oxygen content, and oxygen consumption decrease, and tidal volume increases.¹²⁷ Xylazine administration also increases airway resistance and resonant frequency in calves.¹³⁸ Intravenous administration of xylazine to horses (0.5 to 1.0 mg/kg) and sheep (0.02 to 0.05 mg/kg) anesthetized with halothane increases airway pressure and decreases arterial PO₂.^{43,139} Similarly, arterial PO₂ decreases after administration of xylazine (0.05 to 0.3 mg/kg IV) to conscious sheep.^{140–142} The results of these studies suggest that the decrease in arterial PO₂ is produced by activation of peripheral α_2 receptors and a perfusion-related imbalance between ventilation and the pulmonary circulation. Additionally, the dramatic decrease in arterial PO₂ observed in sheep after administration of xylazine may be primarily caused by a pulmonary inflammatory response that is confined to ruminants with a unique population of intravascular macrophages.^{143,144} Thus, although the bulk of the evidence indicates a minimal detrimental effect on respiratory function in most domestic animals, caution is advised when administering xylazine or other α_2 -agonists to small ruminants, when administering high singular or cumulative doses to any species, or when combining α_2 -agonists with injectable or inhalational anesthetics that produce significant cardiopulmonary depression.

Alterations in gastrointestinal function after xylazine administration have been reported in several species. Excessive salivation can occur in animals that have not been given anticholinergics. In dogs, gastroesophageal sphincter pressure decreases, which may increase the incidence of gastroesophageal reflux.⁵⁰ Most cats and 10% to 20% of dogs vomit shortly after IM administration of xylazine. Emesis may be linked to activation of central α_2 receptors because prior administration of yohimbine—but not cholinergic, dopaminergic, histaminergic, serotonergic, or opioid receptor antagonists—prevents emesis.¹⁴⁵ Occasionally, acute gastric distension can occur in large dogs (>25 kg) given xylazine IV or IM.¹⁴⁶ This distension may be caused by aerophagia or by the parasympatholytic effects of xylazine on the gastrointestinal tract, leading to atony and accumulation of gas.

Xylazine administration decreases gastrointestinal motility and prolongs gastrointestinal transit time in several species. In dogs, it decreases gastrin secretion and gastrointestinal motility, and prolongs gastrointestinal transit time.^{147–149} In sheep and cattle, cyclical contractions of the reticulum and rumen are inhibited by administration of xylazine and other α_2 -agonists, and administration of α_2 -antagonists (tolazoline or yohimbine) antagonizes these gastrointestinal effects.¹⁵⁰ In horses, motility of the cecum and colon are inhibited by administration of xylazine or xylazine-butorphanol, and normal bowel myoelectrical activity returns slowly after administration of xylazine-ketamine.^{151,152} However, intestinal smooth muscle relaxation and analgesia me-

diated by activation of central and peripheral α_2 receptors also play an important role in the relief of visceral pain.¹⁵³ Indeed, xylazine is reportedly more effective than either opioids or nonsteroidal anti-inflammatory drugs in relieving visceral pain in ponies and horses.^{119,154} In addition to increasing the visceral pain threshold, xylazine administration effectively sedates and calms painful horses and helps to prevent self-induced trauma. As expected, these desirable modifications in behavior are also accompanied by a decrease in intestinal motility and blood flow. This decrease in intestinal blood flow is disproportionate to the total decrease in cardiac output, which suggests that α_2 receptors mediate vasoconstriction within the intestinal vasculature.¹⁵⁵ Additionally, administration of an α_2 -antagonist (yohimbine) attenuates ileus and hypoperfusion associated with endoxemia in horses, which provides further evidence of the important role of α_2 receptors in the regulation of gastrointestinal function.¹⁵⁶

Urine output increases after xylazine administration in cattle, horses, ponies, and cats.^{157–160} Urine specific gravity and osmolality also decrease in horses and ponies.^{158,159} Although urethral closure pressure decreases in both male and female dogs given xylazine, normal micturition reflexes are maintained.¹⁶¹ Decreases in urethral closure pressure are coupled to a reduction in electromyographic activity of the urethral sphincter, but xylazine administration does not appear to alter the detrusor reflex in dogs.^{162,163}

Transient hypoinsulinemia and hyperglycemia have been reported in several species sedated with xylazine or that are anesthetized using a regimen that incorporates xylazine.^{164–169} Hyperglycemia results from α_2 -receptor-mediated inhibition of insulin release from pancreatic beta cells, and the magnitude and duration of these actions appear to be dose dependent.¹⁶⁷ Other hormonal changes induced by xylazine include transient alterations in growth hormone, testosterone, prolactin, antidiuretic hormone, and follicle-stimulating hormone levels.

Myometrial tone and intrauterine pressure increase after xylazine administration in cattle.¹⁷⁰ In pregnant sheep, myometrial activity doubled for 1 h after xylazine administration, whereas fetal diaphragmatic activity is reduced.¹⁷¹ In horses, administration of equipotent doses of xylazine, detomidine, or romifidine produces comparable increases in intrauterine pressure.¹⁷² Clinically, α_2 -agonists have been administered during all stages of pregnancy in several domestic species but have not been definitively associated with an increased incidence of reproductive complications.⁶³ α_2 -Agonists also reduce cardiac output and could impair fetal oxygen delivery. Although administration of xylazine and other α_2 -agonists has not been linked definitively to abortion and premature labor, the indiscriminate use of these drugs in pregnant animals during the last trimester is not advised.

Xylazine administration causes mydriasis, which may be due to either central inhibition of parasympathetic input to the iris, direct activation of α_2 receptors located in the iris, or both.^{173,174} Xylazine administration also lowers intraocular pressure in rabbits, cats, and monkeys by reducing sympathetic tone and decreasing aqueous flow.¹⁷⁵ More importantly, administration of xylazine to dogs and cats can cause vomiting, which increases intraocular pressure dramatically.

Xylazine can also be administered epidurally to horses and cattle. In addition to an analgesic effect mediated by activation of spinal α_2 receptors (heteroreceptors), xylazine has a significant membrane-stabilizing or local anesthetic effect when applied to neurons or nerve fibers. This effect is characterized by a reduction in conduction velocity and blockade of action potentials.¹⁷⁶ Ionophoretic application of xylazine to rat cortical neurons suppresses spontaneous firing rates, and this effect is not blocked by an α_2 -antagonist.¹⁷⁷ The results of these studies suggest that the action of locally applied xylazine is caused in part by a local anesthetic effect.

In horses, xylazine can be administered epidurally alone or in combination with a local anesthetic. When comparing xylazine and lidocaine at equal doses and volumes in ponies, xylazine induces more profound and longer-lasting analgesia after epidural administration.¹⁷⁸ Analgesia induced by epidural administration of xylazine does not cause the same degree of motor nerve paralysis as that caused by administration of local anesthetics.¹⁷⁹ In horses, the duration of epidural analgesia can be significantly prolonged by coadministration of lidocaine and xylazine, and is not associated with enhanced neurotoxicity or dramatic changes in cardiopulmonary function.¹⁸⁰

In cattle, epidural administration of xylazine produces longer-lasting analgesia than does epidurally administered lidocaine or IM administered xylazine.¹⁸¹ Cardiopulmonary and GI effects of epidural administration of xylazine (0.05 mg/kg) include decreases in heart rate, respiratory rate, and rumen motility.¹⁸² Intravenous administration of tolazoline (0.3 mg/kg) rapidly antagonizes these effects but does not alter sedative and regional analgesic effects.¹⁸² In sheep, intrathecal administration of xylazine or clonidine produces dose-dependent analgesia of the forelimbs, and analgesia is abolished by intrathecal administration of an α_2 -antagonist (idazoxan).¹⁸³ These results indicate that xylazine produces part of its analgesic effect through activation of spinal α_2 receptors. This mechanism of analgesic action is further substantiated by the prolongation of analgesia observed after coadministration of morphine and a selective α_2 -agonist (medetomidine) epidurally.¹⁸⁴

Clinical Uses The clinical uses of xylazine are usually restricted to healthy animals. There is considerable variation among species in the dose of xylazine required to produce an equivalent sedative effect (Table 9.6). Generally, the lowest dose that will provide the required degree of sedation is administered to limit cardiovascular side effects. Xylazine is currently approved for use as a sedative in cats, dogs, horses, deer, and elk in the United States, and for cats, dogs, horses, and cattle in Canada. Xylazine—especially the 10% (100 mg/mL) solution—should be handled carefully to avoid accidental self-administration. If the drug is absorbed through mucous membranes or administered IM, profound sedation and bradycardia can occur. Medical treatment should be sought immediately, and the package insert should be given to the attending physician.

In dogs and cats, xylazine is used alone or in combination with opioids to provide sedation and analgesia for diagnostic and minor surgical procedures. The drug is also used in combination

Table 9.6. Xylazine doses for several domesticated species

Species	Dose
Cats	0.25–0.5 mg/kg IV
	0.5–1.0 mg/kg IM
Dogs	0.25–0.5 mg/kg IV
	0.5–1.0 mg/kg IM
Horses	0.5–1.0 mg/kg IV
	1.0–2.0 mg/kg IM
Cattle	0.05–0.1 mg/kg IV
	0.1–0.2 mg/kg IM
Sheep	0.05–0.1 mg/kg IV
	0.1–0.2 mg/kg IM
Goats	0.05–0.1 mg/kg IV
	0.1–0.2 mg/kg IM
Llama	0.1–0.2 mg/kg IV
	0.2–0.4 mg/kg IM

IM, intramuscularly; IV, intravenously.

with ketamine, ketamine-diazepam, or tiletamine-zolazepam to provide anesthesia for brief surgical procedures. As a preanesthetic, xylazine is used alone or in combination with opioids to facilitate placement of IV catheters and to decrease requirements for injectable and inhalational anesthetics. Anticholinergics (atropine and glycopyrrolate) can be administered with xylazine to prevent development of severe bradyarrhythmias perioperatively. Small doses of xylazine (0.1 mg/kg) can be administered postoperatively to smooth recovery and to potentiate the effects of other analgesic drugs (opioids), provided that patients are hemodynamically stable. Xylazine can be given IV or IM, but the IM route is preferred because cardiovascular side effects are reduced. Intramuscular doses for healthy dogs and cats range from 0.5 to 1.0 mg/kg.

In horses and cattle, xylazine is used alone or in combination with butorphanol to provide sedation and analgesia for diagnostic and surgical procedures. Xylazine can also be used as a preanesthetic before induction of anesthesia with ketamine, ketamine-diazepam, ketamine-guaifenesin, or thiopental-guaifenesin. In horses anesthetized with halothane, isoflurane, or sevoflurane, small doses of xylazine (0.1 to 0.2 mg/kg) can be given IV during the maintenance and recovery phases to reduce anesthetic requirements and smooth recovery, respectively. Xylazine can be also be used in combination with ketamine and guaifenesin for total IV anesthesia. After induction of anesthesia with xylazine and ketamine, anesthesia can be maintained with a combination of xylazine, ketamine, and guaifenesin (“triple drip”) for approximately 1 h.

As a general rule, cattle usually require one-tenth of the dose of xylazine that horses require to produce an equivalent level of sedation. For sedation and analgesia alone or in combination with butorphanol, IV doses for horses range from 0.2 to 0.8 mg/kg, and those for cattle range from 0.02 to 0.08 mg/kg. As a preanesthetic before induction with an injectable anesthetic and maintenance with an inhalational anesthetic, IV doses for horses range from

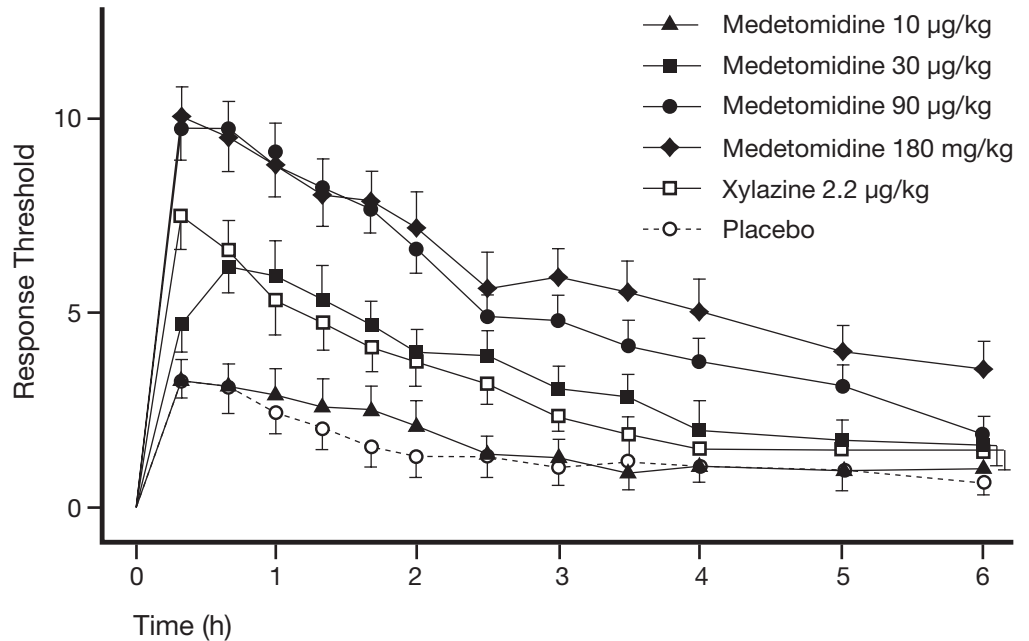

Fig. 9.9. Analgesic effects of intramuscular administration of medetomidine in dogs. Higher response threshold equates with improved analgesic action. With permission from Vainio et al.¹¹⁵

0.4 to 0.8 mg/kg, and those for cattle range from 0.04 to 0.08 mg/kg. As a preanesthetic before induction of anesthesia with ketamine or ketamine-diazepam, an IV dose of 1.0 mg/kg is typically administered to horses and a dose of 0.1 mg/kg is given to cattle. Xylazine can be administered to healthy foals and calves over 1 month of age but is not usually given to neonates. Doses of xylazine should be decreased in very large animals (draft horses and bulls) and in breeds with increased sensitivity to the drug (Brahman and Brahman crosses).⁶³ Xylazine doses should also be decreased in sick or debilitated animals but may need to be increased in excited animals. In horses or cattle that are fractious and difficult to restrain, xylazine can be administered IM at a dose of 1.0 to 2.0 mg/kg or 0.1 to 0.2 mg/kg, respectively.

Sudden death has been reported in horses after xylazine administration.⁷⁷ Excitement, violent seizures, and collapse can occur after accidental intracarotid injection or after IV administration of an overdose. Seizure activity that occurs immediately after intracarotid administration of xylazine is probably mediated by the activation of central α_1 receptors.^{74,75} After intracarotid injection, pharmacodynamic effects extend beyond the “window of sedation” typically achieved when recommended doses of xylazine are administered IV or IM. Seizures caused by accidental intracarotid injection of xylazine can usually be controlled by IV administration of thiopental or thiopental-guaifenesin to effect. Once seizures are controlled, the horse should be intubated and supplemental oxygen administered.⁶³

Medetomidine

This is the most widely used α_2 -agonist in small animals. The chemical name for the drug is (\pm)-4-(1-[2,3-dimethylphenyl]ethyl)-1H-imidazole monohydrochloride (Fig. 9.6). It is more potent than xylazine and is dosed on a microgram-per-kilogram basis rather than a milligram-per-kilogram basis. In North America, medetomidine is approved for use in dogs as a sedative-

analgesic. Studies on the sedative, analgesic, and cardiopulmonary effects of medetomidine in cats have also been reported.¹⁸⁵⁻¹⁸⁷

Pharmacokinetics Medetomidine is a highly selective α_2 -agonist that is supplied as a racemic mixture of two optical enantiomers. Dexmedetomidine is the active enantiomer, and levomedetomidine has no apparent pharmacological activity.¹⁸⁸⁻¹⁹² Shortly after medetomidine was approved for use in dogs as a sedative-analgesic in North America, dexmedetomidine was approved for use in people as a postoperative sedative in the United States. As expected, dexmedetomidine is approximately twice as potent as the racemic mixture that is available for use in animals. In dogs and cats, medetomidine has a rapid onset of action and can be administered IV or IM. After IM administration, the drug is rapidly absorbed, and peak plasma concentrations are reached within 30 min. The elimination half-life of medetomidine (80 µg/kg) after IV and IM administration in dogs and after IM administration in cats is 0.97, 1.28, and 1.35 h, respectively.¹⁹³ At this dose, the apparent volume of distribution after IV and IM administration in dogs and after IM administration in cats is 2.8, 3.0, and 3.5 L/kg, respectively.¹⁹³ Therapeutic effects of medetomidine are terminated by removal from target tissues, which parallels clearance of the drug from plasma. Elimination occurs mainly by biotransformation in the liver, and inactive metabolites are excreted in the urine.

Pharmacodynamics Onset of sedation, analgesia, and muscle relaxation is rapid after IM administration of medetomidine to dogs and cats, and the intensity and duration of these effects depend on dose. When medetomidine is given IM to dogs at a dose of 30 µg/kg, significant sedation is apparent within 5 min and persists for 1 to 2 h.¹¹⁵ Similarly, when medetomidine is given to cats at a dose of 50 µg/kg, significant sedation is apparent within 15 min and persists for 1 to 2 h.¹⁸⁶ At these doses, analgesia peaks within 30 min and persists for 1 to 2 h (Fig. 9.9).^{115,186} In

dogs, sedation induced by IM administration of medetomidine at a dose of 30 µg/kg is comparable in intensity to that induced by IM administration of xylazine at a dose of 2.2 mg/kg but lasts longer.¹¹⁵ Medetomidine has also been used as a sedative-analgesic and as a preanesthetic in horses, but, even at low doses (5 to 10 µg/kg IV), ataxia is a significant problem.^{117,194,195} Sedation following IV administration of a 10-µg/kg dose of medetomidine in horses is comparable to that induced by a 1-mg/kg IV dose of xylazine.¹⁹⁴

Medetomidine administration decreases injectable and inhalational anesthetic requirements dramatically in several species. Premedication with medetomidine decreases induction doses of thiopental and propofol by over 50% in dogs. Administration of medetomidine IM at doses of 10, 20, and 40 µg/kg decreases the amount of thiopental required for intubation to 7.0, 4.5, and 2.4 mg/kg, respectively.^{85,196} Similarly, administration of medetomidine IM at a dose of 20 µg/kg decreases the amount of propofol required for intubation to 1.8 mg/kg.¹²² Administration of medetomidine IM also appears to reduce the dose of ketamine required to induce anesthesia in dogs and cats.^{197–199} Premedication with medetomidine also reduces halothane and isoflurane requirements. Administration of medetomidine IV at a dose of 10 µg/kg is reported to decrease the MAC of halothane by 90%.²⁰⁰ In contrast, administration of medetomidine IV at a dose of 30 µg/kg decreased the MAC of isoflurane by only 47%.⁸⁷ Additionally, administration of medetomidine IM at a dose of 8 µg/kg consistently reduced the bispectral index value (an index of anesthetic depth) in dogs anesthetized with isoflurane (1.0, 1.5, and 2.0 MAC).²⁰¹

As with other α_2 -agonists, medetomidine administration produces dose-dependent changes in cardiovascular function.²⁰² Cardiovascular effects are best described in two phases: an initial peripheral phase characterized by vasoconstriction, increased blood pressure, and reflex bradycardia; and a subsequent central phase characterized by decreased sympathetic tone, heart rate, and blood pressure. Occasionally, AV blockade occurs secondary to the initial increase in blood pressure, and reflex (baroreceptors) increase in vagal tone. In conscious dogs, mean arterial pressure increases transiently, and heart rate and cardiac index decrease by approximately 60% after IV administration of medetomidine at doses ranging from 5 to 20 µg/kg.²⁰² At these doses, changes in mean arterial pressure, central venous pressure, and vascular resistance are dose dependent, whereas changes in heart rate and cardiac index are not. In conscious cats, mean arterial pressure does not appear to change, and heart rate and cardiac index decrease by approximately 50% after IM administration of medetomidine at a dose of 20 µg/kg (Fig. 9.10).¹⁸⁷ In conscious horses, IV administration of a low dose of medetomidine (4 µg/kg) produces less dramatic changes in arterial pressure, heart rate, and cardiac output.¹¹⁷ In cats anesthetized with isoflurane (2%), mean arterial pressure increases from 77 to 122 mm Hg, heart rate decreases from 150 to 125 beats/min, and mean arterial flow decreases from 578 to 325 mL/min, 20 min after the IM administration of medetomidine at a dose of 10 µg/kg.²⁰³ As with xylazine, cardiovascular responses to medetomidine administration appear to be attenuated in animals anesthetized with isoflurane.^{89,90} Cerebral vasodilation is attenuated

by the IV administration of low doses of dexmedetomidine (0.5, 1.0, and 2.0 µg/kg) in dogs anesthetized with isoflurane or sevoflurane (0.5, 1.0, and 1.5 MAC).²⁰⁴ In dogs anesthetized with isoflurane for ovariohysterectomy, heart rate is lower but blood pressure better maintained with medetomidine premedication (20 µg/kg IM) when compared with acepromazine premedication (0.05 mg/kg IM) (Fig. 9.11).²⁰⁵ In conscious animals, the decrease in cardiac output is caused primarily by the decrease in heart rate and increase in vascular resistance, and not by a direct depression of myocardial contractility.^{206,207} Peripheral cardiovascular effects are most pronounced when α_2 -agonists are administered IV at high doses, and these effects can be reduced by administering α_2 -agonists IM at low doses.^{126,208} Although cardiac output decreases after medetomidine or dexmedetomidine administration, blood flow to the heart, brain, and kidneys is maintained by redistribution of flow from less vital organs and tissues.²⁰⁹

Medetomidine administration has little effect on pulmonary function. Respiratory rate and minute ventilation decrease after medetomidine administration, but this decrease in minute ventilation appears to coincide with a decrease in carbon dioxide production, and arterial blood-gas values do not change. In conscious dogs, IV administration of medetomidine (5 to 10 µg/kg) decreases the neurorespiratory response (ventilatory drive) to increases in inspired carbon dioxide.²¹⁰ In another study in conscious dogs and cats, IM administration of medetomidine at doses of 40 and 20 µg/kg, respectively, does not alter arterial pH, PCO₂, and PO₂.^{187,211} Similarly, IV administration of medetomidine (4 µg/kg) does not alter arterial pH, PCO₂, and PO₂ in conscious horses.¹¹⁷ The IV administration of medetomidine (20 µg/kg) or dexmedetomidine (3 µg/kg) does not alter arterial blood-gas values and produces less depression of ventilatory drive than does isoflurane (1 MAC) in dogs.^{212,213} Parenteral administration of a low dose of dexmedetomidine (0.5 µg/kg) also appears to protect against bronchoconstriction induced by nebulization of histamine in dogs anesthetized with thiopental.²¹⁴

Medetomidine administration has significant effects on gastrointestinal function in animals. Vomiting occurs in 10% of dogs and over 50% of cats administered medetomidine IM at mean doses of 40 and 80 µg/kg, respectively.¹⁸⁵ Normally, this is not a problem and can be advantageous if owners or hospital staff fail to withhold food from patients before induction of anesthesia. However, the potential for development of aspiration pneumonia exists if a properly inflated, cuffed endotracheal tube is not in place. Vomiting also dramatically increases intraocular pressure, which is a potential problem for some patients with ocular injury or disease. Medetomidine administration decreases gastrin release and intestinal and colonic motility in dogs.^{149,215} These effects are mediated by activation of visceral α_2 receptors and inhibition of acetylcholine release.

Medetomidine administration has significant effects on renal and urogenital function in animals. In dogs, administration of medetomidine (10 to 20 µg/kg IV) decreases urine specific gravity and increases urine production for approximately 4 h.²¹⁶ Apparently, α_2 -agonists interfere with the action of antidiuretic hormone on the renal tubules and collecting ducts, which increases the production of dilute urine.^{217,218} Activation of α_1 re-

Fig. 9.10. Hemodynamic effects of intramuscular administration of medetomidine (20 µg/kg) in conscious cats. With permission from Lamont et al.¹⁸⁷

ceptors increases myometrial contractility, and activation of α_2 receptors has limited effects on uterine tone in most species. In dogs, IV administration of medetomidine at a dose of 20 µg/kg decreases electrical activity of the myometrium, and a dose of 40 µg/kg increases electrical activity in dogs during the last trimester of pregnancy.²¹⁹ Medetomidine administration also produces significant cardiovascular effects, and use of the drug in animals during the last trimester of pregnancy should be avoided.

Medetomidine administration has dramatic effects on endocrine function in animals. In dogs, IM administration of medetomidine (10 to 80 µg/kg) decreases plasma norepinephrine, epinephrine, and nonesterified fatty acid concentrations for up to 4 h, whereas cortisol and glucagon concentrations do not change.⁷⁶ Preoperative administration of α_2 -agonists also attenuates the stress response associated with surgical trauma. In dogs undergoing ovariohysterectomy, preoperative administration of medetomidine reduces catecholamine and cortisol concentrations post-

operatively.^{220,221} Similarly, preoperative administration of medetomidine (20 µg/kg IM) attenuates perioperative increases in norepinephrine, epinephrine, and cortisol concentrations to a greater degree than does acepromazine (Fig. 9.12).²⁰⁵ Administration of xylazine or medetomidine activates α_2 receptors on pancreatic beta cells and inhibits release of insulin for approximately 2 h.^{76,168,222} Although both drugs produce a comparable inhibition of insulin release, medetomidine produces a less dramatic change in plasma glucose concentrations.^{76,222} This difference may be due to a difference in selectivity for the α_2 receptor compared with the α_1 receptor. Xylazine, a less selective agonist, appears to increase plasma glucose concentrations directly by activating α_1 receptors and stimulating hepatic glucose production. Changes in catecholamine, nonesterified fatty acids, insulin, and glucose concentrations induced by administration of α_2 -agonists (xylazine or medetomidine) are reversed by administration of α_2 -antagonists (yohimbine or atipamezole).²²³

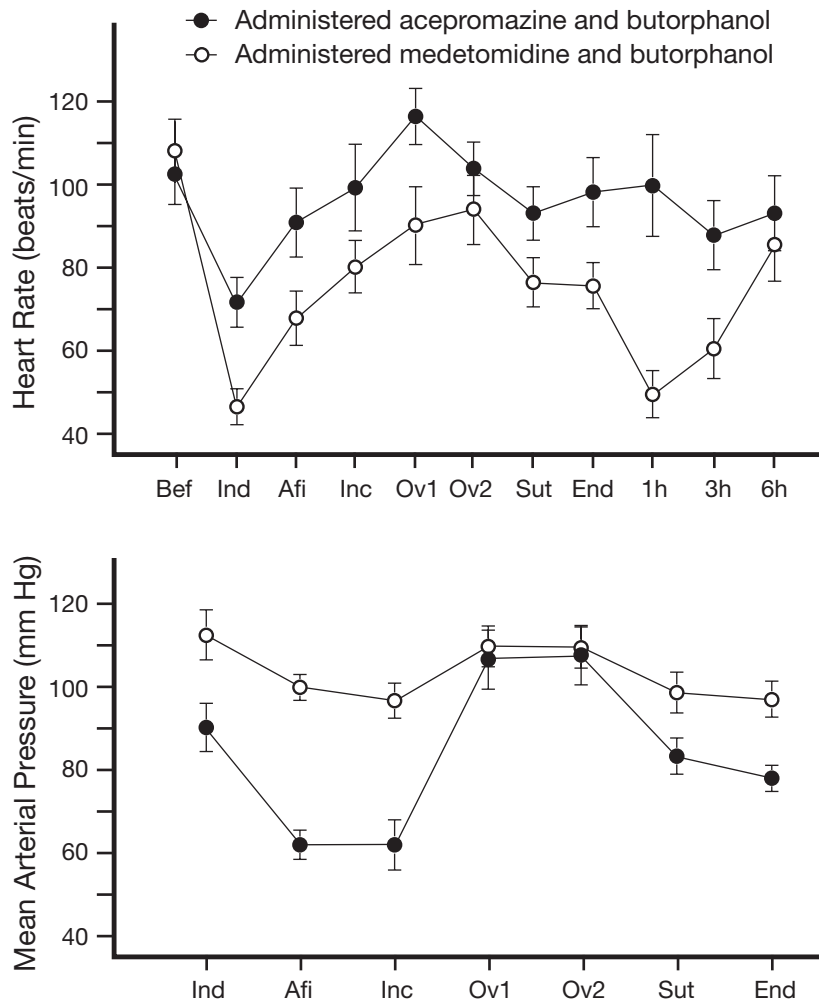

Fig. 9.11. Effects of preoperative intramuscular administration of medetomidine (20 $\mu\text{g}/\text{kg}$) or acepromazine (0.05 mg/kg) on heart rate and mean arterial pressure in dogs anesthetized with isoflurane for ovariectomy. Bef, before surgery; Ind, induction; Afi, after induction; Inc, abdominal incision; OV1, removal of ovary; OV2, removal of second ovary; Sut, abdominal suturing; End, end of surgery; and 1h, 3h, and 6h mean 1 h, 3 h, and 6 h after surgery. With permission from Vaisanen et al.²⁰⁵

Medetomidine administration has significant effects on pupillary diameter and intraocular pressure. Topical administration of medetomidine readily induces mydriasis and decreases intraocular pressure in rabbits and cats.^{224,225} In contrast, the IV administration of medetomidine to dogs reportedly induces miosis and does not alter intraocular pressure.²²⁶ Administration of medetomidine to dogs and cats can cause vomiting, which increases intraocular pressure dramatically.

Medetomidine administration also has significant effects on cerebral blood flow, intracranial pressure, and thermoregulation. In one study performed in spontaneously breathing dogs anesthetized with isoflurane (0.5 and 1.5 MAC), the administration of dexmedetomidine (10 $\mu\text{g}/\text{kg}$ IV) decreased cerebral blood flow but did not alter cerebral metabolic rate.²²⁷ In another study in mechanically ventilated dogs anesthetized with isoflurane (1.0 MAC), the administration of medetomidine (30 $\mu\text{g}/\text{kg}$ IV) increased cerebral perfusion pressure but did not change intracranial pressure.⁹⁰ Again, administration of medetomidine to dogs and cats can cause vomiting, which increases intracranial pressure dramatically. Decreases in body temperature are attributed to depression of the thermoregulatory center, muscle relaxation, and reduced shivering. In conscious dogs, only slight reductions

in body temperature (1°C over 1 h) are observed after IV administration of medetomidine at doses ranging from 1 to 20 $\mu\text{g}/\text{kg}$.²⁰²

Clinical Uses As an adjunct to general anesthetics, medetomidine has a favorable pharmacodynamic profile in dogs and cats. In addition to providing sedation, analgesia, and muscle relaxation, the preoperative administration of medetomidine substantially reduces the amount of injectable and inhalational anesthetic required to induce and maintain anesthesia. Medetomidine administration also attenuates the stress response to surgical trauma by reducing catecholamine and cortisol levels postoperatively.^{220,221} The initial increase in vascular resistance and blood pressure and subsequent bradycardia are potential problems, but these side effects are well tolerated by healthy dogs and cats. Vomiting is also a potential problem for some patients. As a general rule, medetomidine should not be administered to pediatric or geriatric animals, or to animals with significant neurological, cardiovascular, respiratory, hepatic, or renal disease. Once pre-anesthetic and anesthetic drugs are administered, patients should be monitored carefully throughout the perioperative period, with special attention being paid to heart rate and rhythm.

α_2 -Agonists and acepromazine are the only reliable sedatives

Fig. 9.12. currently available for use in dogs and cats. Acepromazine is routinely used preoperatively to provide sedation for catheter placement and induction of anesthesia, and is often given in combination with opioids to provide both sedation and analgesia. However, acepromazine is not suitable for every patient (e.g.,

brachycephalics, epileptics, and boxers) and can cause significant hypotension in animals anesthetized with isoflurane.⁴¹ Medetomidine can be administered preoperatively at low doses to healthy dogs and cats, alone or in combination with opioids (Table 9.7).⁶⁷ Compared with acepromazine, low doses of

^aMedetomidine should not be given to dogs with significant neurological, cardiac, respiratory, hepatic, or renal disease. Some of these drugs are not approved for use in dogs in Canada or the United States.

^bMedetomidine should not be given to cats with significant neurological, cardiac, respiratory, hepatic, or renal disease. Some of these drugs are not approved for use in cats in Canada or the United States.

medetomidine produce better analgesia for catheter placement and greater reductions in anesthetic requirements, and are less likely to cause hypotension in animals anesthetized with isoflurane. In patients with good cardiopulmonary reserve, the concurrent administration of an anticholinergic agent will prevent bradyarrhythmias while slightly improving cardiac output at the expense of a rather large increase in myocardial work and oxygen consumption. Thus, the use of an anticholinergic preoperatively with α_2 -agonists to prevent bradycardia and AV blockade continues to be somewhat controversial.^{208,211,228,229} The use of an anticholinergic has been recommended for the following reasons: Firstly, even at low preanesthetic doses, significant bradycardia can occur if an anticholinergic is not administered concurrently. Secondly, the potential for severe vagotonic responses and profound bradycardia, secondary to surgical manipulation and administration of other anesthetic drugs (opioids), is higher during the perioperative period. Thirdly, while the concurrent administration of anticholinergics with high doses of medetomidine can cause dramatic increases in vascular resistance and myocardial work, these increases can be minimized and are generally well tolerated by healthy patients given low doses of medetomidine prior to inhalant (vasodilatory) anesthesia.

Bradycardia and AV blockade are more consistently prevented when anticholinergics are given 10 to 20 min before medetomi-

dine administration, although this is not always practical.^{97,211,230} Atropine has a more rapid onset of action than does glycopyrrolate and can be given at the same time as low doses of medetomidine (5 to 20 µg/kg). However, anticholinergic administration increases vagal tone transiently, which can increase the incidence of bradyarrhythmias induced by administration of any α_2 -agonist. For example, if atropine or glycopyrrolate is administered at the same time as, or after, high doses of medetomidine (30 to 60 µg/kg), bradycardia and AV blockade are not consistently prevented and ventricular arrhythmias may develop.²²⁸ Therefore, when high doses of medetomidine are administered, the use of anticholinergics should be avoided, heart rate and rhythm should be monitored closely, and atipamezole should be administered to correct severe bradyarrhythmias. Concurrent administration of anticholinergics with α_2 -agonist–ketamine combinations should also be avoided, because a prolonged high heart rate can occur.²³¹

Very low doses of medetomidine have been given postoperatively to dogs and cats, alone or in combination with opioids (Table 9.8).⁶⁷ Administration of selective α_2 -agonists in very low doses may enhance and prolong the analgesic effects of opioids, with limited effects on cardiovascular function. Lower doses of opioids may also be used, which reduces the frequency of postoperative respiratory depression. α_2 -Agonists also can be used to manage anxiety and dysphoria postoperatively. Because the duration of action of medetomidine is significantly less than that of acepromazine, sedation can be more readily controlled.

Detomidine

This agent is used primarily for sedation and analgesia in horses. The chemical name for the drug is 1H-imidazole, 4-([2,3-

dimethylphenyl)methyl)-hydrochloride (Fig. 9.6). Detomidine is more potent than xylazine and is dosed on a microgram-per-kilogram basis rather than a milligram-per-kilogram basis. The drug produces sedation, analgesia, and muscle relaxation that are comparable to those produced by xylazine in intensity but last longer. In North America and Europe, the drug is sold as detomidine hydrochloride and is approved for use in horses as a sedative-analgesic.

Pharmacokinetics Pharmacokinetic parameters have been determined in calves and horses after IV administration of detomidine at a dose of 50 $\mu\text{g}/\text{kg}$.²³² In calves, the drug is 86% protein bound, and the elimination half-life, clearance, and volume of distribution are 20.0 h, 24.9 mL/min · kg, and 29.4 L/kg, respectively. In horses, the drug is 84% protein bound, and the elimination half-life, clearance, and volume of distribution are 9.7 h, 8.1 mL/min · kg, and 6.8 L/kg, respectively. In calves, detomidine is eliminated primarily by metabolism, and most of the metabolites are excreted in the urine. Tissue liver residues are less than 1 $\mu\text{g}/\text{kg}$ at 80 h.

Pharmacodynamics Onset of sedation, analgesia, and muscle relaxation is rapid after IV or IM administration of detomidine. When detomidine is administered IV to horses at a dose of 20 $\mu\text{g}/\text{kg}$, peak sedation and analgesia are achieved within 15 min and persist for approximately 1 h.^{116,233} When the same dose is administered IM, depth of sedation and intensity of analgesia are reduced, and peak effects are achieved within 30 min and persist for approximately 1 h.²³³ Sedative and analgesic effects are comparable in duration when electrical stimulation is used to evaluate somatic analgesia. Administration of detomidine at a dose of 20 $\mu\text{g}/\text{kg}$ induces sedation and analgesia comparable in intensity to, but longer than, those induced by administration of xylazine at a dose of 1.1 mg/kg.^{116,233} At these doses, detomidine and xylazine also induce comparable levels of muscle relaxation and ataxia.¹¹⁶ In a colic model (ponies with cecal balloons), IV administration of detomidine at a dose of 20 $\mu\text{g}/\text{kg}$ provides analgesia for 45 min, whereas IV administration of xylazine at a dose of 1.1 mg/kg provides analgesia for approximately 20 min.²³⁴ Sedation lasted longer than analgesia when a cecal balloon was used to evaluate visceral analgesia. In a 2003 placebo-controlled study using electrical stimulation to evaluate somatic analgesia, IV administration of detomidine at a dose of 20 $\mu\text{g}/\text{kg}$ provided analgesia for approximately 30 min, whereas administration of xylazine at a dose of 1.1 mg/kg provided analgesia for approximately 15 min (Fig. 9.13).⁸² Detomidine administration also reduces catecholamine and cortisol concentrations in horses.²³⁵

Detomidine administration produces dose-dependent changes in cardiovascular function. In conscious ponies, arterial pressure increases and heart rate decreases by over 50% immediately (1 min) after IV administration of detomidine at doses ranging from 10 to 60 $\mu\text{g}/\text{kg}$.²³⁶ In conscious horses, heart rate decreases by 30% to 35% and cardiac output decreases by 40% to 45% after IV administration at doses of 10 to 20 $\mu\text{g}/\text{kg}$.²³⁷ At these doses, 30% of horses develop AV block within 5 min, heart rate

Fig. 9.13. Antinociceptive effects of intravenous administration of xylazine (1.1 mg/kg), detomidine (20 $\mu\text{g}/\text{kg}$), or romifidine (80 $\mu\text{g}/\text{kg}$) in horses. With permission from Moens et al.⁸²

and cardiac output are reduced for 45 min to 1 h, and mean arterial pressure is reduced for 90 min to 2 h. After IM administration of detomidine at a dose of 40 $\mu\text{g}/\text{kg}$, heart rate and cardiac output decrease by 27% and 39%, respectively.²³⁷ Intravenous infusion of detomidine at a constant rate produces decreases in heart rate and cardiac output that are comparable to bolus administration, but mean arterial pressure remains elevated for the duration of the infusion.²³⁸ Hematocrit and total protein decrease after parenteral administration of detomidine.^{237,238} These changes are probably produced by fluid shifts and sequestration of erythrocytes in the spleen that occur as sympathetic tone decreases.

Detomidine administration has little effect on pulmonary function. Respiratory rate decreases after detomidine administration, but the apparent decrease in minute ventilation appears to coincide with a decrease in carbon dioxide production, and arterial blood-gas values do not change appreciably. In horses administered detomidine IV at doses of 10 to 20 $\mu\text{g}/\text{kg}$, respiratory rate decreases by approximately 50% for 2 h after drug administration.²³⁷ At these doses, arterial pH and PCO_2 do not change, and PO_2 decreases transiently but returns to normal values within 15 to 30 min. The decrease in arterial PO_2 coincides with the dramatic drop in heart rate and cardiac output that occurs immediately after administration of detomidine. Intravenous infusion of detomidine at a constant rate alters respiratory rate and arterial blood-gas values that are comparable to bolus administration.²³⁸

Detomidine administration has significant effects on esophageal transit time and gastrointestinal motility. In horses, IV administration of detomidine (10 to 20 $\mu\text{g}/\text{kg}$) produces dose-dependent increases in esophageal transit time and retrograde peristalsis, and a decrease in duodenal motility.^{239,240} Detomidine administration also reduces cecal and colonic motility in ponies.¹⁵³ Detomidine is a very effective visceral analgesic, and its use in horses with colic should not be abandoned because of unwarranted concerns about gastrointestinal side effects. After all, increases in sympathetic tone associated with uncontrolled abdominal pain also reduce gastrointestinal motility.

Detomidine produces sedation and analgesia in horses when administered epidurally at the first intercoccygeal space. Its administration at doses of 30 to 60 $\mu\text{g}/\text{kg}$ diluted in 10 mL of sterile water produces perineal analgesia with variable bilateral analgesia up to the 14th thoracic dermatome.^{241,242} Analgesia begins in 10 to 15 min and lasts for 2 to 3 h. Doses under 30 $\mu\text{g}/\text{kg}$ do not produce reliable analgesia, and those over 60 $\mu\text{g}/\text{kg}$ may cause recumbency. The drug is lipophilic and is rapidly absorbed into the systemic circulation from the epidural space. Systemic effects include marked sedation and ataxia, a decrease in heart rate and 2° AV blockade, an increase followed by a decrease in mean arterial pressure, decreases in respiratory rate and arterial PO_2 , and diuresis.^{241,242} Caudal epidural administration of xylazine (0.25 mg/kg) produces longer-lasting perineal analgesia with fewer systemic side effects than does caudal epidural administration of detomidine.²⁴³ Detomidine has also been administered epidurally in combination with morphine to horses with experimentally induced hind-limb lameness and to horses undergoing bilateral stifle arthroscopy.^{244–246}

Clinical Uses Detomidine administration produces reliable sedation, analgesia, and muscle relaxation in horses. The drug is used alone and in combination with butorphanol to produce standing sedation for diagnostic and surgical procedures, and as an analgesic for horses with abdominal pain. Detomidine is usually given IV at doses ranging from 5 to 20 $\mu\text{g}/\text{kg}$, but it can be given IM at doses ranging from 10 to 40 $\mu\text{g}/\text{kg}$. Sedation is more reliable and horses are less responsive to external stimuli when detomidine is given with butorphanol or another opioid.²⁴⁷ As with other α_2 -agonists, excited or fractious animals may require higher doses of detomidine. Ataxia can be a problem in healthy horses, and the drug should be used with discretion in animals with neurological disease. Detomidine administration also produces marked cardiovascular side effects, and it should be used with caution in horses with significant cardiovascular disease and in those with endotoxic or traumatic shock.

Romifidine

This selective α_2 -agonist derived from clonidine is used primarily to produce sedation and analgesia in horses. The chemical name for the drug is 2-([2-bromo-6-fluorophenyl]imino)-imidazolidine hydrochloride. Romifidine administration produces sedation and analgesia that are comparable in duration to those produced by detomidine administration.^{82,116} Muscle relaxation is comparable but with less ataxia than seen with equivalent sedative doses of xylazine or detomidine.¹¹⁶ Romifidine is approved or licensed for use in horses in North America and Europe. Although not approved for use in small animals, the sedative and cardiovascular effects of romifidine have been reported in both dogs and cats.^{248–251}

Pharmacokinetics and Pharmacodynamics Onset of sedation and analgesia is rapid after parenteral administration of romifidine. When romifidine is administered IV to horses at doses of 40 to 80 $\mu\text{g}/\text{kg}$, sedation begins within 2 min, peak effects are reached within 10 min, and sedation lasts for 40 to 80 min.¹¹⁶ Similar results were reported after IV administration of romifidine at a dose of 80 $\mu\text{g}/\text{kg}$ (Fig. 9.13).⁸² In small animals, romifidine has a longer duration of action than xylazine or medetomidine. In dogs, the IM administration of romifidine at doses of 10 to 40 $\mu\text{g}/\text{kg}$ produces mild to moderate sedation within 10 min and lasts for 1 to 2 h.²⁴⁸ Sedation produced by IM administration of romifidine at a dose of 40 $\mu\text{g}/\text{kg}$ is comparable in intensity to that produced by xylazine at a dose of 1 mg/kg but lasts longer.²⁴⁸ The onset of action is faster after IV administration of romifidine at doses ranging from 20 to 120 $\mu\text{g}/\text{kg}$, but the incidence of neuromuscular, respiratory, and cardiovascular side effects increases.^{249,250} In cats, IM administration of romifidine (40 $\mu\text{g}/\text{kg}$) in combination with butorphanol produces moderate sedation.²⁵¹

Romifidine can also be used preoperatively to facilitate induction of anesthesia with ketamine and postoperatively to facilitate recovery from inhalational anesthesia. In horses, administration of romifidine before induction of anesthesia with diazepam and ketamine produces short-term anesthesia that is comparable to that produced by preanesthetic administration of xylazine.²⁵² Romifidine has also been used as a preanesthetic before induc-

tion and maintenance of anesthesia with ketamine and halothane, respectively.²⁵³ Small doses of romifidine have also been administered postoperatively to facilitate recovery from isoflurane anesthesia.²⁵⁴ Like other α_2 -agonists, preanesthetic administration of romifidine (20 to 40 $\mu\text{g}/\text{kg}$ IV) to dogs reduces the amount of thiopental or propofol required to induce anesthesia by 40% to 60% and the amount of halothane required to maintain anesthesia by 20%.^{255,256}

At doses that produce equivalent degrees of sedation, romifidine produces changes in cardiovascular function that are comparable to those produced by other α_2 -agonists. In conscious horses, IV administration of romifidine (80 $\mu\text{g}/\text{kg}$) induces a 20% increase in mean arterial pressure and a 30% to 60% decrease in heart rate within 5 min.²⁵⁷ During the next 30 min, bradycardia persists, AV blockade is common, and cardiac output decreases by 30% to 40%.^{257,258} As with other α_2 -agonists, respiratory rate decreases, but arterial pH, PCO_2 , and PO_2 do not change, and gastrointestinal motility decreases after romifidine administration.^{257–259} In dogs, IV administration of romifidine at doses ranging from 5 to 50 $\mu\text{g}/\text{kg}$ induces a dose-dependent increase in mean arterial pressure and decreases in heart rate and cardiac output.²⁶⁰ After IM administration of romifidine (20 to 40 $\mu\text{g}/\text{kg}$), bradycardia lasts for up to 2 h, respiratory rate decreases, and arterial pH, PCO_2 , and PO_2 do not change.¹⁸ Administration of glycopyrrolate 15 min before administration of romifidine (20 to 40 $\mu\text{g}/\text{kg}$ IM) reduces the incidence and severity of bradycardia but is associated with a dose-dependent increase in mean arterial pressure.¹⁸

Clinical Uses Romifidine administration produces reliable sedation and analgesia in horses. The drug is used alone and in combination with butorphanol to produce standing sedation for diagnostic and surgical procedures, and can also be used as an analgesic. Romifidine is usually administered IV to horses at doses ranging from 40 to 80 $\mu\text{g}/\text{kg}$ and produces less ataxia than equivalent sedative doses of xylazine or detomidine.¹¹⁶ Sedation is more reliable and horses are less responsive to external stimuli when romifidine is administered in combination with butorphanol.^{257,261} Romifidine (100 $\mu\text{g}/\text{kg}$ IV) has also been given as a preanesthetic before induction of anesthesia with diazepam and ketamine.²⁵² As with other α_2 -agonists, fractious or excited animals may require higher doses of romifidine. Romifidine also produces marked cardiovascular side effects and should be used with caution in horses with significant cardiovascular disease and in those with endotoxic or traumatic shock. Romifidine is not labeled for use in dogs and cats, and its use in small animals is not recommended until further studies are completed.

α_2 -Antagonists

α_2 -Antagonists are used to reverse the sedative and cardiovascular effects of α_2 -agonists. Currently, three antagonists (tolazoline, yohimbine, and atipamezole) are available for use in animals. Tolazoline is a relatively nonselective α -receptor antagonist, and receptor binding or selectivity ratios (α_2/α_1) for yohimbine and atipamezole are 40:1 and 8526:1, respectively.²⁶² Tolazoline and yohimbine are used primarily to reverse the effects

of xylazine in dogs, cats, ruminants, and several exotic species.^{63,263} Atipamezole is used primarily to reverse the effects of medetomidine in dogs, cats, and several exotic species.^{69,264–266}

In addition to reversing the sedative and cardiovascular effects of α_2 -agonists, α_2 -antagonists can produce significant side effects. If a relative overdose of an antagonist is administered, neurological (excitement and muscle tremors), cardiovascular (hypotension and tachycardia), and gastrointestinal (salivation and diarrhea) side effects can occur. Death has also been reported after rapid IV administration of tolazoline or yohimbine to sheep sedated with xylazine.²⁶⁷ Therefore, the dose of antagonist should be calculated carefully, and these calculations should be based on the amount of agonist administered initially and the time that has elapsed since the agonist was administered. Generally, calculations are based on an agonist/antagonist ratio, not a simple milligram-per-kilogram calculation. When in doubt, it is usually better to underdose than to overdose the antagonist. α_2 -Mediated analgesia is also reversed, and antagonists should be used with discretion postoperatively.

Tolazoline

This agent is a nonselective α -receptor antagonist used primarily to reverse the sedative and cardiovascular effects of xylazine in ruminants.^{63,263} The drug is a synthetic imidazoline derivative (2-benzyl-2-imidazoline) that produces histaminergic and cholinergic effects in addition to producing nonspecific blockade of α receptors (Fig. 9.14). Tolazoline is approved for use in horses in Canada but not the United States.

Pharmacokinetics and Pharmacodynamics Tolazoline is effective in reversing the sedative cardiovascular and gastrointestinal effects of xylazine in ruminants. Administration of tolazoline (2 mg/kg IV) reverses the sedative and cardiovascular effects of xylazine (0.3 to 0.4 mg/kg IV) in sheep, 5- to 7-month old calves, and adult cattle equally well.^{142,267–270} In steers and lactating dairy cattle given tolazoline IV at a relatively high dose (4 mg/kg), tolazoline concentrations were below 10 $\mu\text{g}/\text{kg}$ by 4 days in tissue samples and by 2 days in milk samples.¹¹³

Clinical Uses Tolazoline is used primarily to reverse the sedative and cardiovascular effects of xylazine in ruminants. Dose calculations are made based on an agonist/antagonist ratio of approximately 1:10. Therefore, if the initial xylazine dose is 0.1 to 0.2 mg/kg, then tolazoline would be administered IV at a dose of 1 to 2 mg/kg. The time that has elapsed since the agonist was administered should be considered, as well. Tolazoline should be administered slowly when given IV to avoid neurological (excitement) and cardiovascular (hypotension and tachycardia) side effects.

Yohimbine

This agent is used as a selective α_2 -receptor antagonist of the sedative and cardiovascular effects of xylazine in dogs, cats, and several exotic species.^{63,263} This drug is an indolealkylamine alkaloid (17-hydroxyyohimban-16-carboxylic acid methyl ester) that is related structurally to reserpine (Fig. 9.14). At high con-

Yohimbine Hydrochloride

Tolazoline Hydrochloride

Atipamezole Hydrochloride

Fig. 9.14. Chemical structures of α_2 -receptor antagonists. With permission from Gross.³²⁵

centrations, yohimbine may interact with dopaminergic and serotonergic receptors, and, at very high concentrations, it may have a nonspecific local anesthetic effect.²⁷¹ Yohimbine is approved for use in dogs in Canada and in dogs and deer in the United States.

Pharmacokinetics and Pharmacodynamics The pharmacokinetics of yohimbine have been reported for dogs, horses, and cattle.²⁷²

In dogs given yohimbine (0.4 mg/kg IV), the volume of distribution, total body clearance, and elimination half-life were 4.5 L/kg, 30 mL/min · kg, and 104 min, respectively. In horses given yohimbine (0.15 mg/kg IV), the volume of distribution, total body clearance, and elimination half-life were 4.6 L/kg, 40 mL/min · kg, and 76 min, respectively. In cattle given yohimbine (0.25 mg/kg IV), the volume of distribution, total body clearance, and elimination half-life were 4.9 L/kg, 70 mL/min · kg, and 47 min, respectively.

Many reports on a variety of species have documented yohimbine's efficacy in antagonizing the various actions of xylazine. Examples include use in dogs where yohimbine (0.1 mg/kg IV) reverses the sedative and cardiovascular effects of xylazine (1 mg/kg) when administered IV or IM^{263,273–275} and in cats where

yohimbine (0.5 mg/kg IV) reverses the sedative and cardiovascular effects of xylazine (1 mg/kg IM).²⁶³ In white-tailed deer, yohimbine (0.3 mg/kg IV) reportedly reverses the sedative and cardiovascular effects of a high dose of xylazine (3 mg/kg IM),^{263,276} whereas, in calves, it (0.25 mg/kg IV) rapidly reverses the cardiovascular and gastrointestinal effects of xylazine (0.05 mg/kg IV), with minimum effect on sedation.²⁷⁷

Clinical Uses Dose calculations are made based on agonist/antagonist ratios of approximately 10:1, 2:1, and 10:1, for dogs, cats, and deer, respectively. Therefore, if the initial dose of xylazine is 0.5 mg/kg for a dog, then yohimbine would be given IV at a dose of 0.05 mg/kg. The time that has elapsed since the agonist was administered should be considered, as well. Like tolazoline, yohimbine is usually administered slowly IV to avoid neurological (excitement) and cardiovascular (hypotension and tachycardia) side effects.

Atipamezole

This highly selective α_2 -receptor antagonist is used to reverse the sedative and cardiovascular effects of medetomidine in dogs, cats, and several other species.^{69,264–266,278} The chemical name of the drug is (4-2-ethyl-2,3-dihydro-1H-inden-2-yl)-1H-imidazole (Fig. 9.14). Atipamezole is 200 to 300 times more selective for the α_2 receptor than is yohimbine and has no effect at β -adrenergic, dopaminergic, serotonergic, histaminergic, muscarinic, opiate, γ -aminobutyric acid (GABA), or benzodiazepine receptors.²⁶² Atipamezole is approved for use in dogs in North America and Europe.

Pharmacokinetics and Pharmacodynamics The pharmacokinetics of atipamezole (250 μ g/kg IM), alone and 30 min after administration of medetomidine (50 μ g/kg IV), have been reported for dogs.²⁷⁹ When atipamezole is given alone, peak plasma concentrations are reached within 15 min, and the volume of distribution, total body clearance, and elimination half-life are 2.3 L/kg, 27 mL/min · kg, and 56 min, respectively. When atipamezole is given after medetomidine, peak plasma concentrations are reached within 25 min, and the volume of distribution, total body clearance, and elimination half-life are 2.5 L/kg, 24 mL/min · kg, and 72 min, respectively. Apparently, prior administration of medetomidine reduces cardiac output and hepatic blood flow, which delays absorption and metabolism of atipamezole.

Atipamezole is used primarily to reverse the sedative and cardiovascular effects of medetomidine in dogs.^{264,265} Animals given atipamezole (200 μ g/kg IM), 15 to 30 min after administration of medetomidine (40 μ g/kg IM), show increases in heart rate and initial signs of arousal within 5 min and are walking within 10 min. Occasionally, tachycardia and excitation occur shortly after atipamezole administration, and resedation can occur 30 to 60 min after administration of the antagonist. Atipamezole has also been used to reverse the sedative and cardiovascular effects of medetomidine in cats.²⁶⁶ Cats administered atipamezole (200 to 400 μ g/kg IM), 15 to 30 min after administration of medetomidine (100 μ g/kg IM), show increases in heart rate and initial signs of arousal within 5 min and are walking within 10 min. Occasionally,

Fig. 9.15. The structure and major binding sites of the GABA_A-receptor complex. GABA, γ -aminobutyric acid. With permission from Chou.³²⁶

tachycardia and excitation occur shortly after atipamezole administration. Atipamezole has also been used to reverse the sedative effects of medetomidine in cattle²⁷⁸ and several exotic species.⁶⁹ Medetomidine/atipamezole ratios for nondomestic carnivores and ruminants are 1:2–3 and 1:4–5, respectively. Atipamezole has been used to reverse the sedative and cardiovascular effects of xylazine in several species.^{69,280–283} The xylazine/atipamezole ratio for reversal of most mammals is approximately 10:1.

Clinical Uses Atipamezole is usually administered to reverse the effects of medetomidine after nonpainful diagnostic or therapeutic procedures, and it is not usually administered perioperatively. Complete reversal of the sedative, analgesic, and cardiovascular effects of medetomidine is achieved when atipamezole is administered IM to dogs and cats at four to six times and two to four times the dose of medetomidine, respectively.^{265,266} Therefore, if the initial dose of medetomidine is 20 $\mu\text{g}/\text{kg}$ for a dog, then atipamezole would be given IM at a dose of 100 $\mu\text{g}/\text{kg}$. Similarly, if the initial dose of medetomidine is 40 $\mu\text{g}/\text{kg}$ for a cat, then atipamezole would be given IM at a dose of 120 $\mu\text{g}/\text{kg}$.

In both of these examples, the dose of atipamezole should be reduced if more than 30 min has elapsed since medetomidine administration. Because of the potential for excitation and cardiovascular side effects (hypotension and tachycardia), atipamezole is not labeled for IV use. However, it can be given IV to reverse the cardiovascular effects of medetomidine in emergency situations. Atipamezole and anticholinergics can both cause dramatic increases in heart rate, and the concurrent use of these drugs should be avoided.

Benzodiazepine Agonists

Benzodiazepines produce most of their pharmacological effects by modulating GABA-mediated neurotransmission.²⁸⁴ GABA is the primary inhibitory neurotransmitter in the mammalian nervous system and cell membranes of most CNS neurons express GABA receptors. These receptors are also found outside the CNS in autonomic ganglia. Two main types of GABA receptors are involved in neuronal transmission: The GABA_A receptor complex is a ligand-gated chloride channel that consists of a central pore surrounded by five glycoprotein subunits (Fig. 9.15).

Activation requires binding of GABA molecules to both α subunits of the receptor. The GABA_B receptor is a metabotropic receptor that consists of a single glycoprotein subunit that is closely associated with a G protein. These G proteins are coupled directly to potassium or calcium channels or to a second-messenger system (adenylate cyclase or phospholipase C). Activation of ionotropic GABA_A receptors increases chloride conductance rapidly and generates fast inhibitory postsynaptic potentials. Activation of metabotropic GABA_B increases potassium conductance slowly and generates slow inhibitory postsynaptic potentials. Presynaptic GABA_B autoreceptors are coupled to calcium channels and regulate neurotransmitter release.

The benzodiazepine-binding site, as well as the binding sites for other injectable anesthetics (barbiturates, propofol, and etomidate), is located on the GABA_A receptor complex (Fig. 9.15). Benzodiazepines enhance binding between GABA and the GABA_A receptor, and increase the frequency of channel opening. In contrast, barbiturates enhance intrinsic activity and increase the duration of channel opening. Both mechanisms increase chloride conductance and hyperpolarize the cell membrane, which reduces neuronal excitability. Benzodiazepines have no intrinsic agonist activity and cannot alter chloride conductance in the absence of GABA. This lack of intrinsic activity limits CNS depression and provides benzodiazepines with a much wider margin of safety than barbiturates.

Modulation of GABA-mediated neurotransmission also plays a role in nociception.²⁸⁵ At the supraspinal level, activation of GABA_A receptors inhibits descending antinociceptive pathways and enhances sensitivity to noxious stimuli. In fact, systemic administration of benzodiazepines and barbiturates antagonizes the analgesic effect of opioids.^{286,287} However, at the spinal level, activation of GABA_A and GABA_B receptors produces an antinociceptive effect, and antagonism of spinal GABA_B receptors may contribute to the development of allodynia.

Ligands that bind to benzodiazepine receptors are classified as agonists, inverse agonists, and antagonists. *Agonists* bind to benzodiazepine receptors and produce sedative, anxiolytic, muscle relaxant, and anticonvulsant effects in most animals. *Inverse agonists* bind to the same receptor and produce the opposite effects. *Antagonists* have high affinity for the benzodiazepine receptor and have little or no intrinsic activity. These ligands block or reverse the effects of both agonists and inverse agonists. Diazepam, midazolam, and zolazepam are the benzodiazepine agonists used most commonly in animals. Diazepam and midazolam are used primarily as sedatives, muscle relaxants, and anticonvulsants. Zolazepam is available in combination with a dissociative anesthetic (tiletamine), which is approved for use as an anesthetic in dogs and cats in the United States.

Diazepam

This is the most widely used benzodiazepine in both small and large animals. The chemical name for the drug is 7-chloro-1,3-dihydro-1-methyl-5-phenyl-2H-1,4-benzodiazepin-2-one (Fig. 9.16). Diazepam is not soluble in water, and parenteral formulations contain 40% propylene glycol and 10% ethanol. Because of this insolubility, diazepam should not be mixed with diluents or

Fig. 9.16. Chemical structures of benzodiazepine receptor agonists and antagonists. With permission from Gross.³²⁵

other drugs. Further, the drug should not be administered IM because it is very irritating and is poorly absorbed. The parenteral formulation of diazepam is administered by slow IV injection to avoid pain, thrombophlebitis, and cardiotoxicity. The drug is also sensitive to light and adheres to plastic, so therefore should not be stored in plastic syringes for extended periods.²⁸⁸ Diazepam is used primarily as a muscle relaxant and as an anticonvulsant for dogs, cats, and horses. The drug is not approved for use in animals in Canada or the United States.

Pharmacokinetics Diazepam is highly lipid soluble and is rapidly distributed throughout the body. Approximately 90% of the drug is protein bound, and diazepam is metabolized by demethylation and hydroxylation to *N*-desmethyldiazepam (nordiazepam), 3-hydroxydiazepam, and oxazepam.²⁸⁹ Nordiazepam and oxazepam produce significant pharmacological effects at clinically relevant concentrations. The pharmacokinetics of diazepam have been determined in dogs, cats, and horses. In dogs, the elimination half-life of diazepam after administration of a relatively high dose (2 mg/kg IV) is 3.2 h.²⁹⁰ Nordiazepam appears rapidly in plasma and quickly exceeds concentrations of diazepam, whereas oxazepam concentrations peak within 2 h. The elimination half-lives of nordiazepam and oxazepam are 3.6 and 5.7 h, respectively. In cats, the mean elimination half-life of diazepam after administration of relatively high doses (5, 10, and 20 mg/kg IV) is 5.5 h.²⁹¹ Approximately 50% of the diazepam

dose is converted to nordiazepam, and the mean elimination half-life of the metabolite is 21 h—which is approximately four times longer than the half-life of diazepam. In horses, the elimination half-life ranges from 7 to 22 h after IV administration of diazepam at a dose 0.2 mg/kg.²⁹² Metabolites are not detectable in plasma, but glucuronide conjugates are detectable in the urine. In contrast to dogs and cats, conjugation and elimination of the nordiazepam and oxazepam is rapid in the horse.

Pharmacodynamics Diazepam does not sedate dogs and horses reliably, and can cause excitement, dysphoria, and ataxia. In dogs, IV administration of diazepam (0.5 mg/kg) produces arousal and excitement.²⁹³ Diazepam administration can produce dysphoria and aggressive behavior in cats, and the drug should be used with caution in this species.¹²⁰ In horses, IV administration of diazepam at doses greater than 0.2 mg/kg produces mild sedation but also marked muscle relaxation, ataxia, and recumbency.²⁹² Because of these behavioral effects, diazepam alone has limited value as a sedative for dogs, cats, and horses. In dogs and horses, it is used primarily as a muscle relaxant before induction of anesthesia with ketamine. Diazepam administration (0.3 to 0.5 mg/kg IV) immediately before ketamine administration improves muscle relaxation and facilitates intubation in dogs.^{293,294} In horses premedicated with xylazine, diazepam administration (0.05 to 0.1 mg/kg IV) immediately before ketamine administration improves muscle relaxation and induction quality.²⁹⁵ In cats premedicated with diazepam and then administered either ketamine or thiopental, dysphoria and aggressive behavior can occur during the recovery period.^{120,296} This type of aberrant behavior limits the utility of diazepam as an anesthetic adjunct in cats.

Diazepam administered preoperatively reduces injectable and inhalational anesthetic requirements. Preoperative administration of diazepam (0.1 to 0.2 mg/kg IV) reduces the dose of thiamylal required to induce anesthesia, whereas the intraoperative administration reduces the amount of inhalant required to maintain anesthesia.²⁹⁷ Diazepam reduces isoflurane requirements by 20% in dogs anesthetized with isoflurane and fentanyl.²⁹⁸ Similarly, in horses, diazepam administration (0.04 mg/kg) reduces halothane requirement by 29%.²⁹⁹ Not surprisingly, diazepam administration (0.2 mg/kg IV) decreases the absolute power of the electroencephalogram in all frequencies in dogs anesthetized with isoflurane.³⁰⁰

Diazepam produces limited effects on cardiovascular and pulmonary function in animals. In dogs, heart rate, myocardial contractility, cardiac output, and arterial blood pressure do not change appreciably after the IV administration of diazepam at doses of 0.5, 1.0, and 2.5 mg/kg.³⁰¹ The IV administration of diazepam at a dose of 0.5 mg/kg followed by the IV administration of ketamine (10 mg/kg) increases heart rate, as well cardiac output, with little change in blood pressure.²⁹³ Respiratory rate decreases, but tidal volume is unchanged after ketamine administration. In horses, IV administration of diazepam over a wide range of doses (0.05 to 0.4 mg/kg) does not produce significant changes in heart rate, cardiac output, arterial blood pressure, respiratory rate, or arterial blood-gas values.²⁹²

Clinical Uses Diazepam is not a reliable sedative, but is a good muscle relaxant and anticonvulsant in most species. In dogs, diazepam is commonly administered IV at a dose of 0.3 to 0.5 mg/kg immediately before induction of anesthesia with ketamine.^{293,302} Diazepam also can be administered prior to induction of anesthesia with thiopental, propofol, etomidate, or an opioid. Diazepam appears to be a more reliable sedative in older dogs and can be administered alone or in combination with an opioid to produce sedation in this subpopulation. In horses premedicated with xylazine or romifidine, diazepam is routinely administered IV at a dose of 0.05 to 0.1 mg/kg immediately before induction of anesthesia with ketamine.^{295,303} Diazepam is also a reliable sedative in foals under 1 month of age and can be administered IV at a dose of 0.1 to 0.2 mg/kg. Higher doses are often administered when diazepam is used as an anticonvulsant. In small animals, diazepam is administered IV at a dose of 0.5 to 1.0 mg/kg to control seizures, and, in large animals, a dose of 0.1 to 0.2 mg/kg is usually effective. Again, the parenteral formulation of diazepam is very irritating and potentially cardiotoxic, and should always be administered by slow IV injection.

Midazolam

This is probably the most underutilized sedative in veterinary medicine. Although the drug is not a reliable sedative in dogs and cats, it produces excellent sedation and muscle relaxation in many small mammals (ferrets and rabbits), some large mammals (swine), and many birds. Midazolam is a benzodiazepine with a fused imidazole ring that accounts for the water solubility of the drug at pH values below 4.0. The chemical name of midazolam is 8-chloro-6-(2-fluorophenyl)-1-methyl-4H-imidazo(1,5- α)(1,4)-benzodiazepine (Fig. 9.16). The pH of the parenteral formulation is 3.5, and the drug is light sensitive like diazepam. After injection, midazolam changes its chemical configuration and becomes lipid soluble at physiological pH. Unlike diazepam, the drug is nonirritating and well absorbed after IM administration. Midazolam is used primarily as a perioperative sedative and muscle relaxant in ferrets, rabbits, swine, and birds. In dogs, it can be used as a sedative in older or debilitated animals, and in combination with ketamine to induce anesthesia. Midazolam is not approved for use in animals in Canada or the United States.

Pharmacokinetics In dogs, midazolam is almost completely (>90%) absorbed after IM injection, and peak plasma concentrations are reached within 15 min.³⁰⁴ The drug is also highly protein bound (>95%) and rapidly crosses the blood-brain barrier. Midazolam is hydroxylated in the liver, and glucuronide conjugates are excreted in the urine.³⁰⁵ After IV administration of midazolam (0.5 mg/kg), the volume of distribution, elimination half-life, and clearance are 3.0 L/kg, 77 min, and 27 mL/kg · min, respectively.³⁰⁴ In dogs given midazolam (0.5 mg/kg IV) and ketamine (10 mg/kg IV) as a bolus, the elimination half-life of midazolam is 28 min.³⁰⁶ In dogs anesthetized with enflurane, the volume of distribution, elimination half-life, and clearance of midazolam when given IV as a bolus are 3.9 L/kg, 98 min, and 29 mL/kg · min, respectively.³⁰⁷ In piglets given midazolam (0.4 mg/kg) IV or intranasally, the elimination half-lives were 138

and 158 min, respectively.³⁰⁸ Bioavailability is 64% and maximum plasma concentrations are reached within 5 min after intranasal administration.

Pharmacodynamics Midazolam is more lipophilic than diazepam and has twice the affinity for the benzodiazepine receptor. It also appears to have a greater sedative effect than diazepam in most species. Onset of sedation and muscle relaxation is rapid after IV or IM administration in most species. In most dogs administered midazolam (0.5 mg/kg) IV or IM, muscle relaxation, ataxia, transient agitation, or mild sedation are quickly observed.³⁰⁴ In cats administered midazolam IV or IM over a wide range of doses (0.05 to 5.0 mg/kg), muscle relaxation becomes evident but so does arousal and excitement in many cats.^{309–311} Some cats are difficult to approach and restrain after midazolam administration. Likewise, many cats administered midazolam and ketamine exhibit abnormal behavior (excitation or vocalization) during recovery. In contrast to its effect on cats, midazolam reliably sedates many other small mammals. In ferrets and rabbits, IM administration of midazolam at a dose of 0.5 to 1.0 mg/kg produces excellent sedation and muscle relaxation. It can also be administered intranasally to rabbits at dose of 2.0 mg/kg.³¹² In piglets and adult swine, midazolam is an effective sedative when administered either IM or intranasally at a dose of 0.1 to 0.2 mg/kg.^{308,313} In parrots and raptors, IM administration of midazolam at dose of 0.5 to 1.0 mg/kg produces mild to moderate sedation and muscle relaxation. It is also effective as a sedative in quail and geese when administered IM at doses ranging from 2 to 4 mg/kg.^{314,315}

Midazolam is commonly given to enhance muscle relaxation and facilitate intubation in dogs and cats coadministered ketamine.^{294,311} Preanesthetic administration (0.1–0.2 mg/kg IV) reduces the induction dose of barbiturates and propofol and the concentration of isoflurane required to maintain anesthesia during surgery.^{316–318} Like diazepam, midazolam (0.2 mg/kg IV) decreases the absolute power of the electroencephalogram in dogs anesthetized with isoflurane.³¹⁹

Midazolam administration produces minimal effects on cardiopulmonary function in mammals and birds. In dogs, heart rate and cardiac output increase by 10% to 20% after IV administration of midazolam at doses of 0.25 and 1.0 mg/kg.³⁰¹ In swine, even though heart rate decreases by 20% and respiratory rate decreases by 50%, cardiac output and blood-gas values do not change after IM midazolam injection (0.1 mg/kg).³¹³ The IV coadministration of midazolam with ketamine induces changes in cardiopulmonary function comparable to those induced by diazepam and ketamine in dogs.²⁹⁴

Clinical Uses Midazolam can be used alone and in combination with opioids to sedate older dogs, small mammals, swine, and birds. It is also administered in combination with injectable anesthetics to improve muscle relaxation and to reduce the dose of anesthetic required to induce anesthesia. Because midazolam has limited effects on cardiopulmonary function, the drug is an ideal sedative for many older or compromised animals. In dogs, midazolam is typically administered alone at doses of 0.2 to 0.4

mg/kg IM or in combination with opioids (butorphanol, hydromorphone, or oxymorphone) to induce sedative-analgesic effects. It can be administered IV at doses of 0.1 to 0.2 mg/kg before induction of anesthesia with ketamine, thiopental, propofol, or etomidate. In ferrets and rabbits, midazolam is administered IM at doses of 0.5 to 1.0 mg/kg, either alone or in combination with opioids (butorphanol or hydromorphone), prior to induction of anesthesia with ketamine. A 0.5- to 1.0-mg/kg dose given IM alone or in combination with butorphanol before induction of anesthesia with isoflurane or sevoflurane has proven quite effective in calming parrots and raptors. Midazolam is also an excellent sedative for most birds undergoing routine diagnostic procedures. In swine, midazolam is typically given IM at doses of 0.1 to 0.2 mg/kg, alone or in combination with opioids, prior to induction with ketamine. Midazolam can also be combined with ketamine to immobilize swine for diagnostic procedures and to facilitate placement of IV catheters. Anticonvulsant doses of midazolam are comparable to those for diazepam in most species. Midazolam is not approved for use in animals in Canada or the United States.

Benzodiazepine Antagonists

These bind to the GABA_A receptor complex and block the effects of both agonists and inverse agonists. Antagonists have a strong affinity for the benzodiazepine receptor but have no intrinsic activity and are relatively free of side effects. Additionally, benzodiazepine antagonists cannot reverse the effects of anesthetic drugs (barbiturates) that bind to other sites on the GABA_A receptor complex. Flumazenil is the only benzodiazepine antagonist currently available for clinical use. In animals, it is used primarily to reverse the sedative and muscle-relaxant effects of diazepam and other benzodiazepines.

Flumazenil

This is a highly selective, competitive benzodiazepine receptor antagonist. The chemical name of the drug is ethyl-8-fluro-5,6-dihydro-5-methyl-6-oxo-4H-imidazolo-(1,5- α)benzodiazepine-3-carboxylate (Fig. 9.16). Flumazenil has a strong affinity for the benzodiazepine receptor and has minimal intrinsic activity. The drug is used to reverse the unwanted behavioral and muscle-relaxing effects of diazepam and midazolam in mammals and birds. Flumazenil is not approved for use in animals in Canada or the United States.

Pharmacokinetics and Pharmacodynamics Limited pharmacokinetic data are available for animals. An elimination half-life of 0.4 to 1.3 h has been reported for dogs.³²⁰ In people, midazolam and flumazenil have similar pharmacokinetic profiles, which makes flumazenil a suitable antagonist for midazolam.³²¹ After IV administration, flumazenil is widely distributed and has an elimination half-life of approximately 1 h. The drug is not highly protein bound (<40%) and has a relatively high hepatic extraction ratio (0.6). Flumazenil undergoes hepatic metabolism and the primary metabolite is inactive.

Flumazenil rapidly reverses the sedative and muscle relaxant effects of benzodiazepine agonists in animals. In dogs, flumaze-

nil administration completely reverses the behavioral and muscle-relaxant effects of an overdose of diazepam (2 mg/kg IV) or midazolam (1 mg/kg IV) within 5 min.³²⁰ In addition, flumazenil may reverse the anticonvulsant effects of benzodiazepine agonists. Although flumazenil has minimal intrinsic activity, administration of the antagonist could facilitate development of seizures in predisposed animals. Flumazenil also appears to have minimal effects on cardiopulmonary function in animals.

Clinical Uses Currently, flumazenil is the only benzodiazepine antagonist used in veterinary medicine. In dogs, an overdose of diazepam (2.0 mg/kg IV) or midazolam (1.0 mg/kg IV) can be effectively antagonized with flumazenil at a dose of 0.08 mg/kg.³²⁰ These doses correspond to agonist/antagonist ratios of 26:1 and 13:1 for diazepam/flumazenil and midazolam/flumazenil, respectively. Flumazenil can be used in combination with opioid antagonists to reverse diazepam-oxymorphone sedation in dogs or alone to improve recoveries in cats given benzodiazepine-ketamine combinations.^{322,323} In birds, flumazenil (0.1 mg/kg IM) has been used to reverse sedation and muscle relaxation induced by high doses of midazolam (2 to 6 mg/kg IM).³¹⁴ Following tiletamine-zolazepam (Telazol) administration in pigs, flumazenil can be used to reverse rear-limb muscle paralysis during recovery.

Introduction

There are three major classes of analgesic agents employed in veterinary medicine for the management of pain: opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), and local anesthetics. In addition to these three traditional drug classes, another diverse group of agents used to manage pain is known collectively as analgesic adjuvants. This chapter reviews the pharmacology of the opioids, NSAIDs, and analgesic adjuvants. For a complete discussion of the local anesthetics, the reader is referred to Chapter 14.

Opioids

All opioid analgesics are chemically related to a group of compounds that have been purified from the juice of a particular species of poppy: *Papaverum somniferum*. The unrefined extract from the poppy is called *opium* and contains approximately 20 naturally occurring pharmacologically active compounds, including familiar ones like morphine and codeine. This group of

purified natural agents is specifically referred to as *opiates*. In addition, numerous semisynthetic and synthetic analogs of the opiates have been developed for clinical use. The word *opioid* is used broadly to cover all drugs that are chemical derivatives of the compounds purified from opium and is the term that is used throughout this chapter.

The opioids continue to be the cornerstone of effective pain treatment in veterinary medicine. They are a versatile group of drugs with extensive applications in the management of pain in patients with acute trauma, in patients undergoing surgical procedures, in patients with painful medical conditions or disease processes, and in patients suffering from chronic pain that require long-term therapy. In order for today's practitioner to be in a position to exploit this class of drugs to their fullest potential, a discussion encompassing the current state of knowledge of opioid pharmacology is appropriate.

Receptors

It is well known that exogenously administered opioids such as morphine or heroin exert their effects by interacting with specific opioid receptors and mimicking naturally occurring molecules known as *endogenous opioid peptides*. Based on work carried out over the past 20 years, it is now accepted that there are three well-defined types of opioid receptors, most commonly known by their Greek letter designations as μ (mu), δ (delta), and κ (kappa).¹⁻⁴ This classic system of nomenclature has been under reconsideration for a number of years and, during this time, several alternative naming systems have been proposed, leading to considerable confusion. In addition, a fourth type of opioid receptor, the nociceptin receptor (also known as the orphanin FQ receptor) has been characterized.^{5,6} According to the most recent recommendations of the International Union of Pharmacology Subcommittee on Nomenclature, variations based on the Greek letters remain acceptable. Thus, mu, μ , or MOP (for *mu opioid peptide*); delta, δ , or DOP (for *delta opioid peptide*); kappa, κ , or KOP (for *kappa opioid peptide*); and NOP (for *nociceptin opioid peptide*) are considered interchangeable abbreviations. Distinct complementary DNA (cDNA) sequences have been cloned for all four opioid receptor types, and each type appears to have a unique distribution in the brain, spinal cord, and periphery.⁷

The diversity of opioid receptors is further extended by the existence of several subtypes of μ , δ , and κ receptors. Based on pharmacological studies, there are thought to be at least three μ -receptor subtypes, μ_1 , μ_2 , and μ_3 ; two δ -receptor subtypes, δ_1

and δ_2 ; and perhaps as many as four κ -receptor subtypes, κ_{1a} , κ_{1b} , κ_2 , and κ_3 .⁷ The discovery of opioid receptor subtypes generated great enthusiasm among researchers and introduced the possibility of developing subtype-specific therapeutic agents with favorable side-effect profiles. At this point, however, the functional significance of these receptor subtypes remains unclear, and distinct cDNA sequences corresponding to these subtypes have not yet been identified.⁷

In general, it appears that the μ receptor mediates most of the clinically relevant analgesic effects, as well as most of the adverse side effects associated with opioid administration.² Drugs acting at the δ receptor tend to be poor analgesics, but may modify μ receptor-mediated antinociception under certain circumstances and mediate opioid receptor “crosstalk.” The κ receptor mediates analgesia in several specific locations in the central nervous system (CNS) and the periphery, but distinguishing μ - and κ -mediated analgesic effects has proven to be difficult.^{2,7} In contrast to the classic opioid receptors, the nociceptin receptor does not mediate typical opioid analgesia,^{3,6} but instead produces antiopioid (pronociceptive) effects.^{5,6} Because of the considerable structural homology among the three classically described opioid receptors, it is likely that there are significant interactions among these receptors in different tissues, and the loosely defined physiological roles ascribed to each receptor type still require further clarification.

Endogenous Receptor Ligands

The aforementioned opioid receptors discussed are part of an extensive opioid system that includes a large number of endogenous opioid peptide ligands. *Endogenous opioid peptides* are small molecules that are naturally produced in the CNS and in various glands throughout the body, such as the pituitary and the adrenal.³ Three distinct families of endogenous opioid peptides have been identified: the enkephalins, the dynorphins, and β -endorphin. Each of these is derived from a distinct precursor polypeptide: proenkephalin, prodynorphin, and proopioidmelanocortin, respectively.³ These endogenous opioid peptides are expressed throughout the CNS, and their presence has been confirmed in peripheral tissues, as well.³ There are considerable structural similarities among these three groups of peptides, and each family demonstrates variable affinities for μ , δ , and κ receptors. None of them bind exclusively to a single opioid receptor, and none of them have any significant affinity for the nociceptin receptor. The physiological roles of these peptides are not completely understood at this time. They appear to function as neurotransmitters, neuromodulators and, in some cases, as neurohormones. They mediate some forms of stress-induced analgesia and also play a role in analgesia induced by electrical stimulation of discrete regions in the brain, such as the periaqueductal gray area of the mesencephalon.⁴

Nociceptin (also known as orphanin FQ) is the endogenous ligand for the more recently discovered nociceptin receptor. Nociceptin is derived from pronociceptin, and its amino acid sequence is closely related to that of the aforementioned endogenous opioid peptides.^{3,5} Despite this homology, nociceptin binding is specific for the nociceptin receptor, and the peptide does not

appear to interact with μ , δ , or κ receptors. Furthermore, the physiological effects of nociceptin are in direct contrast to the actions of the classical endogenous opioid peptides, with nociceptin producing a distinctly pronociceptive effect.^{3,5,6} The functional significance of nociceptin and its receptor remains to be elucidated, but additional insight into this novel opioid peptide may have substantial implications in future therapeutic drug development.

In addition to the enkephalins, dynorphins, β -endorphin, and nociceptin, there are now two other recently discovered endogenous opioid peptides called endomorphin 1 and endomorphin 2.⁸ These peptides are putative products of an, as yet, unidentified precursor and have been proposed to be the highly selective endogenous ligands for the μ receptor.^{3,8} The endomorphins are small tetrapeptides that are structurally unrelated to the endogenous opioid peptides.⁸ Their identification has heralded a new era in research of the μ opioid system, which may contribute to our understanding of the neurobiology of opioids and provide new avenues for therapeutic interventions.

Signaling and Mechanisms of Analgesia

Binding of an opioid agonist to a neuronal opioid receptor, regardless of whether the agonist is endogenous or exogenous, typically leads to several events that serve to inhibit the activation of the neuron. Opioid receptors are part of a large superfamily of membrane-bound receptors that are coupled to G proteins.⁷ As such, they are structurally and functionally related to receptors for many other neurotransmitters and neuropeptides that act to modulate the activity of nerve cells. Opioid receptor binding, via activation of various types of G proteins, may inhibit adenylyl cyclase (cyclic adenosine monophosphate) activity, activate receptor-operated phosphate ion (K^+) currents, and suppress voltage-gated calcium ion (Ca^{2+}) currents.⁴

At the presynaptic level, decreased Ca^{2+} influx will reduce release of transmitter substances, such as substance P, from primary afferent fibers in the spinal cord dorsal horn thereby inhibiting synaptic transmission of nociceptive input.⁴ Postsynaptically, enhanced K^+ efflux causes neuronal hyperpolarization of spinal cord projection neurons and inhibits ascending nociceptive pathways. A third potential mode of opioid action involves upregulation of supraspinal descending antinociceptive pathways in the periaqueductal gray matter. It is now known that this system is subject to tonic inhibition mediated by GABAergic neurons, and opioid receptor activation has been shown to suppress this inhibitory influence and augment descending antinociceptive transmission.^{4,9} The proposed cellular basis for this involves μ receptors that activate voltage-dependent K ions present on presynaptic GABAergic nerve terminals that inhibit γ -aminobutyric acid (GABA) release into the synaptic cleft.⁹ It is important to note that although our collective understanding of opioid receptor-mediated signaling has increased dramatically in recent years, the relationship of such subcellular events to clinical analgesia at the level of the organism continues to require further clarification.

Distribution and Therapeutic Implications

Although cellular and molecular studies of opioid receptors and ligands are invaluable in understanding their function, it is criti-

cal to place opioid receptors in their anatomical and physiological context to fully appreciate the opioid system and its relevance to pain management. It has long been a principle tenet of opioid analgesia that these agents are centrally acting, and this understanding has shaped the way we use opioid analgesics clinically. It has been well established that the analgesic effects of opioids arise from their ability to directly inhibit the ascending transmission of nociceptive information from the spinal cord dorsal horn, and to activate pain-control circuits that descend from the mid-brain via the rostral ventromedial medulla to the spinal cord. Within the CNS, evidence of μ , δ , and κ opioid receptor messenger RNA and/or opioid peptide binding has been demonstrated in supraspinal sites, including the mesencephalic periaqueductal gray matter, the mesencephalic reticular formation, various nuclei of the rostral ventromedial medulla, and forebrain regions including the nucleus accumbens, as well as spinally within the dorsal horn.^{10,11} The interactions between groups of opioid receptors at various spinal and supraspinal locations, as well as interactions among different receptor types within a given location are complex and incompletely understood at this time.

Systemic administration of opioid analgesics via intravenous, intramuscular, or subcutaneous injection will induce a relatively rapid onset of action via interaction with these CNS receptors. Oral, transdermal, rectal, or buccal mucosal administration of opioids will result in variable systemic absorption, depending on the characteristics of the particular agent, with analgesic effects being mediated largely by the same receptors within the CNS. In addition, neuraxial administration, either into the subarachnoid or epidural space, is a particularly efficacious route of administration. Small doses of opioids introduced via these routes readily penetrate the spinal cord and interact with spinal and/or supraspinal opioid receptors to produce profound and potentially long-lasting analgesia, the characteristics of which will depend on the particular drug used.

Even though opioids have long been considered the prototype of centrally acting analgesics, a body of evidence has emerged that clearly indicates that opioids can produce potent and clinically measurable analgesia by activation of opioid receptors in the peripheral nervous system.¹² Opioid receptors of all three major types have been identified on the processes of sensory neurons,^{13,14} and these receptors respond to peripherally applied opioids and locally released endogenous opioid peptides when upregulated during inflammatory-pain states.^{12,15,16} Furthermore, although sympathetic neurons and immune cells have also been shown to express opioid receptors, their functional role remains unclear.¹⁴ Although the binding characteristics of peripheral and central opioid receptors are similar, the molecular mass of peripheral and central μ opioid receptors appears to be different, suggesting that selective ligands for these peripheral receptors could be developed that would produce opioid analgesia without the potential to induce centrally mediated adverse side effects.^{12,14,17–19}

Side Effects

Although opioids are used clinically primarily for their pain-relieving properties, they also produce a host of other effects on

a variety of body systems. This is not surprising in light of the wide distribution of endogenous opioid peptides and their receptors in supraspinal, spinal, and peripheral locations. Some of these side effects, such as sedation, may be classified as either desirable or undesirable depending on the clinical circumstances. The following is a brief summary of these major side effects as they relate to opioids as a class of drugs.

Central Nervous System

Arousal There are considerable species differences in the CNS response to opioid analgesics that cannot be attributed to pharmacokinetic variations alone. CNS depression (i.e., sedation) is typically seen in dogs, monkeys, and people, whereas CNS stimulation (i.e., excitement and/or spontaneous locomotor activity) may be elicited in cats, horses, goats, sheep, pigs, and cows after systemic administration of various opioids, most notably morphine.²⁰ Reasons for these different responses are not entirely clear at this time, but are presumably related to differing concentrations and distributions of μ , δ , and κ receptors in various regions of the brain in these species.²¹ Despite these fundamental differences, it must be remembered that there are numerous factors that may affect the CNS response to opioids within a given species, including the temperament or condition of the patient; the presence or absence of pain; the dose, route, and timing of drug administration; and the specific opioid administered.

Thermoregulatory Center The hypothalamic thermoregulatory system is also affected by opioid administration. Hypothermia tends to be the most common response, particularly when opioids are used during the perioperative period in the presence of other CNS-depressant drugs.^{10,20} Under some clinical circumstances, however, opioid administration causes hyperthermia in cats, horses, swine, and ruminants. Part of this increase in body temperature may be attributed to an increase in muscle activity associated with CNS excitation in these species; however, a specific central hypothalamic mechanism has also been implicated, but remains poorly understood.²⁰ Panting is seen commonly after opioid administration, most often in dogs, but this effect tends to decrease with the onset of hypothermia.

Emetic Center Nausea and vomiting associated with opioid administration are caused by direct stimulation of the chemoreceptor trigger zone for emesis located in the area postrema of the medulla.^{10,22} As with the other centrally mediated side effects, species plays a role in determining an individual's tendency to vomit after an opioid is administered. Horses, rabbits, ruminants, and swine do not vomit with opioid administration. Cats may vomit, but usually at doses that are greater than those which stimulate vomiting in dogs. Dogs will commonly vomit after opioid administration, especially with morphine. Emesis is rarely seen when opioids are administered in the immediate postoperative period or in any patient that may be experiencing some degree of pain.

Cough Center Opioids have variable efficacy in depressing the cough reflex, at least in part by a direct effect on a cough center

located in the medulla.¹⁰ Certain opioids are more effective antitussives than others, and drugs like codeine, hydrocodone, and butorphanol are occasionally prescribed specifically for this indication.

Pupillary Diameter As a general rule, opioids tend to produce mydriasis in those species that exhibit CNS excitation, and miosis in those that become sedated after opioid administration.^{20,23–25} Miosis is produced by an excitatory action of opioids on neuronal firing in the oculomotor nucleus.^{22,24,25} In cats, and presumably in other species that exhibit mydriasis, this increase in activity in the oculomotor nuclear complex still occurs, but the miotic effect is masked by increased release of catecholamines, which produces mydriasis.²⁵

Respiratory System

Opioids produce dose-dependent depression of ventilation, primarily mediated by μ_2 receptors, leading to a direct depressant effect on brain-stem respiratory centers.^{10,22} This effect is characterized by decreased responsiveness of these centers to carbon dioxide and is reflected in an increased resting arterial carbon dioxide partial pressure and displacement of the carbon dioxide response curve to the right. This effect is compounded by the coadministration of sedative and/or anesthetic agents, meaning that significant respiratory depression and hypercapnia are much more likely to occur in anesthetized patients that receive opioids compared with those that are conscious. It should be noted that, in general, humans tend to be more sensitive to the respiratory-depressant effects of opioids when compared with most veterinary species, and the risk of hypoventilation would rarely constitute a legitimate reason for withholding opioid treatment in clinical practice.

Cardiovascular System

Most opioids have minimal effects on cardiac output, cardiac rhythm, and arterial blood pressure when clinically relevant analgesic doses are administered. Bradycardia may be caused by opioid-induced medullary vagal stimulation and will respond readily to anticholinergic treatment if warranted. Particular opioids (morphine and meperidine) can cause histamine release, especially after rapid intravenous administration, which may lead to vasodilation and hypotension.^{20,26} Because of their relatively benign effects on cardiovascular function, opioids commonly form the basis of anesthetic protocols for patients with preexisting cardiovascular disease.

Gastrointestinal System

The gastrointestinal effects of the opioids are mediated by μ and δ receptors located in the myenteric plexus of the gastrointestinal tract.^{10,20} Opioid administration will often stimulate dogs and, less frequently, cats to defecate. After this initial response, spasm of gastrointestinal smooth muscle predisposes patients to ileus and constipation. Horses and ruminants in particular may be predisposed to gastrointestinal complications associated with opioid administration, such as colic and ruminal tympany, respectively. These side effects tend to be most significant with prolonged ad-

ministration of opioids in dogs and cats experiencing chronic pain, and such patients may require dietary modifications and stool-softening medications to manage these adverse effects.

In human patients, opioids (most notably fentanyl and morphine) have been shown to increase bile duct pressure through constriction of the sphincter of Oddi.²⁷ The incidence of this side effect in people is, however, quite low.²⁸ Despite anatomical differences, this observation has led to concerns about opioid administration to dogs and cats with pancreatitis and/or cholangitis. A study reviewing the body of human literature found that, despite widespread clinical practice, there was no evidence to indicate that morphine is contraindicated for use in acute pancreatitis.²⁹ As there are no studies that specifically evaluate the effects of opioids in dogs and cats with pancreatitis, it does not at this time seem appropriate to withhold this class of drugs from this subset of severely painful patients.

Genitourinary System

Opioids, particularly when administered neuraxially, may cause urinary retention through dose-dependent suppression of detrusor contractility and decreased sensation of urge.^{30,31} Manual expression of the urinary bladder or catheterization may be required in certain individuals until urodynamic function returns to normal.

Urine volume may also be affected by opioids, and the mechanism of this effect appears to be multifactorial. μ -Agonists tend to produce oliguria in the clinical setting, and this is in part due to increased antidiuretic hormone release leading to altered renal tubular function.^{22,32} Elevations in circulating plasma atrial natriuretic peptide may also play a role in morphine-induced antidiuresis.³² Conversely, κ -agonists tend to produce a diuretic effect, possibly through inhibition of antidiuretic hormone secretion.^{22,32} Other peripheral mechanisms involving stimulation of renal α_2 -adrenergic receptors may also contribute to this κ -agonist effect.³²

Agonists

Almost all clinically useful opioids exert their analgesic effects by acting as agonists at μ receptors. Although a few opioids act as κ -agonists, these drugs also tend to have antagonist or partial agonist effects at μ and/or δ receptors and are thus not classified as *pure* agonists. Pure or full opioid agonists can elicit maximal activation of the receptor when they bind it, and the subsequent downstream processes produce a maximal analgesic effect (Fig. 10.1). Clinically, the full μ -agonists are superior analgesics and are the drugs of choice for pain of moderate to severe intensity in many veterinary species (see Table 10.1 for recommended dosages). The following section contains brief descriptions of full μ -agonists that are in current clinical use.

Morphine (Morphine Sulfate)

Morphine is the prototypical opioid analgesic and acts as a full agonist not only at μ receptors, but also at δ and κ receptors.¹⁰ Despite the development of numerous synthetic opioids, many of which are more potent than morphine and may have other characteristics that make them desirable alternatives to morphine in certain circumstances, no other drug has been shown to be more

Fig. 10.1. A lock-and-key analogy is used to illustrate full agonist drug interactions at opioid receptors, with a relative dose-response curve for analgesic efficacy shown below. A full opioid agonist (in this case, morphine) stimulates both μ - and κ -receptor types, which produces increased analgesic effect with increased dose. Modified from Nicholson and Christie,²⁷⁰ p. 273, with permission from Elsevier.

CRI, continuous-rate infusion; IM, intramuscular(ly); IV, intravenous(ly); NR, not recommended for administration in this species; PO, per os (orally); SC, subcutaneous(ly); ?, reliable doses have not been established for this species.

^aPreservative-free formulations are recommended for epidural administration.

^bDoses are for sustained-release product (MS Contin), which should be dosed q 12 h.

^cLower IV infusion rates are suitable for management of most types of pain, whereas higher rates will produce profound analgesia suitable for surgery.

^dFentanyl transdermal patches are available in 0.025-, 0.05-, 0.075-, or 0.1-mg/h sizes.

efficacious than morphine at relieving pain. Compared with the synthetic opioid agonists, morphine is relatively hydrophilic and crosses the blood-brain barrier more slowly than fentanyl or oxycodone, thereby delaying the peak effect somewhat even after intravenous administration.^{10,22} Clinically, this lag is not likely to be significant under most circumstances, with the onset of analgesia occurring reasonably promptly after a single dose of morphine and typically lasting 3 to 4 h.^{33,34} Morphine's poor lipid solubility means that it can produce long-lasting analgesia when administered into the epidural or subarachnoid space, with effects persisting for 12 to 24 h. The first-pass effect is significant after oral administration, and the bioavailability of oral morphine preparations is only in the range of 25%. If dose adjustments are made, adequate pain relief can be achieved with oral morphine administration, and the duration of action tends to be somewhat longer with this route.

In most species, the primary metabolic pathway for morphine involves conjugation with glucuronic acid leading to the formation of two major metabolites: morphine 6-glucuronide and morphine 3-glucuronide.^{10,35} Despite the low levels of glucuronyl transferase in cats, the pharmacokinetics of morphine in this species seem to be broadly comparable to those in dogs and people, though clearance rates may be marginally slower.^{33–35} This suggests that morphine must undergo a different type of conjugation reaction in this species. Morphine 6-glucuronide has pharmacological activities that are indistinguishable from those of morphine in animal models and in people, whereas morphine 3-glucuronide appears to have little affinity for opioid receptors, but may contribute to the excitatory effects of morphine in some situations.^{10,36} With chronic morphine administration, it is likely that the active metabolite, morphine 6-glucuronide, contributes significantly to clinical analgesia.

Very little morphine is excreted unchanged in the urine. The major metabolites—morphine 3-glucuronide and, to a lesser extent, morphine 6-glucuronide—are eliminated almost entirely via glomerular filtration. In human patients, renal failure may lead to accumulation of morphine 6-glucuronide and persistent clinical effects, whereas liver dysfunction seems to have minimal impact on morphine clearance.^{10,22}

The side effects associated with morphine administration are typical of most opioid agonists and have been discussed previously in this chapter. In particular, the increased incidence of vomiting after morphine administration, as well as its potential to cause histamine release after intravenous administration, helps to distinguish morphine from other full opioid agonists.

Clinically, morphine is a useful analgesic in dogs, cats, horses, and rats. It is often administered to dogs and cats at fixed dosing intervals via the intramuscular, subcutaneous or, less commonly, intravenous routes to manage pain associated with a variety of traumatic injuries and disease processes. Morphine has also been used extensively throughout the perioperative period in these species to manage pain associated with surgical procedures. In dogs and cats, the sparing effect of morphine on both injectable and inhalant anesthetic requirements can be significant.^{37,38} Morphine is particularly effective in dogs when administered intravenously as a continuous infusion, which facilitates more pre-

cise dose titration to achieve optimal analgesic effects.^{38,39} Subcutaneous infusions of morphine and other opioids are being employed in human patients experiencing cancer pain,^{40–43} and, as subcutaneous infusion devices are developed that are applicable to dogs and cats, this route of administration may be accessed by veterinarians in the future. Administration of the drug into the epidural or, less commonly, subarachnoid space is a common analgesic technique employed in both dogs and cats in a variety of clinical situations.^{44,45} More recently, the discovery of peripheral μ opioid receptors has led to the clinical practice of instilling morphine locally into inflamed joints^{46,47} and even topically onto damaged corneas⁴⁸ to supplement analgesia in canine patients.

The analgesic benefits of morphine use in horses are less clear-cut than in dogs and cats. Low doses of morphine can be administered systemically without adverse side effects and may relieve pain in conscious horses, though the analgesic response has been difficult to demonstrate in numerous clinical studies.⁴⁹ A 2003 study showed that morphine, in the absence of other drugs, actually increased the minimum alveolar concentration (MAC) of isoflurane in horses anesthetized in an experimental setting.⁵⁰ While this finding would appear to discourage routine use of morphine in the perioperative period, another retrospective study failed to demonstrate any adverse effects associated with perioperative morphine administration in a typical clinical setting in the presence of other drugs, such as α_2 -agonists and ketamine.⁵¹ Thus, the routine systemic administration of morphine to horses, especially those undergoing surgery, remains controversial.

Regional administration of morphine to horses, however, is becoming increasingly common, and a growing body of evidence seems to support this practice. Morphine produces significant analgesia with few adverse side effects when administered epidurally or intra-articularly and is often combined with other analgesic agents, such as α_2 -agonists and local anesthetics, when administered via these routes.^{49,52,53}

Morphine is used infrequently in ruminants and swine in the clinical setting, and its effects have not been well studied in these species. It is likely that regional and perhaps even systemic administration of morphine may play a role in pain management of these species in the future.

Oxymorphone (Oxymorphone Hydrochloride [Numorphan])

Oxymorphone is a synthetic opioid that acts as a full agonist at μ receptors and is comparable to morphine in its analgesic efficacy and duration of action. It is a more lipid soluble drug than morphine and is readily absorbed after intramuscular or subcutaneous administration. Oxymorphone is not available as an oral formulation.

When compared with morphine, oxymorphone is less likely to cause dogs and cats to vomit, and tends to produce more sedation when administered to these species. Its respiratory-depressant effects are similar to those induced by morphine, but oxymorphone seems more likely to cause dogs to pant. It does not produce histamine release, even when administered intravenously.²⁶ Oxymorphone's other side effects are typical of other full μ -agonist opioids and have been discussed previously.

Oxymorphone has been used extensively in dogs and cats, and is most often administered at fixed dosing intervals, either intramuscularly, subcutaneously, or intravenously, to manage pain in a variety of clinical settings. It is also commonly used in the pre-anesthetic, intraoperative, and postoperative periods in surgical patients. Oxymorphone has been administered epidurally in dogs, but its relative lipid solubility means that its analgesic action is briefer when administered by this route compared with the action of morphine.⁵⁴

Oxymorphone is not commonly administered to horses, ruminants, or swine, and little data exist in these species to make any therapeutic recommendations.

Hydromorphone (Hydromorphone Hydrochloride [Dilaudid])

Hydromorphone is a synthetic opioid that acts as a full agonist at μ receptors and is used in both human and veterinary medicine. Clinically, hydromorphone and oxymorphone have similar efficacy, potency, duration of analgesic action, and side-effect profiles, but hydromorphone remains significantly less expensive. Like oxymorphone, hydromorphone is not associated with histamine release, so bolus intravenous administration is considered safe.²⁶

In dogs and cats, hydromorphone can be used in any clinical situation where oxymorphone is used. Evidence from the human literature suggests that hydromorphone may be suitable for administration via a continuous infusion, either intravenously, subcutaneously, or epidurally,^{42,55,56} and these routes of administration may further expand the use of hydromorphone in veterinary patients in the future. There is little published on the use of hydromorphone in large animal species at this time.

Meperidine (Meperidine Hydrochloride or Pethidine [Demerol])

Meperidine is a synthetic opioid that exerts its analgesic effects through agonism at μ receptors. Interestingly, it also appears able to bind other types of receptors, which may contribute to some of its clinical effects other than analgesia. Meperidine can block sodium channels and inhibit activity in dorsal horn neurons in a manner analogous to local anesthetics.^{57,58} Meperidine also exerts agonist activity at α_2 receptors, specifically the α_{2B} subtype, suggesting that it may possess some α_2 -agonist-like properties.^{59,60}

Meperidine has a shorter analgesic action compared with morphine, oxymorphone, or hydromorphone, typically not extending beyond 1 h.²⁰ Metabolic pathways vary among different species, but, in general, most of the drug is demethylated to normeperidine in the liver and then undergoes further hydrolysis and ultimately renal excretion.^{20,34,61} Normeperidine is an active metabolite and has approximately one-half the analgesic efficacy of meperidine.^{10,20} Normeperidine has produced toxic neurological side effects in human patients receiving meperidine for prolonged periods, especially in the presence of impaired renal function.^{22,62}

Unlike most of the other opioids in clinical use, meperidine has been shown to produce significant negative inotropic effects when administered alone to conscious dogs.⁶³ Because of its

modest atropine-like effects, meperidine tends to increase heart rate rather than predispose patients to bradycardia, as is often seen with other opioids.^{20,22} The clinical significance of these cardiovascular effects in the perianesthetic period has never been clearly ascertained. Like morphine, meperidine also causes histamine release when administered intravenously.²⁰

A rare, but life-threatening, drug interaction that may have relevance in veterinary medicine has been reported in human patients receiving meperidine. The combination of meperidine (and perhaps other opioids) with a monoamine oxidase inhibitor may lead to *serotonin syndrome*, which is characterized by a constellation of symptoms, including confusion, fever, shivering, diaphoresis, ataxia, hyperreflexia, myoclonus, and diarrhea.^{64–67} A monoamine oxidase inhibitor, selegiline (Deprenyl), has been used in canine patients to treat pituitary-dependent hyperadrenocorticism or to modify behavior in patients with canine cognitive dysfunction. Though there have not, to date, been any scientific studies of adverse meperidine-selegiline interactions in dogs, veterinarians must be aware of the potential for complications if analgesia is required in patients receiving monoamine oxidase inhibitors. A recent study that evaluated the effects of other opioids (oxymorphone and butorphanol) in selegiline-treated dogs did not identify any specific adverse drug interactions in these animals.⁶⁸

Clinically, meperidine has been used primarily in dogs and cats during the preanesthetic period, often in combination with sedatives or tranquilizers. In patients undergoing surgery, administration of another full μ -agonist opioid with a longer duration of action is recommended for use postoperatively. Meperidine appears to offer few, if any, advantages over other opioids, such as oxymorphone or hydromorphone, in these species during the perioperative period.

Meperidine is not commonly used in large animals, but may, like morphine, produce useful analgesic effects when administered into the epidural space in these species.⁶⁹ Because of its local anesthetic-like effects, caudal epidural meperidine may offer advantages over other epidural opioids when perineal analgesia is specifically indicated.

Fentanyl (Fentanyl Citrate [Sublimaze])

Fentanyl is a highly lipid soluble, short-acting synthetic μ opioid agonist. A single dose of fentanyl administered intravenously has a more rapid onset and a much briefer action than morphine. Peak analgesic effects occur in about 5 min and last approximately 30 min.^{10,22} Rapid redistribution of the drug to inactive tissue sites, such as fat and skeletal muscle, leads to a decrease in plasma concentration and is responsible for the prompt termination of clinical effects. In most veterinary species, the elimination half-life after a single bolus or a brief infusion is in the range of 2 to 3 h.^{70–72} Administration of very large doses or prolonged infusions may cause saturation of inactive tissues, with termination of clinical effects becoming dependent on hepatic metabolism and renal excretion.^{10,22} Thus, the context-sensitive half-life of fentanyl increases significantly with the duration of the infusion, and clinical effects may persist for an extended period following termination of a long-term intravenous infusion.

Side effects associated with fentanyl administration are similar to those of the other full μ -agonist opioids. In general, cardiovascular stability is excellent with fentanyl, and intravenous administration is not associated with histamine release.^{10,22} Bradycardia may be significant with bolus doses, but readily responds to anticholinergics if treatment is warranted.^{10,20} In human patients, muscle rigidity, especially of the chest wall, has been noted after administration of fentanyl or one of its congeners.^{65,73,74} The potential significance of this adverse effect in animal patients is not clear at this time, and the risk is considered minimal if large, rapid bolus administrations are avoided.

Clinically, fentanyl is used most frequently in dogs and cats, but is also a potentially useful analgesic in other species, including horses, cows, sheep, goats, and pigs. Historically, fentanyl was available in combination with the butyrophenone tranquilizer, droperidol, in a product called Innovar-Vet, which was typically administered in the preanesthetic period to provide sedation and analgesia. This product is no longer available, and systemic administration of fentanyl today is usually via the intravenous route.

Because of its shorter action, fentanyl is typically administered as a continuous infusion to provide analgesia. Intravenous fentanyl can be infused at relatively low doses to supplement analgesia intraoperatively and/or postoperatively in dogs and cats. It is also useful for management of nonsurgical pain, such as that associated with pancreatitis. Alternatively, larger doses can be administered, often in combination with a benzodiazepine like midazolam, to induce general anesthesia in canine patients with cardiovascular or hemodynamic instability. Similarly, higher infusion rates of fentanyl can be used as the primary anesthetic agent for surgical maintenance in patients who will not tolerate significant concentrations of volatile inhalant anesthetics.⁷⁵⁻⁷⁷ In the clinical setting, there are few reports of intravenous fentanyl administration in large animal species, though fentanyl infusions have been employed in a variety of surgical animal research models involving calves, sheep, and pigs.^{78,79}

In addition to intravenous administration, fentanyl may be deposited into the epidural space to produce analgesia. Because of its high lipid solubility, epidural fentanyl, unlike morphine, is rapidly absorbed into the systemic circulation. Consequently, the clinical effects associated with a single bolus of epidural fentanyl resemble those of an intravenous injection. However, the benefits of neuraxial administration can be achieved by administering epidural fentanyl as a continuous infusion through an indwelling epidural catheter, often in combination with other analgesic agents. This technique is typically used in canine patients for management of severe acute pain, but it may have additional applications for the management of chronic pain as well.

The development of novel, less invasive, routes of opioid administration for use in human patients led to the marketing of transdermal fentanyl patches (Duragesic). The patches are designed to release a constant amount of fentanyl per hour that is then absorbed across the skin and taken up systemically. Fentanyl patches are designed for human skin and human body temperature, but their use has been evaluated in a number of veterinary species.^{70,72,80-86} Though transdermal fentanyl appears

to be an effective means of providing analgesia in a number of clinical settings, substantial variations in plasma drug concentrations have been documented, and significant lag times after patch placement are common prior to onset of analgesia.^{70,71,83,84} Furthermore, changes in body temperature have been shown to affect fentanyl absorption significantly in anesthetized cats,⁸⁷ and it is likely that other factors associated with skin preparation and patch placement have the potential to alter plasma fentanyl levels and analgesic efficacy substantially. Two recent studies evaluating the efficacy of pluronic lecithin organogel (PLO gel) delivery of fentanyl through skin in dogs and cats concluded that this method of administration did not result in measurable plasma concentrations and thus could not be justified as an effective means of systemic administration.^{88,89}

Alfentanil, Sufentanil, and Remifentanil (Alfenta, Sufenta, and Ultiva)

Alfentanil, sufentanil, and remifentanil are all structural analogs of fentanyl that were developed for use in human patients in an effort to create analgesics with a more rapid onset of action and predictable termination of opioid effects. All three are similar with regard to onset, and all have context-sensitive half-lives that are shorter than that of fentanyl after prolonged infusions.²² Remifentanil is unique among opioids because it is metabolized by nonspecific plasma esterases to inactive metabolites.^{90,91} Thus, hepatic or renal dysfunction will have little impact on drug clearance, and this, in combination with the robust nature of the esterase metabolic system, contributes to the predictability associated with remifentanil infusion.^{10,22}

All three of these drugs are used during general anesthesia for procedures requiring intense analgesia and/or blunting of the sympathetic nervous system response to noxious stimulation. As yet, they have limited applications for postoperative or chronic pain management. Like fentanyl, they can be administered at relatively low infusion rates as adjuncts to general anesthetic protocols based on volatile inhalant or other injectable agents, or they can be administered at higher rates as primary agents for total intravenous anesthesia. The minimum alveolar-sparing properties of these agents have been demonstrated in both dogs^{91,92} and cats.^{77,93,94} In horses, systemic infusions of alfentanil did not have significant effects on MACs of inhalant anesthetics and, when administered to conscious horses, were associated with increases in locomotor activity.⁹⁵⁻⁹⁷ There is little evidence to suggest that any of the fentanyl analogs offer advantages over morphine when administered into the epidural space for analgesia.⁵²

Methadone (Methadone Hydrochloride [Dolorphine])

Methadone is a synthetic μ opioid agonist with pharmacological properties qualitatively similar to those of morphine, but possessing additional affinity for *N*-methyl-D-aspartate (NMDA) receptors.^{98,99} Methadone's unique clinical characteristics include excellent absorption after oral administration, no known active metabolites, high potency, and an extended duration of action.^{10,20,99} In human patients, the drug has been used primarily in the treatment of opioid-abstinence syndromes, but is being used increasingly for the management of chronic pain. Though

there are reports of intramuscular or intravenous administration of methadone in the perioperative period in dogs, cats, and horses,^{100–102} the drug is not commonly used in this setting in North America at this time. Additional studies may identify a role for oral methadone in the management of chronic pain syndromes in veterinary patients.

Codeine (Codeine Phosphate)

Codeine is the result of substitution of a methyl group onto morphine, which acts to limit first-pass hepatic metabolism and accounts for codeine's high oral bioavailability.^{10,22} Codeine is well known for its excellent antitussive properties and is often combined in an oral formulation with a nonopioid analgesic, such as acetaminophen, for the management of mild to moderate pain in human patients. Codeine, alone or in combination with acetaminophen (Tylenol 3), has been used in dogs for the management of mild pain on an outpatient basis.

Oxycodone and Hydrocodone (Oxycodone Hydrochloride and Hydrocodone Bitartrate)

Oxycodone and hydrocodone are opioids that are typically administered orally for the treatment of pain in human patients. Though oxycodone is available as a single-drug continuous-release formulation (Oxycontin), these drugs are most often prepared in combination with nonopioid analgesics, such as aspirin and acetaminophen (e.g., Percocet, Percodan, Lorcet, and Vicodan). Little has been published regarding the use of these opioids in veterinary patients, and thus specific recommendations regarding their use cannot be made at this time.

Etorphine and Carfentanil (M-99 and Wildnil)

These two opioids are discussed together because they are both used exclusively for the restraint and capture of wild animals rather than as analgesic agents. They are extremely potent opioids, and the immediate availability of a suitable antagonist is mandatory before these drugs are to be used, not only to reverse drug effects in animal patients, but also as a safety precaution in the event of accidental human injection. Though etorphine and carfentanil are most often injected intramuscularly (usually using a remote drug-delivery technique), studies suggest that carfentanil is useful when administered orally in a variety of species.^{103–106} A number of different drugs have been used in combination with etorphine or carfentanil to enhance muscle relaxation, including acepromazine, xylazine, and medetomidine.^{107–110} For more detailed information on the use of these agents for immobilization of free-ranging wildlife, readers are referred to Chapters 12, 31, and 32 in this text.

Agonist-Antagonists and Partial Agonists

This group includes drugs that have varying opioid receptor-binding profiles, but that have one thing in common: They all occupy μ opioid receptors, but do not initiate a maximal clinical response. Drugs such as butorphanol and nalbuphine are classified as agonist-antagonists. They are competitive μ -receptor antagonists, but exert their analgesic actions by acting as agonists at κ receptors (Fig. 10.2). Buprenorphine, on the other hand, is

Fig. 10.2. A lock-and-key analogy is used to illustrate agonist-antagonist drug interactions at opioid receptors, with a relative dose-response curve for analgesic efficacy shown below. An agonist-antagonist opioid (in this case, butorphanol) has agonist activity at κ receptors and antagonist activity at μ receptors. In the presence of a full μ -agonist, these opioids tend to have antagonistic effects and will increase the dose of full agonist required to achieve maximal analgesic effect. Modified from Nicholson and Christie,²⁷⁰ p. 273, with permission from Elsevier.

classified as a partial agonist and binds μ receptors, but produces only a limited clinical effect (Fig. 10.3). These mixed agonist-antagonist drugs were developed for the human market in an attempt to create analgesics with less respiratory depression and addictive potential. Because of their opioid receptor-binding affinities, the side effects associated with these drugs demonstrate a so-called ceiling effect, whereby increasing doses do not produce additional adverse responses. Unfortunately, the benefits of this ceiling effect on ventilatory depression come at the expense of limited analgesic efficacy and only a modest ability to decrease anesthetic requirements.

The coadministration of opioids with differing receptor-binding profiles is currently an active area of research that deserves further attention. The interactions in this setting are complex, and opioid coadministration appears to have the potential to produce additive, synergistic, or antagonistic analgesic effects, depending on the particular species, dosage, drugs, and pain model being evaluated. The following section contains brief descriptions of opioid agonist-antagonists and partial agonists that are currently in clinical use (see Table 10.2 for recommended dosages).

Butorphanol (Butorphanol Tartrate [Torbugesic])

Butorphanol is a synthetic agonist-antagonist opioid and has been used extensively in a wide variety of veterinary species. The drug was originally labeled as an antitussive agent in dogs and,

Fig. 10.3. A lock-and-key analogy is used to illustrate partial agonist drug interactions at opioid receptors, with a relative dose-response curve for analgesic efficacy shown below. A partial opioid agonist (in this case, buprenorphine) weakly stimulates μ receptors, which produces a reduced maximal analgesic effect compared with a full agonist. A large dose of partial agonist will block the receptor actions of a full agonist, moving its dose-response curve to the right and depressing its maximal analgesic effect. Modified from Nicholson and Christie,²⁷⁰ p. 273, with permission from Elsevier.

even now, is approved as an analgesic in cats and horses only.²⁰ Butorphanol exerts its relevant clinical effects through its interactions at κ receptors and acts as an antagonist at μ receptors. The duration of butorphanol's analgesic effects remains somewhat debatable and likely varies with species, type and intensity of pain, dosage, and route of administration.^{111–113} In general, its effects are shorter-lived than those of morphine and are probably in the range of 1 to 3 h. Butorphanol is typically administered via

the intramuscular, subcutaneous, or intravenous route, though an oral formulation is available and is occasionally prescribed for outpatient analgesia in dogs.

Butorphanol does not induce histamine release when administered intravenously and has minimal effects on cardiopulmonary function. There is conflicting evidence regarding the effects of butorphanol on inhalant anesthetic requirements in the dogs, cats, and horses. Earlier studies failed to demonstrate a significant sparing effect on MAC when butorphanol was coadministered with halothane in dogs and ponies.^{114–116} More recently, isoflurane MAC reductions have been documented after administration of clinically relevant doses of butorphanol in both dogs and cats.^{37,117} Reasons for these discrepancies are probably related to differences in study techniques, and, in dogs and cats specifically, it seems that butorphanol can induce at least modest reductions in inhalant anesthetic requirements.

When administered alone to healthy dogs and cats, butorphanol produces minimal sedation only. However, the drug is commonly used in combination with a variety of sedatives and tranquilizers, such as acepromazine, medetomidine, or midazolam, to produce sedation and analgesia for minimally invasive procedures.¹¹⁸ It is also used during the preanesthetic and postoperative periods to provide analgesia for surgical procedures associated with mild to moderate pain.^{85,119,120} Butorphanol does not appear to be an effective monoanalgesic for moderate to severe pain in these species, especially when pain is orthopedic in origin.^{121–123}

Butorphanol, which is the opioid most commonly used in horses, is almost always coadministered with an α_2 -agonist or, occasionally, acepromazine. It is administered intravenously for a variety of standing procedures or prior to induction of general anesthesia. Butorphanol has been shown to be an effective, though short-lived, analgesic for visceral pain in this species, but the α_2 -agonists still seem to be superior for treatment of this type of pain in horses.^{124,125} One study has documented the safety and apparent efficacy of a continuous intravenous infusion of butorphanol that maintained therapeutic plasma levels of drug while minimizing the potential for adverse gastrointestinal and behavioral effects.¹¹³ Butorphanol has not been shown to be particu-

^aButorphanol's oral bioavailability remains uncertain.

^bBuprenorphine injectable solution has been shown to be effective when administered to the buccal mucosa in cats.

larly effective when administered into the caudal epidural space in horses, and other opioids, such as morphine, produce superior analgesia when given by this route.^{52,126}

Butorphanol is occasionally administered to cattle, sheep, goats, and pigs to provide analgesia, but there is limited information in the literature on its analgesic efficacy in these species. The combination of butorphanol with xylazine or detomidine appears to enhance and prolong the sedation induced by the α_2 -agonist. Additional studies evaluating the analgesic potential of butorphanol and other opioids in these species are certainly warranted.

Traditionally, it was thought that the simultaneous or sequential administration of butorphanol with a pure μ opioid agonist such as morphine or hydromorphone would be counterproductive from an analgesic standpoint because butorphanol's ability to antagonize μ receptors could inhibit or even reverse the effects of the agonist drug. Certainly, it has been clearly demonstrated that excessive sedation associated with a pure μ -agonist can be partially reversed by the administration of low doses of butorphanol, and it was presumed that butorphanol would similarly reverse the μ -mediated analgesic effects, as well. It would now appear that the potential interactions between butorphanol and full μ opioid agonists are more complex than originally believed. One study demonstrated that coadministration of butorphanol and oxymorphone to cats subjected to a visceral noxious stimulus enhanced analgesic effects.¹²⁷ A more recent feline study, however, which evaluated the combination of butorphanol and hydromorphone in a thermal threshold-pain model, failed to demonstrate enhanced analgesia and suggested that butorphanol actually did inhibit hydromorphone's analgesic effects.¹²⁸

These contradictory findings illustrate that we still have much to learn about coadministration of opioid agents with differing receptor-binding profiles, and the clinical effects produced by such coadministration likely depend on many factors, including species, type of pain, dose, and the specific drugs involved.

Nalbuphine and Pentazocine (Nalbuphine Hydrochloride [Nubain] and Pentazocine Hydrochloride [Talwin])

Nalbuphine and pentazocine are classified as agonist-antagonist opioids and are clinically similar to butorphanol. They induce mild analgesia accompanied by minimal sedation, respiratory depression, or adverse cardiovascular effects. In human patients, nalbuphine is used more commonly than butorphanol, whereas, in veterinary medicine, butorphanol is used far more frequently. In the past, pentazocine was used in equine patients for management of colic pain, but it has largely been replaced by the α_2 -agonists (xylazine and detomidine), nonsteroidal anti-inflammatories (flunixin meglumine), and butorphanol. Like butorphanol, nalbuphine is occasionally used to partially reverse the effects of a full μ -agonist opioid while maintaining some residual analgesia.

Buprenorphine (Buprenex [Temgesic])

Buprenorphine is a semisynthetic, highly lipophilic opioid derived from thebaine. Unlike other opioids in this category, buprenorphine is considered to be a partial agonist at μ opioid receptors. The drug binds avidly to, and dissociates slowly from, μ receptors, but cannot elicit a maximal clinical response. Because

of its receptor-binding characteristics, buprenorphine has a delayed onset of action and takes at least 1 h to attain peak effect after intramuscular administration. It also has a relatively long action, with clinical analgesic effects persisting for 6 to 12 h in most species. Also, its high affinity for the μ receptor means that it may be difficult to antagonize its effects with a drug such as naloxone. Buprenorphine has most often been administered intravenously or intramuscularly; however, because of the long lag time before clinical effects are achieved after intramuscular administration, the intravenous route is preferred. A recent study has documented comparable plasma drug levels and analgesic efficacy with oral transmucosal administration in cats.¹²⁹ This route seems to be well tolerated by feline patients and is becoming increasingly popular in clinical practice. A transdermal buprenorphine patch (Transtec) is now commercially available and currently being evaluated in cats.

In dogs and cats, buprenorphine is used most often in the postoperative period to manage pain of mild to moderate intensity.¹³⁰⁻¹³² As with the other opioids in this category, buprenorphine may not be adequate for management of severe pain such as that associated with thoracotomies or invasive orthopedic procedures.¹³³ The drug is a popular analgesic in laboratory-animal species because it can be formulated with a variety of foodstuffs and given orally to rodents.

In horses, buprenorphine is occasionally administered in combination with an α_2 -agonist to enhance and prolong sedation and analgesia.¹³⁴ There is little information published on the use of buprenorphine in cattle, and, though the drug is commonly used as an analgesic agent in research laboratories in sheep and swine, few reports actually evaluate its analgesic efficacy in these species.

Antagonists

These drugs have high affinities for the opioid receptors and can displace opioid agonists from μ and κ receptors. After this displacement, the pure antagonists bind to and occupy opioid receptors, but do not activate them (Fig. 10.4). Under ordinary circumstances, in patients that have not received exogenous agonist opioids, the opioid antagonists have few clinical effects when administered at clinically relevant dosages.¹⁰ It is important to recognize that these drugs will rapidly reverse all opioid-induced clinical effects, including analgesia (see Table 10.3 for recommended dosages). Therefore, use of pure opioid antagonists should be reserved for emergency situations such as opioid overdose or profound respiratory depression. Their routine use for reversal of excessive sedation in patients experiencing prolonged anesthetic recoveries or in patients that develop bradycardia secondary to opioid administration is inappropriate and may cause the development of intense acute pain and activation of the sympathetic nervous system.

Naloxone (Naloxone Hydrochloride [Narcan])

The use of this pure opioid antagonist can reverse all opioid agonist effects, producing increased alertness, responsiveness, coordination and, potentially, increased perception of pain. Naloxone's effects are shorter than that of many of the opioid agonists, with recommended intravenous doses lasting between 30

Fig. 10.4. A lock-and-key analogy is used to illustrate pure antagonist drug interactions at opioid receptors, with a relative dose-response curve for analgesic efficacy shown below. A pure opioid antagonist (in this case, naloxone) blocks both μ - and κ -receptor types, but has no intrinsic activity at these receptors. Receptor binding is competitive, so more agonist is required in the presence of antagonist to produce a maximal analgesic effect. Modified from Nicholson and Christie,²⁷⁰ p. 273, with permission from Elsevier.

and 60 min. Consequently, animals need to be closely monitored for re-narcotization after a dose of naloxone. Occasionally, excitement or anxiety may be seen after naloxone reversal of an opioid agonist. Premature ventricular contractions have also been documented after reversal, but are not common and seem to be more likely if there are high levels of circulating catecholamines. This drug is sometimes administered sublingually to neonatal patients exhibiting respiratory depression that have been delivered by cesarean section after maternal administration of an opioid agonist.

Naloxone has also been shown in animal models and human patients to produce a dose-related improvement in myocardial contractility and mean arterial blood pressure during shock.^{135–137} Further studies are needed to clarify the role of the endogenous opioid system in the pathophysiology of various forms of shock.

Nalmefene and Naltrexone (Revex and Trexonil)

Both of these drugs are pure opioid antagonists with clinical effects that last approximately twice as long as those of naloxone.¹³⁸ Though little is published about the use of these drugs in veterinary patients, they may be advantageous in preventing re-narcotization when used to antagonize the effects of a long-acting opioid.

Nonsteroidal Anti-inflammatories

The nonsteroidal anti-inflammatory drugs (NSAIDs) relieve mild to moderately severe pain, with efficacy dependent on the particular NSAID administered. This class of analgesics dates back thousands of years, with the salicylates being among the oldest and still most commonly used analgesics.¹³⁹ *Salicylate* is a naturally occurring substance found in willow bark and, prior to production of the synthetic compound, was used for centuries to manage pain associated with rheumatism. In 1878, Felix Hoffman, working at Bayer in Germany, made the acetylated form of salicylic acid that has come to be known as aspirin.¹³⁹ Although aspirin (acetylsalicylic acid or ASA) has been found to be effective in the management of acute and chronic mild discomfort, the newer injectable NSAIDs appear to have comparable efficacy to the pure μ -agonist opioids in controlling moderate to severe soft tissue and orthopedic pain. The NSAIDs appear to confer synergism when used in combination with opioids and may demonstrate an opioid-sparing effect should lower dosages of opioid be required. Their extended duration of action, in addition to their analgesic efficacy, make the NSAIDs ideal for treating acute and chronic pain in veterinary patients. Careful patient and drug selection is critical, however, because of their potential for harmful side effects.

Cyclooxygenases and Prostaglandin Synthesis

In 1971, Vane discovered the mechanism by which aspirin exerts its anti-inflammatory, analgesic, and antipyretic actions. He proved that aspirin and other NSAIDs inhibited the activity of a cyclooxygenase (COX) enzyme that produced prostaglandins (PGs) involved in the pathogenesis of inflammation, swelling, pain, and fever.¹⁴⁰ Twenty years later, a second COX enzyme was discovered and, more recently, a newly identified COX-3 has been identified.^{141–143} *Cyclooxygenase* (previously termed *prostaglandin synthase*) oxidizes arachidonic acid (previously termed *eicosatetraenoic acid*) to various eicosanoids (including PGs and other related compounds) (Fig. 10.5).¹⁴⁴ Oxidation of arachidonic

Table 10.3. Dosage ranges (mg/kg) for opioid antagonists in several domestic species

Opioid	Dogs	Cats	Horses	Cattle	Swine
Naloxone	0.002–0.02 IV	0.002–0.02 IV	0.002–0.02 IV	a	a
Nalmefene	0.025–0.03? IV	0.025–0.03? IV	?	?	?
Naltrexone	0.0025–0.003? IV	0.0025–0.003? IV	?	?	?

IV, intravenously; ?, reliable doses have not been established for this species.

^aDoses have not been specifically reported for these species; however, 0.01 mg/kg IV is probably appropriate

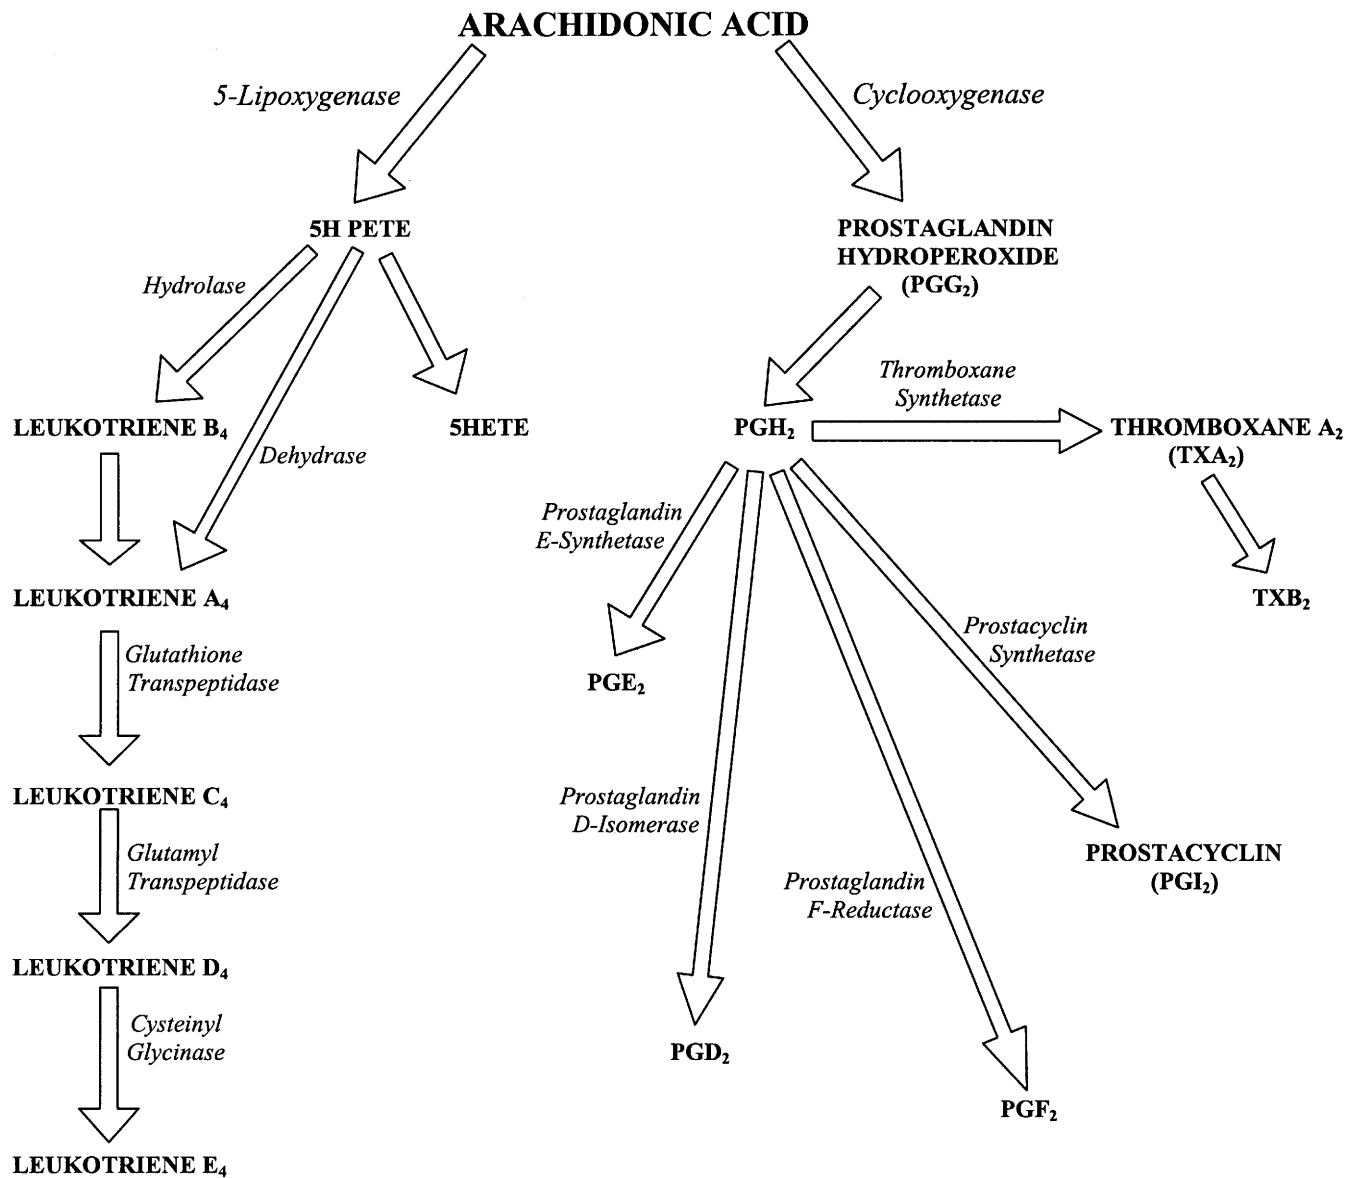

Fig. 10.5. The arachidonic acid cascade: eicosanoid synthesis. 5-HETE, 5-hydroxy-6,8,11,14-eicosatetraenoic acid; and 5-HPETE, 5-hydroperoxy-6,8,11,14-eicosatetraenoic acid.

acid by 5-lipoxygenase (5-LOX), the most biologically important of the mammalian oxygenases, produces the series of eicosanoids termed *leukotrienes* (Fig. 10.5). The release of arachidonic acid from membrane phospholipid is catalyzed by the enzyme phospholipase A₂ and is the rate-limiting step in PG and leukotriene synthesis. Prostaglandin G₂ is the initial prostenoid formed, followed by prostaglandin H₂, which serves as a substrate for prostaglandin E synthetase, prostaglandin D isomerase, prostaglandin F reductase, prostacyclin synthetase, and thromboxane synthetase for conversion to a variety of other prostenoids ubiquitous throughout cells and tissues in the body.¹⁴⁴ These include the PGs PGE₂, PGD₂, PGF₂, and PGI₂ (prostacyclin), and the thromboxanes TXA₂ and TXB₂, all with diverse functions.¹⁴⁵ The PGs are not stored, but are synthesized at a constant rate. They have

short half-lives of 4 to 6 min at 37°C and act locally at the site of production.

The PGs produced by both COX-1 and COX-2 are ubiquitous throughout the body and serve to facilitate many physiological functions during both health and illness. Consequently, the clinical use of NSAIDs has the potential to disrupt these functions, with the possibility of significant organ dysfunction. Thus, in addition to their role as analgesics, the effects of NSAIDs on the constitutive functions of the PGs must always be considered. There are several key points to note: (a) COX-1 generates PGs that are responsible for *mucosal defense* (i.e., secretion of bicarbonate and mucus, mucosal blood vessel attenuation of constriction, and mucosal epithelial regeneration), as well as TXA₂, which is necessary for platelet function; (b) COX-2 produces

PGs that function in the prevention and promotion of healing of mucosal erosions, and exert anti-inflammatory effects by inhibiting leukocyte adherence, as well as play a role in renal protection and maturation;¹⁴⁵ and (c) COX-3 produces PGs that exert a protective function by initiating fever.¹⁴³

Thus, depending on the NSAID selected, primary plug formation of platelets, modulation of vascular tone in the kidney and gastric mucosa, cytoprotective functions within the gastric mucosa, smooth muscle contraction, and regulation of body temperature will all be affected.¹⁴⁵ In this regard, however, not all NSAIDs are created equal. As already noted, the COX-1, COX-2, and COX-3 enzymes make variable contributions to these functions, and individual NSAIDs inhibit each of these enzymes differently. Some NSAIDs inhibit both COX-1 and COX-2 (i.e., aspirin, phenylbutazone, ketoprofen [Anafen], ketorolac [Toradol], and flunixin meglumine [Banamine]); other NSAIDs preferentially inhibit COX-2 with only weak inhibition of COX-1 (i.e., meloxicam [Metacam], carprofen [Rimadyl], etodolac [Eto-gesic], vedaprofen [Quadrisol-5], and tolfenamic acid [Tol-fedine]); and others inhibit COX-2 exclusively (i.e., deracoxib [Deramaxx] and firocoxib [Previcox]); whereas still another drug, acetaminophen, only weakly inhibits both COX-1 and COX-2 while inhibiting COX-3 activity preferentially.¹⁴¹

Several *in vitro* studies investigating NSAID selective inhibition of the COX-1 and COX-2 isoenzymes have been published, but their findings are very difficult to interpret because of inconsistencies in the assays used.¹⁴⁶ Clinically, this information is confusing because it does not consider the pharmacokinetics of particular drugs and their concentrations in various tissues.¹⁴⁷ Most NSAIDs that inhibit COX have been shown to result in diversion of arachidonate to the 5-LOX pathway. The 5-LOX is principally found in polymorphonuclear cells, mast cells, monocytes, basophils, and B lymphocytes that are recruited during inflammatory and immune reactions.¹⁴⁷ This enzyme catalyzes the initial step in leukotriene biosynthesis, which subsequently produces various eicosanoids, with leukotriene B₄ (LTB₄) being the most notable potent mediator of inflammation. The excessive production of leukotrienes has been implicated in the creation of NSAID-induced ulcers.^{148,149} As always, however, the biological system is not clear-cut. Although the LOX pathway is proinflammatory, there is also an anti-inflammatory pathway,¹⁵⁰ which is discussed in more detail later.

The contribution of the leukotrienes to the inflammatory process would seem to suggest that inhibition of both the COX and 5-LOX pathways by a therapeutic agent would enhance the safety profile and may confer even greater analgesic efficacy because of broader anti-inflammatory and antinociceptive effects.¹⁵¹ Data available show that dual acting compounds are effective in arthritic models, where they also retain antithrombotic activity, produce little or no gastrointestinal damage, and do not adversely affect the asthmatic state.¹⁴⁷ A dual COX-5-LOX inhibitor (tepoxalin [Zubrin]) has undergone clinical trials and is now approved for veterinary use.^{151,152} Tepoxalin has demonstrated gastrointestinal anti-inflammatory activity in mice,¹⁵³ which supports the theory that 5-LOX inhibition can play a vital role in preventing NSAID-induced gastric inflammation.

Mechanisms of Analgesia

Prostaglandins, notably PGE₂ and prostacyclin, are potent mediators of inflammation and pain. These molecules exert hyperalgesic effects and enhance nociception produced by other mediators, such as bradykinin. The NSAIDs' analgesic mechanism of action is through inhibition of COX-1, COX-2, and COX-3 activity, with subsequent prevention of PG synthesis.

The antinociceptive effects of the NSAIDs are exerted both peripherally and centrally.¹⁵⁴ The NSAIDs penetrate inflamed tissues, where they have a local effect, which makes them excellent analgesic choices for treatment of injuries with associated inflammation, as well as conditions such as synovitis, arthritis, cystitis, and dermatitis.¹⁵⁴ The central action is at both the spinal and the supraspinal levels, with contributions from both COX-1 and COX-2.¹⁵⁴⁻¹⁵⁸ This central effect may account for the overall well-being and improved appetite that are often observed in patients receiving parenterally administered NSAIDs for relief of acute pain.

The rational use of NSAIDs as analgesics should be based on an understanding of pain physiology and pathophysiology. Nociceptive pathways may involve either the COX-1 or COX-2 gene, and these genes are expressed in different locations and under different circumstances. The COX-2 isoenzyme, which is known as the inducible isoform because it is upregulated in inflammatory states, is known to play a key role in nociception. Although the COX-1 gene has traditionally been thought of as being expressed constitutively, this isoenzyme also plays an integral role in the pain experience.¹⁴² The COX-1-selective NSAIDs are superior to COX-2-selective NSAIDs at inhibiting visceronociception caused by chemical pain stimulators in a mouse peritoneal model.¹⁵⁹ This has been confirmed by visceronociception being greatly reduced in COX-1, but not COX-2, knockout mice.¹⁶⁰ These studies concluded that peripheral COX-1 mediates nociception in slowly developing pain in mice, such as in visceral pain, and that central COX-1 may be involved in rapidly transmitted, nonvisceral pain, such as that caused by thermal stimulation.¹⁶⁰ Visceral pain may be mediated, at least in part, by stimulation of intraperitoneal receptors located on sensory fibers by COX-1-produced prostacyclin.¹⁴³ There may even be gender differences as in Ballou's mouse model, which demonstrated that spinal COX-2 did in fact contribute to visceral nociception, but only in female mice.¹⁶⁰ The analgesic potency of a range of NSAIDs in relieving tooth-extraction pain in human patients correlates closely with increasing selectivity toward COX-1 rather than COX-2. These findings highlight the importance of both COX-1 and COX-2 contributions to pain and the selective efficacy of the NSAIDs in treating various painful conditions and syndromes.

The COX-2 or inducible isoenzyme can increase by 20-fold over baseline in the presence of tissue injury and inflammation.¹⁵⁵ Proinflammatory cytokines and mitogens, such as interleukin 1 β (IL-1 β), interferon γ , and tumor necrosis factor α (TNF- α), induce COX-2 expression in macrophages, as can platelet-activating factor and PGE₂.¹⁴⁷ These events may also occur in chondrocytes, osteoblasts, and synovial microvessel endothelial cells. Higher COX levels increase prostenoid produc-

tion where these compounds serve as amplifiers of nociceptive input and transmission in both the peripheral and central nervous systems.¹⁵⁵ The COX-2-selective NSAIDs have been shown to be clinically useful in managing inflammatory pain in human and animal patients. This has been a focus of the pharmaceutical industry as a more selective COX-2 inhibitor might show efficacy in alleviating pain and hyperalgesia while sparing COX-1-constitutive activity and potential adverse effects traditionally associated with NSAID administration. Unfortunately, this biological system is not as simple as first envisioned. Although COX-2 is induced during inflammation, it has also been shown to be induced during resolution of the inflammatory response where the anti-inflammatory PGs (PGD₂ and PGF_{2α}), but not proinflammatory PGE₂, are produced. Potentially, inhibition of COX-2 during this phase may actually prolong inflammation.¹⁴⁷ As is the case for COX-1, it now appears that the COX-2 isoenzyme also has important constitutive functions. Studies indicate there may be a protective role for COX-2 in maintenance of gastrointestinal integrity,¹⁶¹ in ulcer healing,¹⁶² and in experimental colitis in rats.¹⁶³ In addition, the COX-2 isoenzyme appears to have constitutive functions associated with nerve, brain, ovarian and uterine function, and bone metabolism.¹⁶¹ Therefore, the potential for NSAID-associated side effects with these systems is of concern. Of major importance are the COX-2-constitutive functions within the kidney, which differ from those of COX-1 in hypotensive and hypovolemic states.¹⁶⁴ Also, COX-2 appears to be important in nephron maturation.¹⁶⁵ The canine kidney is not fully mature until 3 weeks after birth,¹⁶⁶ and administration of a NSAID during this time, or to the bitch prior to birth, may cause a permanent nephropathy. In fact, in COX-2 null mice, which lack the gene for COX-2, all animals die of renal failure before 8 weeks of age.¹⁶⁷ Renal failure does not occur in COX-1-null-developing mice, and they do not develop gastric pathology.¹⁶⁷

When considering the COX selectivity of a particular NSAID, the concentration (i.e., dose) of the NSAID may also influence its actions. A drug may function as a competitive, nonpreferential, or selective COX inhibitor (COX-1 or COX-2) at higher concentrations, and as a COX-2-selective inhibitor at lower concentrations.¹⁶⁸ The significance of this is the potential for inhibition of COX-1 with administration of an allegedly COX-2-selective NSAID. The COX selectivity may be present *in vitro*; however, at the dosing required to achieve analgesia, such selectivity may be lost. Cloning studies comparing canine COX isoenzymes with human COX isoenzymes found that they are highly homologous.¹⁶⁹ Canine COX-1 and COX-2 had a 96% and 93% DNA-sequence homology, respectively, with their human counterparts. This suggests that they would be similarly affected by pharmaceuticals such as NSAIDs designed to inhibit their function. However, the distribution of the COX enzymes may differ among species. When reviewing the adverse effects of NSAIDs (e.g., gastrointestinal ulceration, renal perturbations, and hemorrhage), hemorrhage is the only pathology that appears to be clinically diminished by the use of the more COX-2-selective NSAIDs.

COX 2 is reduced after administration of glucocorticoids, which may partially explain the anti-inflammatory and analgesic effects of this class of medications. Of interest, in addition to the

COX-2 role in inflammation, aberrantly upregulated COX-2 expression is increasingly implicated in the pathogenesis of a number of epithelial cell carcinomas, including colon, esophagus, breast, and skin, and in Alzheimer's disease and other neurological conditions.^{170–172} For this reason, the COX-2 inhibitors are being researched as potential anticarcinogenic agents.¹⁷³

Dissecting out the details of the derivation and specific actions of COX-1 and COX-2 continues to provide important insight into the management of pain with NSAIDs. The picture, however, remains incomplete because some NSAIDs do not significantly inhibit these enzymes. This finding stimulated the search for a potential COX-3 isoenzyme. Based on studies using canine cortex, a COX-3 isoenzyme was discovered that was derived from the same gene as COX-1.¹⁴² The COX-3 isoenzyme is also present in human brain and heart tissues. It is distinct from COX-1 and COX-2 as demonstrated in studies using common analgesic-antipyretic NSAIDs in suppressing COX production. Acetaminophen inhibited COX-3 activity, but not COX-1 and COX-2, as does dipyron.¹⁴² Both of these agents are frequently used to reduce fever in animals. Other analgesic-antipyretic NSAIDs found to be effective COX-3 inhibitors are diclofenac (the most potent) and aspirin and ibuprofen (which preferentially inhibit COX-3 over COX-1 and COX-2). The overall conclusion of this particular study was that COX-3 possesses COX activity that differs pharmacologically from both COX-1 and COX-2, but is more similar to COX-1.¹⁴² These findings indicate that the COX-3 isoenzyme is more susceptible to inhibition by drugs that are analgesic and antipyretic, but that lack anti-inflammatory activity. This observation again emphasizes the potential utility of administering NSAIDs with different COX selectivities for managing pain of different etiologies. As the COX-3 isoenzyme genetic profile is derived from the COX-1 gene, it appears that the COX-1 gene plays an integral role in pain and/or fever, depending on the physiological context.¹⁴² This has been confirmed by the aforementioned studies.^{143,159,160} The COX-1-selective NSAIDs with poor CNS penetration (i.e., ketoprofen and ketorolac) that are used in veterinary and human patients may, in fact, reach sufficient concentrations in the brain to inhibit COX-3.¹⁷⁴ It is also recognized that the analgesic effects of these NSAIDs frequently occur at lower dosages than those required to inhibit inflammation.

Fever Inhibition

Just as the relationship between pain and the various activities of the COX system is complex, so too is the association between fever and the COX isoenzymes. The mechanisms leading to the generation of fever vary depending on the inciting factor, which may be peripheral (i.e., endotoxin) or central (i.e., endogenous pyrogens, such as interleukin 1). Interspecies variation is also substantial, and the definitive role of the COXs in pyresis remains to be clearly elucidated. Evidence suggests that COX-2 plays a role in endotoxin pyrexia, whereas, based on the antipyretic effects of acetaminophen and aspirin, COX-1 and COX-3 appear to function in endogenous pyrexia.^{141–143} Both of these drugs are effective in reducing fever in dogs. As an alternative in feline patients, ketoprofen¹⁷⁵ and meloxicam¹⁷⁶ have been

shown to be effective antipyretic agents. Ketoprofen appears to be a good antipyretic in both cats and dogs, and this action can often be achieved at a relatively low dose.

Endogenous Anti-inflammatory Mechanisms

Endogenously generated small chemical mediators, or *autacoids*, play a key role in controlling inflammation by inhibiting polymorphonuclear cell recruitment and enhancing monocyte activity in a nonphlogistic manner.¹⁴⁹ Arachidonic acid–derived lipoxins, particularly lipoxin A₄, have been identified as anti-inflammatory mediators, indicating that the LOX pathway has a dual proinflammatory and anti-inflammatory function.

The NSAIDs may amplify or decrease this endogenous anti-inflammatory system. Aspirin is more COX-1 selective and can impair many components of mucosal defense and enhance leukocyte adherence within the gastric and mesenteric microcirculation.¹⁷⁷ However, with chronic use of aspirin, an adaptation of the gastric mucosa is associated with a marked upregulation of COX-2 expression and lipoxin production. This lipoxin is specifically termed *aspirin-triggered lipoxin* (ATL). Aspirin is unique among current therapies because it acetylates COX-2, thereby enabling the biosynthesis of 15(R)-hydroxyeicosatetraenoic acid from arachidonic acid, which is subsequently converted to ATL by 5-LOX. Inhibition of either the COX-2 or 5-LOX enzymes causes blockade of ATL synthesis.¹⁷⁷ Lipoxin A₄ and ATL (a carbon-15 epimer of lipoxin) attenuate aspirin-induced leukocyte adherence, whereas administration of selective COX-2 inhibitors blocks ATL synthesis and has been shown to augment aspirin-induced damage and leukocyte adherence to the endothelium of mesenteric venules in rats.¹⁷⁷

In addition to the lipoxins, aspirin-induced COX-2 acetylation generates numerous other endogenous autacoids derived from dietary omega-3 fatty acids.¹⁷⁸ Some of these local autacoids are potent inhibitors of neutrophil recruitment, thereby limiting the role of these cells during the resolution phase of inflammation, and thus are referred to as *resolvins*.¹⁷⁸ The identification of both the lipoxins and the resolvins has introduced new potential therapeutic avenues for the treatment of inflammation, cardiovascular disease, and cancer.

Pharmacological Considerations

The NSAIDs are effective analgesics as indicated by the human consumption of 120 billion aspirin tablets per year in addition to the many other NSAIDs currently on the market. Despite this, the safety profile of these analgesics remains a concern. A search for the NSAID without adverse gastrointestinal effects is still ongoing. Incorporation of a nitric oxide–generating moiety into the molecule of several NSAIDs has shown attenuation of the ulcerogenic effects of these drugs. However, nitric oxide has also been implicated in the pathogenesis of arthritis and subsequent tissue destruction.¹⁴⁷

Because of their high protein binding, NSAIDs can displace other drugs from their plasma protein-binding sites and potentially increase their plasma concentration. This is rarely a concern unless NSAIDs are administered to patients with organ dys-

function or in those receiving other highly protein-bound medications with a narrow therapeutic index. Interference with the metabolism and excretion of certain coadministered drugs may occur; therefore, verifying the safety of combination therapy is always mandatory.

Some NSAIDs may induce the syndrome of inappropriate secretion of antidiuretic hormone (ADH). Renal water reabsorption depends on the action of ADH mediated by cyclic adenosine monophosphate (cAMP). As PGs exert a controlled negative-feedback action on cAMP production, inhibition of PG synthesis produces above-normal levels of cAMP with potential for enhanced ADH activity. In addition, the administration of a COX-2-selective NSAID may enhance sodium and water reabsorption. Clinically, both mechanisms may result in high-specific-gravity urine with dilutional hyponatremia. Urine volume may be decreased through this mechanism, but without renal injury.^{179,180}

NSAID-induced renal insufficiency is usually temporary and reversible with drug withdrawal and administration of intravenous fluids. Accidental ingestion of NSAIDs should be managed with gastric lavage (if within 1 h) followed by administration of activated charcoal and gastric protectants. If evidence of gastric ulcers exist, aggressive sucralfate therapy is necessary. Intravenous fluid therapy should continue for at least 1 day. Therapy beyond this period will depend on the renal and gastric status of the individual patient.

Patient Selection and Therapeutic Considerations

The general health of a patient greatly influences the decision to use NSAIDs. Cats and dogs are more susceptible than people to the adverse effects of this class of drugs. Thus, the reported safety of any one NSAID in human patients should not be assumed to be so in veterinary patients. Most NSAIDs have a narrow safety margin, so accurate dosing is absolutely necessary.

The administration of NSAIDs for perioperative pain management should be restricted to animals older than 6 weeks that are well hydrated and normotensive. Patients should have normal hemostatic function, no evidence or concern for gastric ulceration, and normal renal and hepatic function. Although these are general guidelines, future studies may indicate that short-term management of acute pain by using COX-1-sparing and, to some degree, COX-2-sparing NSAIDs may prove safe in animals with minimally compromised liver or renal function. Patients should not receive corticosteroids and NSAIDs concurrently,¹⁸¹ nor should different NSAIDs be administered concurrently.

The preemptive use of NSAIDs is controversial because of their potential for harm. An earlier study assessing the effects on the kidney of preoperative administration of ketorolac, ketoprofen, or carprofen resulted in variable alterations in parameters measured. The conclusions of the study were that, in clinically normal dogs undergoing elective surgery, the use of these NSAIDs was not contraindicated, although renal function was not measured and two dogs in each of the ketoprofen and ketorolac groups were azotemic.¹⁸² Another study assessing effects of preoperative administration of ketoprofen on whole blood

platelet aggregation, buccal mucosal bleeding time, and hematologic indices in dogs undergoing elective ovariohysterectomy showed a decrease in platelet aggregation for at least 1 day after surgery. Mucosal bleeding time and hematologic indices did not change.¹⁸³ Other studies, specifically assessing efficacy and safety of NSAIDs given preoperatively in a variety of surgical procedures where intraoperative fluid therapy was administered and patient monitoring was conducted, noted adverse reactions with some of the NSAIDs.^{123,184,185} A study conducted at the Ontario Veterinary College demonstrated no adverse effects with the administration of meloxicam or carprofen prior to orthopedic or soft tissue surgery in both cats (meloxicam) and dogs (meloxicam or carprofen) (unpublished data). In these studies, the preoperative administration of a NSAID provided very good to excellent analgesia. A laboratory study investigating potential adverse effects on glomerular filtration rate in dogs receiving meloxicam, carprofen, or saline prior to anesthesia and a painful stimulus failed to demonstrate a reduced glomerular filtration rate, and intravenous fluids were not administered in this study.¹⁸⁶ The benefit of preoperative administration of NSAIDs is the potential for a preemptive effect and the presence of analgesia upon recovery. When NSAIDs are administered postoperatively, opioids are often given concurrently, as 45 min is required to obtain a therapeutic effect with a NSAID, regardless of route. Another potential approach could be to administer the NSAID parenterally prior to completing the surgical procedure at least 45 min prior to extubation. Often it is difficult to distinguish the difference in the analgesic effects produced by preoperative versus intraoperative NSAID administration. For prolonged operative procedures, the benefit of a longer postoperative effect may be seen with administration of the NSAID upon completion, rather than at the start, of the procedure.

Effective plasma levels of NSAIDs are reached within 1 h after oral administration.^{187–189} When NSAIDs are administered per os, they must be given with food to protect the gastric mucosa. If food is not present in the stomach, the contact area of the tablet on the mucosa results in a high localized concentration of the drug, increasing the potential for localized ulcer formation. It is important to remember that the potential for ulceration exists with all NSAIDs regardless of the route of administration.

Pain Management

The indications proposed here assume there are no contraindications to their use.

Postoperative Pain

The NSAIDs are extremely valuable in selected orthopedic^{123,182,190,191} and soft tissue surgical procedures,^{184,192–197} especially where extensive inflammation or soft tissue trauma is present. Opioid administration is preferred immediately after any surgical procedure, because the sedative-analgesic effects of this class of drugs help to ensure a smooth recovery. Injectable NSAIDs (carprofen, ketoprofen, meloxicam, or tolfenamic acid) can be coadministered initially with an opioid and subsequently used alone following orthopedic and selected soft tissue surgery; however, this depends on the degree of pain an animal is experi-

encing. Oral NSAIDs may be administered when an animal is able to eat. The initial dose of NSAID depends on the expected severity of pain. For example, a difficult fracture repair would require the recommended loading dose, but a laparotomy without complications could be successfully treated with half this dose. A sliding-scale approach similar to that used with the opioids for managing varying degrees of anticipated pain is also recommended for the NSAIDs; however, the upper dosing limit must not be exceeded.

Inflammatory Conditions

For relief of pain caused by meningitis, bone tumors (especially after biopsy), soft tissue swelling (mastitis), polyarthritis, cystitis, otitis, or severe inflammatory dermatologic diseases or injury (e.g., degloving and animal bites), the NSAIDs may be more efficacious than opioids. However, as many of these patients may be more prone to NSAID toxicity, careful patient selection and management are advised. The combination of an opioid with a low dose of NSAID is also effective in these conditions. An exception is necrotizing fasciitis, where NSAIDs may actually increase morbidity and mortality.¹⁹⁸

Osteoarthritis

Few long-term studies evaluating the adverse effects of NSAIDs have been completed. A short-term study (12 days) assessing the effect of carprofen on platelet aggregation and activated partial thromboplastin time in Labrador retrievers showed, after 5 days of treatment, a reduction in platelet aggregation that persisted after treatment was discontinued for 7 days. The activated partial thromboplastin time was similarly affected as times were prolonged over baseline during this period, although they remained within normal range. The conclusions of this study, however, were that these alterations were minor and not clinically important.¹⁹⁹ The major adverse effects associated with long-term use of carprofen,²⁰⁰ meloxicam,²⁰¹ or etodolac²⁰² for osteoarthritis are predominantly associated with the gastrointestinal tract. Gastrointestinal pathology associated with buffered aspirin, carprofen, etodolac, and placebo has been evaluated in healthy dogs after a 4-week course of administration. Two independent studies concluded that the administration of carprofen, etodolac, or placebo produced significantly fewer gastrointestinal lesions in dogs than did buffered aspirin.^{203,204} Similar studies comparing ketoprofen with aspirin and placebo,²⁰⁵ and comparing carprofen, meloxicam, and ketoprofen to aspirin and placebo,²⁰⁶ noted that these NSAIDs produced mild to moderate gastrointestinal lesions that were similar to placebo, but significantly less severe than those produced by aspirin. A sliding-scale approach of NSAID administration for chronic use is highly recommended. As many patients with osteoarthritis are geriatric, a rapid reduction of the dose to affect a comfortable state is advised to reduce potential toxicity. For example, alternating to every-third-day therapy of meloxicam with half the recommended label dose proved efficacious in some dogs during a 1-year period.²⁰¹ If an individual patient requires persistent high doses of a particular NSAID to manage pain, prescribing a different NSAID may be more effective because of individual vari-

ation in response and effect, as previously discussed. When the adverse effects of a NSAID are a concern, reducing the dose and adding an analgesic of a different class (e.g., tramadol) may be equally effective for the treatment of chronic severe pain. However, for many geriatric animals with renal insufficiency, NSAIDs may be the only effective class of analgesic. For these animals, quality of life is a major issue. In this situation, meloxicam (in both cats and dogs) or carprofen (in dogs only) titrated down to the lowest effective dose has been used in patients with renal insufficiency with minimal or no worsening of renal function over time (personal communication).

During NSAID therapy, all patients should be monitored for hematochezia or melena, vomiting, increased water consumption, and nonspecific changes in demeanor. If any of these occur, the owner should be instructed to stop the medication and consult a veterinarian. Intermittent monitoring of creatinine and alanine aminotransferase (ALT) is recommended when the use of NSAIDs is prescribed on a chronic basis. Another important consideration for chronic use is the potential effect of NSAID therapy on joint and cartilage metabolism. Studies investigating the effects of carprofen^{207,208} and meloxicam²⁰⁹ at therapeutic doses found no toxicological or pharmacological actions on cartilage proteoglycan metabolism. In addition, meloxicam may have the potential for controlling cellular inflammatory reactions at inflamed sites in the joints of patients with osteoarthritis.²⁰⁹

Miscellaneous Conditions

Other indications for the use of NSAIDs are panosteitis, hypertrophic osteodystrophy (HOD), cancer pain (especially of bone), and dental pain. The NSAIDs with selective COX-1 inhibition should be used with caution after dental extractions where bleeding is, or may be, of concern. Meloxicam and carprofen have minimal, if any, antithromboxane activity and should, therefore, not interfere with platelet adhesion. For severe panosteitis and HOD, the full loading dose of a NSAID is required to obtain a suitable effect. The HOD of Weimaraners is poorly responsive to NSAID therapy and is better treated with high-dose, short-term corticosteroids, provided infectious disease has been ruled out and clinical signs are consistent with HOD alone.²¹⁰

Contraindications

NSAIDs should not be administered to patients with acute renal insufficiency, hepatic insufficiency, dehydration, hypotension, or conditions associated with low *effective circulating volume* (e.g., congestive heart failure or ascites), coagulopathies (e.g., factor deficiencies, thrombocytopenia, or von Willebrand's disease), or evidence of gastric ulceration (i.e., vomiting with or without the presence of "coffee ground material" or melena). Administration of NSAIDs following gastrointestinal surgery must be determined by the overall health of the gut at the time of surgery. As the COX-2 isoenzyme is important for healing, intuitively NSAIDs producing potent COX-2 enzyme inhibition would be contraindicated where compromised bowel is noted. Concurrent use of other NSAIDs (e.g., aspirin) or corticosteroids is not recommended. The use of COX-1-preferential NSAIDs is contraindicated in patients with spinal injury (including herniated

intervertebral disc) because of the potential for hemorrhage and neurological deterioration, and because of excessive bleeding at the surgical site should surgical treatment be pursued. The NSAIDs should never be administered to patients in shock, trauma patients upon presentation, or patients with evidence of hemorrhage (e.g., epistaxis, hemangiosarcoma, or head trauma). The condition of patients with severe or poorly controlled asthma, such as feline asthma, or other types of moderate to severe pulmonary disease, may deteriorate with NSAID administration. Aspirin administration has been documented to exacerbate asthma in human patients, but the administration of COX-2-specific NSAIDs did not worsen clinical signs.²¹¹ It is unknown whether animals may be affected in this way. Although administration of NSAIDs in head trauma, pulmonary diseases, or thrombocytopenia is generally contraindicated, the use of COX-2-preferential NSAIDs (i.e., meloxicam, etodolac, carprofen, tolfenamic acid, firocoxib, or deracoxib) may prove to be safe with further study. Because of inhibition of PG activity, the NSAIDs may be detrimental to reproductive function. Indomethacin may block prostaglandin activity in pregnant women, causing cessation of labor, premature closure of the ductus arteriosus in the fetus, and disruption of fetal circulation.¹⁶¹ These effects may also occur in animals, so NSAIDs should not be administered during pregnancy. As COX-2 induction is necessary for ovulation and subsequent implantation of the embryo,¹⁶¹ the use of NSAIDs should also be avoided in breeding females during this stage of the reproductive cycle. As previously mentioned, the COX-2 isoenzyme is required for maturation of the embryological kidney, so COX-2 administration to lactating mothers should be avoided.

Topical NSAIDs do not appear to be associated with the same adverse gastrointestinal effects noted when these same drugs are taken orally,²¹² and topical administration has proven to be significantly more effective than placebo in many human clinical trials involving acute and chronic painful conditions.²¹³ A liposomal topical cream formulation of 1% diclofenac sodium (Surpass) has recently been approved by the U.S. Food and Drug Administration as a topical anti-inflammatory cream for the control of joint pain and inflammation associated with osteoarthritis in horses. The results of clinical field trials indicate that the product is safe, easy to use, and effective in reducing lameness caused by degenerative joint disease in this species. When applied topically (a 5-inch strip of cream) for 10 consecutive days to a single fetlock, diclofenac was present in all serum samples up to 2 days after the final application.²¹⁴ The term *locally enhanced topical delivery* (LETD) has been used to describe the local accumulation of drug to the target tissues. This effect has been documented in horses when using the 1% diclofenac liposomal formulation.²¹⁵ Consistent with its prolonged effect at the target tissue, diclofenac was slowly absorbed and eliminated following its application. When compared with other conventional topical creams and ointments, liposomal preparations provide better penetration and a more sustained release of agent. There are no well controlled published studies investigating the clinical use of topical formulations of NSAIDs in dogs and cats at the date of this writing.

Specific NSAIDs

Recommended dosages are listed in Tables 10.4 through 10.6.

Meloxicam (Oral Liquid and Parenteral Formulations)

Meloxicam is a COX-2-preferential NSAID approved for oral use in dogs in Australasia, Europe, and North America. The parenteral formulation is approved for cats in Australasia and the United States. Its use in cats in Canada is under investigation at the time of this writing, with completed studies indicating safety and efficacy. Its use in horses is also under investigation, with pharmacokinetic studies indicating that the half-life is shorter and clearance greater than in dogs, which suggests that dosing more than once a day may be necessary.²¹⁶

Studies indicate no renal or hepatic abnormalities with acute administration¹⁸⁴ and minimal to no antithromboxane activity,²¹⁷ suggesting that hemostasis in normal animals may not be a problem. Very few adverse reactions have been documented, and most involve the gastrointestinal tract. A 2003 study showed no difference in gastric erosions over saline placebo when meloxicam was administered at 0.1 mg/kg for 3 days after electrical stimulation (i.e., surgical stimulation) under anesthesia. However, the administration of corticosteroids plus meloxicam caused significant gastric erosions.¹⁸¹ A case report of the administration of a combination of aspirin and meloxicam in a dog detected duodenal perforation.²¹⁸ This case illustrates the importance of COX-2 in intestinal protection when aspirin is coadministered, and rein-

Table 10.4. Dosage ranges (mg/kg unless otherwise indicated) for NSAIDs in dogs and cats

NSAID ^a	Indication	Species/Dose/Route	Frequency
Ketoprofen	Surgical pain	Dogs, ≤ 2.0 IV, SC, IM, PO	Once
		Cats, ≤ 2.0 SC then dogs and cats, ≤ 1.0 IV, SC, IM, PO Dogs and cats, ≤ 2.0 PO	Once q 24 h
Meloxicam	Chronic pain	then ≤ 1.0	Once
	Surgical pain	Dogs, ≤ 0.2 IV, SC then ≤ 0.1 IV, SC, PO	Once q 24 h
	Chronic pain	Dogs, ≤ 0.2 PO then ≤ 0.1 PO	Once q 24 h
	Surgical pain	Cats, ≤ 0.2 SC, PO then ≤ 0.1 SC, PO lean weight	Once q 24 h for 2–3 days
	Chronic pain	Cats, ≤ 0.2 SC, PO then ≤ 0.1 PO lean weight then 0.025 PO or (0.1 mg/CAT max) lean weight	Once q 24 h for 2–3 days 3–5 × weekly
Carprofen	Surgical pain	Dogs, ≤ 4.0 IV, SC, IM then ≤ 2.2 PO Cats, ≤ 4.0 SC lean weight	Once at induction Repeat q 12–24 h Once at induction only
	Chronic pain	Dogs, ≤ 2.2 PO	q 12–24 h
Etodolac	Chronic pain	Dogs, ≤ 10–15 PO	q 24 h
Tolfenamic acid	Acute, chronic pain	Dogs and cats, ≤ 4 SC, PO	q 24 h for 3 days, 4 days off, then repeat cycle
Firocoxib	Chronic pain	Dogs, 5.0 PO	q 24 h
Flunixin meglumine	Surgical pain	Dogs, ≤ 1.0 IV, SC, IM Cats, 0.25 SC	Once q 12–24 h PRN × 1 or 2 doses
		Dogs and cats, 0.25 SC	q 12–24 h PRN × 1 or 2 doses
	Pyrexia Ophthalmologic procedures	Dogs, 0.25–1.0 SC, IM	q 12–24 h PRN × 1 or 2 doses
Ketorolac	Surgical pain	Dogs, 0.3–0.5 IV, IM Cats, 0.25 IM	q 8–12 h × 1 or 2 doses q 12 h × 1 or 2 doses
	Panosteitis	Dogs, 10-mg total dose in dogs ≥ 30 kg PO 5-mg total dose in dogs > 20 kg < 30 kg PO	q 24 h for 2–3 days
Deracoxib	Surgical pain	Dogs, ≤ 3–4 PO	q 24 h for 3–7 days
	Chronic pain	Dogs, ≤ 1–2 PO	q 24 h
Tepoxalin	Chronic pain	Dogs, 10 PO	q 24 h
Piroxicam	Inflammation of the lower urinary tract	Dogs, 0.3 PO	q 24 h × 2 doses then q 48 h
Acetaminophen	Acute, chronic pain	Dogs, 15 PO (contraindicated in cats)	q 8 h
Aspirin	Acute, chronic pain	Dogs, 10 PO	q 12 h

CAT max, maximal dose in cats; IM, intramuscularly; IV, intravenously; NSAID, nonsteroidal anti-inflammatory drug; PO, per os (orally); PRN, as necessary; SC, subcutaneously.

^aSee the text for details on contraindications for use.

Table 10.5. Dosage ranges (mg/kg) of NSAIDs in horses

NSAID ^a	Dose	Route	Frequency	Notes
Phenylbutazone	2–4	PO, IV	q 12 h	Reduce to 2 mg/kg on day 2
Flunixin meglumine	1	PO, IV, IM	q 12–24 h	
Ketoprofen	2–3	IV	q 24 h	
Carprofen	0.7	IV	q 24 h	
Eltenac	0.5	IV	q 24 h	
Diclofenac	5-inch ribbon of cream	Transdermal	q 12 h	Apply liposomal cream over 1 joint only twice daily
Vedaprofen	1	IV	q 24 h	
Meloxicam	0.6	IV	q 12 h	

IM, intramuscularly; IV, intravenously; NSAID, nonsteroidal anti-inflammatory drug; PO, per os (orally).

^aSee text for details on contraindications for use.

Table 10.6. Dosage ranges (mg/kg) of NSAIDs in ruminants

NSAID ^a	Dose	Route	Frequency	Notes
Phenylbutazone	2–6	PO, IV	q 24 h	Prohibited in dairy cattle >20 months of age
Flunixin meglumine	1	PO, IV, IM	q 12 or 24 h	
Ketoprofen	3	IV, PO	q 24 h	
Carprofen	0.7	IV	q 24–48 h	Sheep
Aspirin	100	PO	q 12 h	

IM, intramuscularly; IV, intravenously; NSAID, nonsteroidal anti-inflammatory drug; PO, per os (orally).

^aSee text for details on contraindications for use.

forces the concept that different NSAIDs should not be administered concurrently. Analgesia is excellent when meloxicam is combined with an opioid. Meloxicam has proven to be beneficial in the treatment of sodium urate–induced synovitis²¹⁹ and panostitis²²⁰ in dogs, and radiation-induced stomatitis in cats.²²¹

Carprofen (Tablet and Parenteral Formulations)

Although classified as a NSAID, carprofen administration to beagles did not inhibit PGE₂, 12-hydroxyeicosatetraenoic acid, or TXB₂ synthesis in an experimental study using subcutaneous tissue cage fluids.²²² It was concluded that the principle mode of action of carprofen must be by mechanisms other than COX or 12-lipoxygenase inhibition. However, more recent studies indicate that it is a COX-2-preferential NSAID.^{146,223} Carprofen is approved for perioperative and chronic pain management in dogs in Australasia, Europe, and North America. Carprofen is approved for single-dose, perioperative use in cats in Europe and is licensed for use in horses in the United Kingdom. In sheep, carprofen (0.7 mg/kg intravenously) produced plasma concentrations of 1.5 µg/mL, similar to those required to confer analgesia in horses, for up to 48 h.²²⁴ However, analgesia was not assessed in this sheep study.²²⁴ Antithromboxane activity is minimal,^{217,225} suggesting that induced coagulopathy may not be a problem in patients with intact hemostatic mechanisms.

According to the European literature, potential adverse effects of NSAIDs, such as nephrotoxicity, hepatotoxicity, gastrointestinal

bleeding, or hemostatic deficiencies have not been reported with carprofen use.¹⁹⁸ Acute hepatotoxicity and death after carprofen administration have been reported among dogs with previously reported normal liver function (with Labrador retrievers highly represented).²²⁶ Carprofen provides good analgesia from 12 h^{182,192} to 18 h after a variety of orthopedic procedures. In cats undergoing ovariohysterectomy, carprofen administration provided profound analgesia between 4 and 20 h postoperatively.¹⁹³

Ketoprofen (Tablet and Parenteral Formulations)

Ketoprofen is approved for treatment of postoperative and chronic pain in both dogs and cats in Europe and Canada. It is also approved for use in horses and ruminants. As ketoprofen is an inhibitor of both COX-1 and COX-2, adverse effects are a potential problem requiring careful patient selection. Although several studies using ketoprofen preoperatively indicate its effectiveness in controlling postoperative pain,^{182,184,190} a general consensus among practitioners has restricted its use primarily to the postoperative period to reduce the potential for hemorrhage. Ketoprofen should not be administered to patients with risk factors for hemorrhage. It is often administered to animals immediately after orthopedic procedures (e.g., fracture repair, cruciate repair, or onychectomy); however, it is advised to restrict administration after laparotomy or thoracotomy until such time that hemorrhage is not a concern and when intracavitary drainage tubes have been removed.

In a study investigating the efficacy of NSAIDs in controlling postoperative pain, ketoprofen conferred a very good to excellent analgesic state for up to 24 h when compared with butorphanol.¹⁸⁴ Ketoprofen administration has also been suggested for management of pain associated with hypertrophic osteodystrophy and panosteitis in dogs. Gastroprotectants should be coadministered. Occasional vomiting may be seen when ketoprofen is administered chronically. It has also been recommended in horses.²²⁷ In foals less than 1 day old, the volume of distribution is larger and the clearance is reduced, which indicate that this drug has a longer elimination half-life in foals.²²⁸ In ponies, synovial concentrations of ketoprofen are achieved after intravenous injection and will last for up to 4 h.²²⁹ After oral administration, ketoprofen was an effective analgesic in 4- to 8-week-old calves undergoing dehorning,²³⁰ and in 8- to 16-week-old calves when administered intravenously in conjunction with lidocaine injection of the testicles for castration.²³¹

Etodolac (Tablet Formulation)

Etodolac is a COX-2-preferential NSAID approved in the United States for use in dogs for the management of pain and inflammation associated with osteoarthritis,^{202,232} but is also useful in other painful conditions. The adverse effects appear to be primarily restricted to the gastrointestinal tract.

Deracoxib and Firocoxib (Tablet Formulations)

Deracoxib is a coxib-type COX-2-specific inhibitor approved in the United States and Canada for control of postoperative pain and inflammation associated with orthopedic surgery and chronic osteoarthritic pain in dogs. Firocoxib is the most COX-2 selective NSAID available in veterinary medicine and the most recently approved NSAID for the control of osteoarthritic pain in dogs in the United States. The incidence of vomiting and diarrhea were similar in dogs receiving deracoxib and those receiving placebo in a perioperative field trial, and overall the drug was well tolerated and effective.²³³ It was also shown to be effective in attenuating lameness in dogs with urate crystal-induced synovitis after prophylactic and therapeutic administration.^{234,235} The coxib group of NSAIDs were originally marketed as being more gastroprotective in human patients when compared with the less COX-1-sparing NSAIDs such as aspirin.²³⁶ However, more recent findings and large-scale usage in human patients have indicated that coxib NSAIDs do not necessarily guarantee gastroprotection with chronic use. In a more recent canine study comparing the gastrointestinal safety profile of licofelone (a dual COX-LOX inhibitor) with rofecoxib (a similar coxib-type COX-2 inhibitor to deracoxib and firocoxib), rofecoxib was found to induce significant gastric and gastroduodenal lesions.²³⁷ It has been recommended by some investigators that coxib-type NSAIDs not be administered for a period of 1 week after a previously administered NSAID or steroid has been discontinued.

Tepoxalin (Dissolvable Wafer)

Tepoxalin is a COX-1, COX-2, and LOX inhibitor of varying degrees with efficacy comparable to meloxicam or carprofen and

safety comparable to placebo.²³⁸ Tepoxalin has been approved for management of osteoarthritic pain in dogs. The safety profile of tepoxalin showed no difference from that of placebo when administered prior to a 30-min anesthesia period and a minor surgical procedure in dogs.²³⁹

Tolfenamic Acid (Tablet and Parenteral Formulations)

Tolfenamic acid is approved for use in cats and dogs in Europe and Canada for controlling acute postoperative and chronic pain. The dosing schedule is 3 days on and 4 days off, which must be strictly adhered to. Reported adverse effects are diarrhea and occasional vomiting. Tolfenamic acid has significant anti-inflammatory and antithromboxane activity,²⁴⁰ so posttraumatic and surgical hemostasis may be compromised during active bleeding after administration of this NSAID.

Flunixin Meglumine (Parenteral Formulation)

Flunixin meglumine, which is a COX-1 and COX-2 inhibitor, is approved for use in dogs in Europe, but not in North America. It is also approved for use in ruminants and horses. Flunixin is commonly used to treat colic pain in horses. In foals less than 1 day old, pharmacokinetic data suggest increasing the dose by as much as 1.5 times the adult dose to achieve comparable therapeutic concentrations; however, longer dosing intervals are necessary to avoid toxicity.²⁴¹ Dosages for cattle are similar to those in horses. In dogs, it is reported to be an effective analgesic for surgical pain;^{123,195} however, the potential for side effects such as increased ALT,¹²³ nephrotoxicity,^{123,185,242} and gastric ulceration²⁴³ is a major concern. Flunixin is also used as an anti-inflammatory in selected ophthalmologic surgical procedures, but safer NSAIDs appear to be as effective in this setting.

Phenylbutazone (Powder and Parenteral Formulations)

Phenylbutazone is approved for use in horses, cattle, and dogs in North America. Since safer NSAIDs are approved for dogs, phenylbutazone is not recommended for this species. In horses, there is high risk of gastric ulceration and nephrotoxicity,²⁴⁴ where signs of toxicity may progress from inappetence and depression to colic, gastrointestinal ulceration, and weight loss.^{245,246} In horses recovering from arthroscopic surgery, phenylbutazone administered prior to surgery and for 21/2 days afterward improved analgesic outcome when compared with a placebo group.²⁴⁷ Phenylbutazone has a prolonged elimination half-life in cattle, ranging from 30 to 82 h.^{248,249} Phenylbutazone administration to dairy cattle 20 months of age or older is prohibited by the U.S. Food and Drug Administration to avoid the presence of residues that are toxic to people.

Eltenac (Parenteral Formulation and Topical Gel)

In horses, eltenac induced minimal side effects when 0.5 mg/kg was used during an investigative study.²⁵⁰ When used in an endotoxemic horse model, eltenac improved outcome parameters when compared with placebo, and it was proposed that this NSAID may provide clinical benefit in horses with naturally occurring endotoxemia.²⁵¹

Vedaprofen (Oral and Parenteral Formulations)

The oral form is approved for use in dogs in Europe and Canada. The parenteral form is approved for use in horses in Europe and North America and has very similar pharmacokinetic and pharmacodynamic properties to those of ketoprofen.^{252,253}

Ketorolac (Parenteral Formulation)

Ketorolac, which is a COX-1 and COX-2 inhibitor, is not approved for use in veterinary patients, but is included for the benefit of those working in the research setting where the availability of ketorolac is more likely than other NSAIDs. Ketorolac is comparable to oxymorphone in efficacy and to ketoprofen in duration and efficacy in managing postlaparotomy and orthopedic pain in dogs.¹²³ Only one to two doses should be administered to dogs or cats. Ketorolac has been used successfully for treatment of severe panosteitis in dogs where all other therapies had failed. It is recommended that ketorolac be administered with food or gastroprotectants to decrease the incidence of gastric irritation.

Piroxicam (Capsule Formulation)

Piroxicam is not approved for use in veterinary patients, but has proven valuable for its anti-inflammatory effects on the lower urinary tract in dogs with transitional cell carcinoma or cystitis and urethritis. The administration of gastroprotectants is recommended.²⁵⁴

Acetaminophen (Tablet and Oral Suspension Formulations)

Acetaminophen is a COX-3 inhibitor with minimal COX-1 and COX-2 effects. It is not approved for use in veterinary patients. It should not be administered to cats because of deficient glucuronidation of acetaminophen in this species.²⁵⁵ It may be administered to dogs as an antipyretic and analgesic for mild pain and can be used in combination with opioids for a synergistic analgesic effect or opioid-sparing effect.^{141,142} It can be prescribed as an individual drug that can be coadministered with an opioid (this approach allows more flexibility in dosing of the opioid), or in a proprietary combined formulation with an opioid (e.g., codeine plus acetaminophen, or oxycodone plus acetaminophen).

Aspirin (Tablet Formulation)

Aspirin, which is primarily a COX-1 inhibitor, is most commonly used as an analgesic for osteoarthritic pain in dogs. It is also available in proprietary combinations with various opioids (aspirin plus codeine, or aspirin plus oxycodone) to achieve a synergistic effect for the treatment of moderate pain. It is also used as an antipyretic and anticoagulant in dogs and cats. Aspirin has also been evaluated as an analgesic in cattle.²⁵⁶

Dipyrone (Tablet and Parenteral Formulations)

Dipyrone, which is a COX-3 inhibitor, is approved for use in cats and dogs in Europe and Canada. It should be given intravenously to avoid the irritation experienced when given intramuscularly. The analgesia produced is not usually adequate for moderate to severe postoperative pain, and dipyrone is reserved for use as an antipyretic in cases where other NSAIDs are contraindicated.

Nephrotoxicity or gastric ulceration is not a major concern in the short term even in critically ill patients. Dipyrone administration induces blood dyscrasias in human patients, but this has not been reported in animals.

Diclofenac (Topical Liposomal Cream Formulation)

Diclofenac is a phenylacetic acid NSAID that is a nonselective cyclooxygenase inhibitor commonly used in human patients. There is no oral or parenteral formulation available in veterinary medicine, but a topical cream has recently been approved by the Food and Drug Administration for use in horses. This liposomal cream formulation of 1% diclofenac provides a novel therapeutic modality for the local application of NSAID-type anti-inflammatory drugs. Dosing is achieved by applying a 5-inch ribbon of topical cream to only one affected joint twice daily for no more than 10 consecutive days. Rubber gloves should be worn when applying and rubbing the cream into the skin covering the painful joint. The cream is stored at room temperature and should not be frozen. Simultaneous multiple-joint application can result in excessive absorption and high serum concentrations with an increased potential for severe NSAID-type adverse reactions.

Analgesic Adjuvants

Analgesic adjuvants are defined as drugs that have primary indications other than pain, but that possess analgesic actions in certain painful conditions. This definition encompasses a very diverse group of drugs and distinguishes the analgesic adjuvants from the so-called traditional analgesics, which include the opioids, the NSAIDs, and the local anesthetics. It is only recently that analgesic adjuvants have begun to be used in veterinary medicine, and most therapeutic recommendations have been extrapolated from experience with human patients and subsequently applied to companion animals.

As the name implies, these agents are typically coadministered with the traditional analgesics. They have been used most often in the management of chronic pain states; however, their use in acute pain settings is increasing, and certain adjuvant agents have become common analgesic supplements during the perioperative period. In the chronic pain setting, the adjuvant analgesics are administered (a) to manage pain that is refractory to traditional analgesics, (b) to enable the dose of traditional analgesics to be reduced in order to lessen side effects, and (c) concurrently to treat a symptom other than pain. In some clinical settings, such as chronic neuropathic pain syndromes, adjuvant analgesics have become so well accepted that they are administered as the first-line therapy in human patients.

When contemplating administration of an adjuvant analgesic, veterinarians must be aware of the drug's clinical pharmacology and its particular use in patients with pain. The following information about the drug is necessary: (a) approved indications, (b) unapproved indications (e.g., for analgesia) that are widely accepted in veterinary medical practice, (c) common side effects and uncommon but potentially severe adverse effects, (d) important pharmacokinetic features, and (e) specific dosing guidelines for pain.

Table 10.7. Potential analgesic adjuvants in veterinary clinical practice

α_2 -Agonists	NMDA receptor antagonists
Medetomidine	Ketamine
Detomidine	Amantadine
Romifidine	Methadone
Antidepressants	Memantine
Amitriptyline	Anticonvulsants
Imipramine	Gabapentin
Paroxetine	Carbamazepine
Oral local anesthetics	Clonazepam
Mexiletine	Miscellaneous analgesics
Tocainide	Tramadol
Flecainide	
Others	
Capsaicin	
Calcitonin	
Magnesium	
Bisphosphonates	
Radiopharmaceuticals	

NMDA, *N*-methyl-D-aspartate.

Numerous drugs may be considered as analgesic adjuvants in veterinary medicine today (Table 10.7). Some of these, such as ketamine and the α_2 -agonists, are familiar to practitioners, whereas others have not been used historically in veterinary medicine. Much of the evidence substantiating the use of these agents comes from laboratory-animal research, clinical trials in humans, or anecdotal reports in human or animal patients. The following section briefly reviews the current state of knowledge regarding selected analgesic adjuvants in veterinary medicine (see Table 10.8 for recommended dosages).

Ketamine

Ketamine is a dissociative anesthetic and has been used for decades in veterinary medicine. More recently, it has been recognized as an NMDA receptor antagonist and, at very low doses, can contribute substantially to analgesia by minimizing CNS sensitization.

α_2 -Agonists

Xylazine and, more recently, medetomidine, detomidine, and romifidine have been used extensively to provide sedation in a variety of veterinary species. Medetomidine and detomidine in particular have considerable analgesic potential, even in microdoses, and can be administered via a number of novel routes and techniques to supplement analgesia and enhance the analgesic actions of other agents in various painful conditions.

Gabapentin

Gabapentin is a human anticonvulsant drug that has been approved by the U.S. Food and Drug Administration since 1993.¹⁰ Several years later, reports of its antihyperalgesic effects in rodent experimental pain models, as well as case reports and un-

Table 10.8. Dosage ranges (mg/kg) for analgesic adjuvants in selected domestic species

Analgesic Adjuvant	Dogs	Cats
Ketamine	0.5 IV loading dose 0.1–0.5/h IV CRI	0.5 IV loading dose 0.1–0.5/h IV CRI
Medetomidine	0.002–0.015 IV, IM	0.005–0.02 IV, IM
Gabapentin	2–10 PO q 8–12 h	2–10 PO q 8–12 h
Amantadine	3–5 PO q 24 h	3–5 PO q 24 h
Tramadol	2–10 PO q 12–24 h	?

CRI, continuous-rate infusion; IM, intramuscular(ly); IV, intravenous(ly); PO, per os (orally); ?, reliable doses have not been established for this species.

controlled clinical trials involving human patients suffering from neuropathic pain, began to appear in the literature. Gabapentin's mechanism of analgesic action is unknown, but there is evidence to suggest that it may increase central inhibition or reduce the synthesis of glutamate, even though it does not appear to interact directly with NMDA receptors.⁹⁹

Despite the lack of controlled data available at this time, gabapentin administration has been advocated for the management of a variety of human neuropathic pain syndromes^{99,257} and more recently for management of incisional pain and arthritis.^{258–261} In human clinical trials, side effects occur in approximately 25% of patients, are usually mild and self-limiting, and include drowsiness, fatigue, and weight gain with chronic administration. There are only anecdotal reports of its use in veterinary patients. Dosing guidelines in dogs and cats have been extrapolated from human dosing recommendations. Dosage modifications are often based on the clinical efficacy achieved in individual veterinary patients. Though it is not possible to make specific scientific recommendations of dosage and indication in specific species, with owner consent, both gabapentin and pregabalin have been increasingly used by veterinary practitioners striving to better manage chronic neuropathic pain of both malignant and nonmalignant origins in companion animals.

Amantadine

Amantadine is an antiviral agent developed to inhibit the replication of influenza A in human patients.¹⁰ It has also been shown to have efficacy in the treatment of drug-induced extrapyramidal effects and in the treatment of Parkinson's disease. More recently, amantadine administration has been advocated for the treatment of various types of pain. The drug appears to exert its analgesic effects through antagonism of NMDA receptors in a manner analogous to ketamine. Though controlled clinical human trials are lacking, amantadine seems most efficacious in the management of chronic neuropathic types of pain characterized by hyperalgesia and allodynia.^{262,263} Patients suffering from opioid tolerance may also respond favorably to amantadine therapy, and some studies suggest that the drug may even find a place in peri-

operative pain management.²⁶⁴ There are, at this writing, no well-controlled published studies evaluating the analgesic effects of amantadine in veterinary patients, and dosing recommendations are based largely on anecdotal reports. As the management of chronic pain in companion animals continues to receive much attention in veterinary medicine, the use of amantadine and other drugs with a similar mechanism of action is likely to become more prevalent.

Tramadol

Tramadol is a synthetic codeine analog that is a weak μ -receptor agonist.¹⁰ In addition to its opioid activity, tramadol also inhibits neuronal reuptake of norepinephrine and 5-hydroxytryptamine (serotonin), and may actually facilitate 5-hydroxytryptamine release.²² It is thought that these effects on central catecholaminergic pathways contribute significantly to the drug's analgesic efficacy.²⁶⁵ Tramadol is recommended for the management of acute and chronic pain of moderate to moderately severe intensity associated with a variety of conditions, including osteoarthritis, fibromyalgia, diabetic neuropathy, neuropathic pain, and even perioperative pain in human patients.^{266–268}

A study published in 2003 compared the effects of intravenous tramadol and morphine administered prior to ovariohysterectomy in dogs.²⁶⁹ In this particular study, tramadol was comparable to morphine in its analgesic efficacy for this type of surgical pain. Clearly, additional studies are necessary before definitive therapeutic recommendations can be made for the management of perioperative pain in a variety of species. There are also anecdotal reports of singular oral tramadol administration for the management of chronic pain in dogs and cats when NSAID usage is contraindicated because of advanced renal disease. Because of its inhibitory effect on 5-hydroxytryptamine uptake, tramadol should not be used in patients that may have received monoamine oxidase inhibitors (MAOIs) such as selegiline (see also the section on meperidine) or in those patients with a recent history of seizure activity.

Introduction

No injectable anesthetic produces all of the components of general anesthesia without depressing some vital organ function. Because the available drugs have rather selective actions within the central nervous system (CNS), combinations of drugs are necessary to provide surgical anesthesia without depressing vital functions. Other than ketamine, intravenous anesthetics generally provide only the mental depression of the anesthetic state. Additional analgesics, inhaled anesthetics, and/or muscle relaxants are required to provide and maintain all of the components of general anesthesia. Thus, drugs discussed in this chapter have been variously described as sedatives, hypnotics, anxiolytics, and incomplete anesthetics. The terms *sleep*, *hypnosis*, and *unconsciousness* have often been used interchangeably in describing

the drug-induced sleep produced by these drugs. Characteristics of the ideal injectable anesthetic are listed in Table 11.1.

Injectable drugs are used to induce an unconscious state or are administered by repeated injection and infusion to maintain the mental depression necessary for anesthesia. In recent years, more specific and controllable compounds that provide hypnosis, analgesia, and muscle relaxation have been developed (e.g., propofol). Total intravenous anesthesia refers to the production of general anesthesia with injectable drugs only. The advantage of total intravenous anesthesia is its facility to provide each component of anesthesia with a dose of a specific drug. In contrast, inhalation anesthetics increase or decrease the intensity of all components of anesthesia (CNS depression, analgesia, and muscle relaxation) simultaneously, including their unwanted side effects. The search for new drugs and combinations with appropriate pharmacokinetic-pharmacodynamic profiles for use in domestic and wild animals is ongoing. In animals, unlike in people, a state approaching general anesthesia is not achievable with the use of opioids alone. Consequently, in veterinary anesthesia, opioids have been primarily used as analgesics perioperatively and as anesthetic adjuncts to induce a state of neuroleptanesthesia and are not employed alone as intravenous anesthetics. Because the dissociatives have such a widespread use in domestic, feral, and wild species, and are commonly combined with a variety of other drugs, they are discussed in Chapter 12.

Structure-Activity Relationships

Structure-activity relationships are descriptions of the way modifications of chemical structure affect pharmacological activity. The addition, modification, or removal of functional groups on the fundamental structure of a drug lends it physiochemical properties that alter its ability to access its site of action (receptor) and determines the effect it has on the receptor and cellular function (intrinsic activity). The structure-activity relationships of anesthetic induction drugs have been reasonably described.

Modification of the structure of barbituric acid converts the inactive compound into a hypnotic. The addition of aliphatic side chains in position 5 and 5' produces hypnotic activity. The length of the side chains influences the duration of action, as well as potency. Replacement of the oxygen atom in position 2 of an active barbiturate with a sulfur atom produces a drug with a faster onset and a shorter action (e.g., thiopental or thiamylal). An active barbiturate methylated in position 1 produces a drug with a rapid onset and short action at the expense of excitatory side effects (e.g., methohexital). Generally, any modification that increases

Table 11.1. Characteristics of an ideal injectable anesthetic.

g. Absence of anaphylaxis
h. Absence of histamine release
III. Side effects
a. Absence of local toxicity
b. No effect on vital organ function, except anesthetically desirable effects on the central nervous system

lipophilicity will increase a drug's potency and rate of onset and shorten its action.

Several imidazoles have hypnotic activity. This activity in such a molecule requires an alkyl branched carbon atom between the aryl moiety and the imidazole nitrogen and an ester moiety. Etomidate is the most widely used imidazole anesthetic derivative. Propofol is a diortho-substituted phenol with strong hypnotic actions. Sleep time increases with side-chain length. Potency increases with the length of the side chain up to a total of seven to eight carbon atoms. Longer chains decrease potency, while induction and recovery times are prolonged. The arylcycloalkylamines, of which ketamine is a derivative, derive their anesthetic activity from a cyclohexanone ring geminally substituted with an aromatic ring and a basic nitrogen. The potency of these compounds is influenced by substitution on the nitrogen, but their pharmacological activity is unaffected.

An often-overlooked aspect of structure-activity relationships is the role of stereoisomerism to biological activity. Except for the asymmetrical centers, the stereoisomers of a given molecule are physically and chemically identical. Nevertheless, activity is predicated on the active stereoisomer of a given neurotransmitter, hormone, or drug interfacing with the chiral active center of a receptor or enzyme. Because side effects are often caused by non-specific action of drugs, the inactive stereoisomer can contribute to side effects of racemic mixtures. Some isomers may have the opposite effect on a receptor or enzyme than that of the active isomer. Several barbiturates have asymmetrical carbon atoms with isomers of varying potency. Nevertheless, all barbiturates are marketed as racemic mixtures. The (+) isomer of etomidate has hypnotic activity and is the only anesthetic to be marketed as a single active isomer. The stereoisomers of ketamine vary in their hypnotic and analgesic potency, with the (+) isomer being threefold more potent than the (−) isomer. The (−) isomer produces more untoward emergence reactions. Nevertheless, keta-

mine is marketed as a racemic mixture. Neither propofol nor the benzodiazepines have asymmetrical carbon atoms.¹

Mechanisms of Action

The complexity of the CNS has contributed to the lack of a full understanding of the mechanisms of action of injectable anesthetic drugs. No drug has a single action. Some theories suggest that anesthetics alter cell membranes. Other theories emphasize interaction with neurotransmitter-receptor-ionophore systems. Considerable evidence suggests that most injectable anesthetics alter γ -aminobutyric acid (GABA)-mediated neurotransmission. GABA is an inhibitory neurotransmitter that activates postsynaptic receptors that, in turn, increase chloride conductance, thus hyperpolarizing and inhibiting the neuron. The specific mechanism of action of each injectable anesthetic will be described subsequently in this chapter.

Barbiturate Drugs

Barbituric acid was first prepared by Conrad and Gutzeit in 1882. In 1903, Fischer and von Mering introduced a derivative, diethyl barbituric acid (veronal or barbital), for use as a hypnotic. Fischer is believed to have named the drug veronal from the Latin *vera*, because he thought it to be the “true” hypnotic.

Chemical Structure

The barbiturates all contain a pyrimidine nucleus produced by the condensation of malonic acid and urea (Fig. 11.1). Barbituric acid itself has no hypnotic activity. Substituting alkyl or aryl groups on the R₁ or R₂ positions (Fig. 11.2) produces various compounds with hypnotic activity. Replacement of the oxygen atom in position X by a sulfur atom produces the ultra-short-acting thiobarbiturates.

Substituted R₁-R₂ derivatives of barbituric acid behave as weak acids and unite with fixed alkalis to form soluble salts. These salts hydrolyze in water to varying degrees and form alkaline solutions. Those commonly employed in veterinary medicine have a pH of 10 or above, and for this reason may cause severe tissue damage and slough if injected perivascularly in any appreciable quantity.

Classification

The barbiturates have been classified into four groups according to duration of action (Fig. 11.3 and Tables 11.2 and 11.3): long, intermediate, short, and ultrashort. All of those used for clinical anesthesia fall in the short or ultrashort classification, whereas those used for sedation or control of convulsions are of long or intermediate action.

General Pharmacology

Racemic mixtures of the barbiturates are used both as hypnotics and as general anesthetics. The principal effect of a barbiturate is depression of the CNS by interference with passage of impulses to the cerebral cortex. Barbiturates act directly on CNS neurons in a manner similar to that of the inhibitory transmitter GABA. At clinical drug concentrations, barbiturates have two mechanisms of action at GABA_A receptors. At lower concentrations, barbiturates exert a GABA-mimetic effect by decreasing the rate of dissociation of GABA from the GABA_A receptor.^{2,3} At increasing drug concentrations, barbiturates directly activate the chloride-ion channel associated with the GABA_A receptor.^{4,5} The

GABA-mimetic effects of barbiturates are thought to produce their sedative hypnotic effects, whereas the direct chloride-ion channel activation produces their anesthetic effects. Barbiturates also inhibit the synaptic actions of some excitatory neurotransmitters such as glutamate and acetylcholine.^{6–8} The role of this action in the production of the anesthetic state remains uncertain.

Ganglionic transmission is approximately 20 times more sensitive to pentobarbital than is axonal conduction.⁹ The fast excitatory postsynaptic potential (EPSP) is approximately 10 times more sensitive to pentobarbital than are the slow potentials (slow EPSP and slow inhibitory PSP). Phenobarbital also exerts some degree of selectivity toward the fast EPSP. Anesthetic concentra-

tions of pentobarbital selectively block the fast EPSP. A selective postsynaptic block of the nicotinic action of acetylcholine also occurs and may account for the anesthetic-depressant effects of pentobarbital on ganglionic transmission. This selective depression on the nicotinic action of acetylcholine could occur by various molecular mechanisms, for example, by altering the binding of acetylcholine.

In hypnotic doses, the barbiturates have little effect on respiration, whereas, in anesthetic doses, respiration is depressed. Overdosage produces respiratory paralysis and death. With anesthetic doses, there is cardiovascular depression, both centrally and peripherally, with a fall in blood pressure. In hypnotic doses,

barbiturates have little effect on the basal metabolic rate. With anesthetic doses, basal metabolism is depressed, resulting in lowered body temperature.

Following barbiturate administration, leukocyte counts decrease in normal and splenectomized dogs.¹⁰ Packed cell volume also decreases in nonsplenectomized dogs, presumably owing to splenic sequestration of red blood cells. There is no significant change in the differential counts (Tables 11.4 and 11.5).

The oxidation of pentobarbital, hexobarbital, and amobarbital is noncompetitively inhibited by halothane, methoxyflurane, and diethyl ether.¹¹ Saturation of the enzyme system by the anesthetic appears responsible. Chloramphenicol, a microsomal in-

hibitor, can markedly prolong recovery from pentobarbital anesthesia.

Barbiturates administered during the prenatal period can produce permanent alterations in sexual maturity of hamsters and rats,^{12,13} and perhaps an increased incidence of congenital malformations in humans.^{14,15}

Distribution

Barbiturates diffuse throughout the body, penetrating cell walls and crossing the placenta. The extent of ionization, lipid solubility (partition coefficient), and protein binding are the three most important factors in distribution and elimination of barbiturates.

Barbiturates are sodium salts of barbituric acid derivatives. When dissolved in water, they ionize. The degree of ionization is determined by the pH of the solution and the dissociation constant (*pKa*) of the agent. This dissociation constant is the pH at which the compound exists in equal quantities in the dissociated (ionized or polar) and undissociated (nonionized or nonpolar) forms (Fig. 11.4). For a barbiturate to penetrate the lipid layer of cell membranes, it must be in the undissociated or nonpolar form (Fig. 11.5). The more acidic the solution is containing the drug, the more undissociated form that exists and the greater the amount that can penetrate cell membranes to produce deeper anesthesia.

**Fig. 11.4.** Dissociation of barbiturates.**Fig. 11.5.** Barbiturate dissociation. Cell membrane is permeable only to undissociated (nonionized) barbiturate.

The reverse is also true: The more alkaline the solution is, the greater the dissociation and the lesser the cell penetration.

At a blood pH of 7.4, a barbiturate assumes a “normal” distribution within the cells of the CNS and produces the desired degree of anesthesia. A change in blood pH, however, may lead to a change in the depth of anesthesia. An increase in acidity, such as commonly occurs with respiratory or metabolic acidosis, increases the depth. An increase in alkalinity, caused by hyperventilation or administration of alkalizing agents, increases dissociation, and barbiturate migrates outward from the cells to the plasma, and anesthesia will lighten.¹⁶ Alkalinization of the urine also decreases tubular reabsorption.

The undissociated form has a high affinity for nonpolar solvents. This varies between compounds, as shown in Table 11.6.

Table 11.6. Barbiturates: relation between physicochemical factors, distribution, and fate.

Pentobarbital	83.4	0.17	0.05

^aThe higher the permeability coefficient, the more rapid is the rate of entry into the CSF.

From Shanker.¹³⁶

The highly lipid-soluble agents have a rapid onset and are short-acting. They are rapidly metabolized and also easily reabsorbed by the kidney tubules.

A reversible bond develops to plasma proteins, chiefly albumin, the degree of which agrees roughly with the partition coefficient. Because cerebrospinal fluid is practically protein free, it contains less barbiturate than does plasma (Table 11.7). Organ tissues contain a slightly higher level of barbiturate, whereas fat contains very high concentrations. Highly lipid-soluble compounds penetrate brain tissue quite rapidly, reaching equilibrium with two or three circulations of blood. Gray matter of the brain is penetrated rapidly, with white matter being slower to reach equilibrium (Table 11.8).

Barbiturate anesthesia is terminated by physical redistribution, metabolic degradation, and renal excretion. Again, the solubility coefficient dictates the chief route of elimination. Short-acting agents with a high solubility coefficient are largely reabsorbed from the kidney tubules. Their action ceases when they are metabolically transformed into inactive substances, principally in the

Table 11.8. Influence of carbon dioxide on penetration of brain by drugs.

Area	Concentration in the Brain		
	Hypercapnic Acidosis	Hypocapnic Alkalosis	Relative Penetration
Urea (1 h)			
Gray	0.40	0.16	2.50
White	0.12	0.05	2.40
Phenobarbital (1/2 h)			
Gray	1.20	0.72	1.67
White	1.08	0.40	2.70
Salicylic Acid (1 h)			
Gray	0.44	0.11	4.00
White	0.38	0.04	9.50

Concentration in brain is expressed as a fraction of levels in plasma (relative penetration is brain fractions under conditions of hypercapnia to brain fraction under conditions of hypocapnia). Note the disproportionate increase in penetration of white matter by salicylic acid under conditions of hypercapnia. Gray, cerebral cortex; white, cerebral white matter.

From Roth and Barlow.¹³⁷ Copyright 1961 by the American Association for Advancement of Science.

liver. Long-acting agents with low lipid solubility are chiefly excreted through the kidneys. As much as 85% of barbital and phenobarbital may be recovered from the urine over several days following administration.¹⁷ The short-acting barbiturates (pentobarbital, amobarbital, and secobarbital) are destroyed principally by the liver. Their rapid destruction in the body accounts for their shorter action. With anesthetic-inducing doses ultra-short-acting barbiturates are quickly redistributed, accounting for their short action. Thiobarbiturates are not metabolized more rapidly than the oxybarbiturates.

The “Glucose Effect”?

A unique reanesthetizing action, termed the *glucose effect*, has been observed in animals recovering from barbiturate anesthesia that were subsequently given glucose. A species variation in susceptibility to this effect has been demonstrated: Guinea pigs, chickens, pigeons, rabbits, and hamsters are susceptible; dogs are intermediate; and mice, rats, goldfish, and tadpoles are refractory or negative. Intermediates in the glycolysis of glucose and in the Krebs cycle have been shown to have the same effect. The glucose effect presumably occurs with most barbiturates and thiobarbiturates, but not with inhalation or other anesthetics. Glucose causes a decrease in activity of the components of the microsomal electron chain, resulting in decreased microsomal metabolism.¹⁸ A study on the glucose effect on respiration and electroencephalogram in dogs following pentobarbital administration found no evidence of significant deepening of anesthesia as judged by cortical depression, decreasing rate or depth of respiration, or a decrease in minute volume.¹⁹

Epinephrine given intravenously (IV) to dogs or mice also causes a return of sleep on awakening from hexobarbital or chloral hydrate anesthesia. Norepinephrine is less effective in producing this effect.²⁰ This phenomenon presumably is caused by increased glucose levels in the blood and should be remembered when the use of epinephrine is considered in barbiturate-anesthetized dogs. The effect of glucose, sodium lactate, and epinephrine on thiopental anesthesia in dogs has also been studied (Table 11.9). The glucose effect does not appear to be of practical concern as long as these drugs are used in therapeutic doses.²¹

Therapeutic Uses

Barbiturates are used to induce sedation and hypnosis, as anti-convulsants, and as anesthetics. Their use as sedatives and hypnotics in low doses has been supplanted, in most instances, by tranquilizers. The ability of barbiturates to depress the motor cortex has been used to treat convulsions associated with poisoning, particularly strychnine, “running fits,” distemper encephalitis, and overdosage of local anesthetics. In modern veterinary medicine, the thiobarbiturates are primarily used as induction agents or short-acting anesthetics, whereas pentobarbital is now used sparingly because of its propensity to cause prolonged, rough recoveries when administered in anesthetic doses.

Addiction

Although barbiturate addiction can be produced in animals, it is by its very nature self-limiting; however, in humans, repeated oral use of barbiturates as soporifics or sedatives may become habit forming. For this reason, legislation in many countries prohibits use of these drugs without a prescription. Veterinarians should be acquainted with applicable laws regarding the use and sale of barbiturates to avoid infraction and to prevent liability.

Oxybarbiturates

Phenobarbital Sodium

Phenobarbital was synthesized in 1912 in Germany and marketed under the trade name Luminal. It is a long-acting barbiturate, and advantage has been taken of its prolonged action in treating var-

From Hatch.²¹

ious convulsive disorders (Fig. 11.3). In control of convulsions caused by distemper encephalitis, it appears to be as effective as any of the newer drugs and considerably cheaper. Because it is excreted slowly in the urine, it tends to be cumulative. An oral loading dose should be administered first, followed by a daily maintenance dose. In average dogs (10 kg), this would be 60 mg initially, followed by 15 mg three times a day. Overdosage causes loss of motor coordination; when this occurs, the dose should be reduced. Serial assays on serum, saliva, and cerebrospinal fluid have shown considerable daily fluctuation in phenobarbital levels, even after several weeks of therapy. The phenobarbital concentration increases gradually in the three fluids up to doses of 9.0 mg/kg. Serum or saliva assays can accurately indicate the phenobarbital concentration in cerebrospinal fluid.²²

In animals suffering from strychnine poisoning, phenobarbital solution may be given IV to effect in the same manner as one would administer pentobarbital sodium. Phenobarbital is a hepatic microsomal enzyme inducer. Concomitant administration of phenobarbital and digoxin can shorten the biological half-life of the latter by approximately 30%.²³

Pentobarbital Sodium

This drug came into general use as an anesthetic agent for dogs and cats in the early 1930s and slowly supplanted ether administered by open-mask methods as the anesthetic of choice. By 1940, its use was widespread. Today, it has largely been replaced by inhalation and balanced anesthetic techniques.

Commercial preparations of pentobarbital are racemic mixtures. Administration of subanesthetic doses is often associated with CNS stimulation and preanesthetic excitation. The R-isomer of pentobarbital causes a transient period of hyperexcitability before depressing the CNS, whereas the S-isomer produces relatively smooth and progressively deeper hypnosis.²⁴ Evidence suggests the S-isomer is more potent, possibly because of increased uptake by the brain.^{25,26}

Fig. 11.6. Long-term changes from pentobarbital in six dogs. Note the large and abrupt increase in heart rate and decrease in stroke volume at the onset of the experiments. CO, cardiac output; HR, heart rate; MAP, mean arterial pressure; PR, peripheral resistance; and SV, stroke volume. From Olmsted and Page.¹⁴⁰

Pentobarbital sodium occurs as a white powder or crystalline granules. It is freely soluble in water or alcohol. It forms a clear, colorless solution that is marketed under several trade names. Aqueous solutions have an alkaline pH and may precipitate on standing, but the drug can be redissolved by addition of an alkali such as sodium hydroxide. The calculated dose for dogs and cats is 30 mg/kg of body weight; however, it should be emphasized that pentobarbital is given *to effect*. Following a single intravenous dose of pentobarbital, arterial blood pressure decreases. The heart rate increases for 10 to 20 min and then stabilizes or decreases. Cardiac output is variable, whereas peripheral vascular resistance increases (Fig. 11.6).

The cardiovascular effects of prolonged pentobarbital (2.5 h) anesthesia in dogs have been assessed. Systolic blood pressure, initial ventricular impulse, stroke volume, pulse pressure, central venous pressure, arterial oxygen partial pressure, pH, and body temperature all decrease after anesthetic doses of pentobarbital. Heart rate, arterial carbon dioxide partial pressure, and peripheral resistance increased after 1.5 h. Cardiac output eventually decreases. Mean arterial pressure significantly decreases during induction, but usually returns to awake values in approximately 30

min (Table 11.10).²⁷ Intravenous pentobarbital administration alters myocardial function and distribution of blood flow. In dogs, it was found that intravenous pentobarbital decreases contractile force by 17.4%, arterial blood pressure by 4.8%, and renal blood flow by 8.4%, while increasing cardiac output by 4.8% and superior mesenteric artery flow by 14.1%. The decreased arterial blood pressure was believed to be caused by vasodilation of major vascular beds, and the increased cardiac output to be caused by increased venous return.²⁸ Respiration is initially depressed and gradually increases during recovery.²⁹

Light pentobarbital anesthesia has little influence on renal hemodynamics. Deep anesthesia depresses renal function, both blood and urine flow, by circulatory depression and also by reflex vasoconstriction. Pentobarbital inhibits water diuresis by stimulating release of antidiuretic hormone.³⁰

Leukopenia is found in dogs anesthetized with pentobarbital.³¹ Leukocyte counts drop to 20% of control values (Fig. 11.7). Although the absolute differential white cell count decreases, there is a relative lymphocytosis that reaches its peak at 90 min and then returns to normal. Red cell numbers decrease also. Hemoglobin and hematocrit values show corresponding changes. Pentobarbital, amobarbital, and thiopental administration dilates the spleen, which presumably accounts for the decrease in erythrocytes via the sequestration of red blood cells.³² Maximum dilation usually occurs 20 to 30 min after injection of the anesthetic. Sedimentation rate and coagulation time are both increased, whereas prothrombin time is decreased. Oral administration of pentobarbital sodium in sedative doses does not affect the blood constituents in the same fashion.

In some animals, the effect produced by high doses of pentobarbital is difficult to differentiate from shock. The size of the dose and method of its administration are the major factors in variation of response to pentobarbital. Individual variations undoubtedly exist. Roughly one of four animals given a dose of 30 mg/kg develops side effects that mimic some phase of shock.³³

On intraperitoneal administration, the peak concentration in the blood is reached more slowly than with intravenous injection, and the portion of drug absorbed into the portal system is subjected to early destruction in the liver. When a 2.5% aqueous solution is given intraperitoneally in a dose of 30 mg/kg of body weight, anesthesia is not accompanied by impaired renal function, and arterial blood pressure increases.³⁴ When given radiolabeled pentobarbital orally, dogs excrete about 60% of the total dose in the urine during the first 24 h.³⁵ Over 92% is excreted as metabolic products derived from the drug, and only 3% is in the form of pentobarbital. Pentobarbital elimination from the blood of both intact and bilaterally nephrectomized dogs is similar because elimination is totally dependent on biotransformation of pentobarbital by the liver.³⁶ The absence of renal function per se does not seem to alter the pharmacokinetics of pentobarbital; however, the sensitivity of a patient to the action of barbiturates may be increased by uremia. This phenomenon is probably caused by the decreased capacity of plasma protein to bind acidic drugs.

Pentobarbital freely crosses the placental barrier and enters the fetus. For this reason, its use as a monoanesthetic (high dose) for

Fig. 11.7. The relative percentage change in white cell counts with intravenous pentobarbital sodium anesthesia in 12 dogs as compared with control levels in unanesthetized dogs. The relative percentage distribution of lymphocytes and granulocytes is shown on the same scale. From Graca and Garst.³¹

cesarean section causes high mortality among newborns. Neonates can be viable at birth, but usually do not recover from anesthesia and cannot nurse.

The duration of surgical analgesia with anesthetizing doses of

pentobarbital varies widely with individual animals, averaging about 30 min. Complete recovery usually occurs in 6 to 18 h. Occasionally, animals, particularly cats, may not rouse for as long as 24 to 72 h.

Pentobarbital is no longer used in North America to produce anesthesia in most small companion animals, cattle, and horses, owing to the prolonged recovery period and marked respiratory depression. It has been administered by slow intravenous injection (15 to 30 mg/kg) in foals and young cattle. Because of prolonged recovery, pentobarbital should not be administered to animals younger than 1 month of age. In adult cattle, anesthesia has been induced with 14 mg/kg IV; half of the dose is injected rapidly, the animal is positioned on its sternum, and the remainder is injected slowly to effect.³⁷ Pentobarbital has also been administered with chloral hydrate or thiopental sodium to induce anesthesia in adult horses³⁸ and in goats before administration of inhalant anesthetics.³⁹

The intravenous anesthetic dose in adult goats is 30 mg/kg, which maintains anesthesia for approximately 20 min. Anesthesia can be maintained by doses of 6 to 36 mg · kg⁻¹ · h⁻¹ of pentobarbital. The induction and intubation dose ranges from 10 to 42 mg/kg. A similar technique for intravenous pentobarbital in

From Grono.⁴²

sheep has been described.⁴⁰ Like goats, sheep rapidly metabolize pentobarbital, and additional doses are required to maintain anesthesia for periods longer than 20 to 30 min. The anesthetic dose of pentobarbital sodium is approximately 25 mg/kg in adult sheep. In all ruminants, immediate intubation to prevent aspiration of regurgitated rumen contents is essential.

In swine, a 10- to 30-mg/kg dose of pentobarbital given IV provides anesthesia for 15 to 45 min. If anesthesia is induced until reflex response to surgical stimulation is abolished, respiratory depression is often severe, and apnea may occur.

Animals awakening from pentobarbital anesthesia tend to exhibit the same signs as when they are anesthetized, except in reverse order. These include crying, shivering, involuntary running movements, thrashing, increased respiratory movements followed by recovery of the righting reflex, and, later, ability to stand with a staggering gait. Because recovery is slow, without preanesthetic medication these actions may become so exaggerated that the animal injures itself through contact with the cage or stall or causes wound disruption. Greyhounds are notable for this effect. Show animals have been known to break teeth, much to the embarrassment of the veterinarian. Administration of a narcotic or a tranquilizer is indicated in cases of emergence excitement. Yohimbine plus 4-aminopyridine will incompletely antagonize pentobarbital-induced CNS depression in dogs preanesthetized with atropine-xylazine or atropine-acepromazine.⁴¹

Methohexital Sodium

This is an ultra-short-acting barbiturate that is unique in that it contains no sulfur atom. Its short duration owes more to redistribution than to rapid metabolism. Blood concentrations necessary to produce anesthesia are approximately one-half of those required with thiopental or thiamylal. According to the manufacturer, a double dose rapidly administered IV causes temporary apnea. The lethal dose is said to be approximately 2.5 times greater than the median anesthetic dose. Animals die of respiratory failure. Methohexital sodium is supplied as 500 mg of dry powder in glass vials. It is diluted with water or normal saline to form a 2.5% solution for injection. Solutions are said to be stable for as long as 6 months at room temperature. The dose for dogs or cats is 6 to 10 mg/kg of body weight. Half of the estimated dose is injected IV at a rapid rate, following which administration is continued to effect. Surgical anesthesia for 5 to 15 min is obtained by an initial injection. More prolonged anesthesia can be maintained by intermittent administration or continuous drip. Recovery is quick and may be accompanied by muscular tremors and violent excitement, which detract from the usefulness of the drug. Dogs are usually ambulatory 30 min after administration ceases.

Methohexital has been used alone and with several preanesthetics in horses (Table 11.11). Even with preanesthetic sedation, the recovery period is characterized by muscle tremors and strug-

gling.⁴² For this reason, the anesthesia produced is undesirable except when followed by administration of an inhalant anesthetic. Under these circumstances, it proves to be a good drug for induction, because its effects are short-lasting. One injection provides just sufficient time for intubation and administration of the inhalant before its effect ceases, leaving horses anesthetized with only the inhalant. The induction dose in horses is approximately 6 mg/kg. It must be given rapidly or anesthesia will not be achieved.

Methohexital has been used to induce anesthesia in calves at the rate of 3 to 5 mg/kg. A smooth, rapid induction enabling endotracheal intubation is produced.⁴³ In adult cattle, the dose for induction is 6 mg/kg.⁴⁴

A high percentage of the metabolites of methohexital is excreted in the bile of dogs and rats. Following administration of [¹⁴C]methohexital to dogs and rats, 30.1% and 82.7% of the radioactivity is found in the feces, respectively. Dogs excrete 21.7% in bile and urine in the first hour and 52.4% in 8 h.⁴⁵

Thiobarbiturates

Thiopental Sodium

Thiopental was the first thiobarbiturate to gain popularity as an anesthetic agent for animals. It is the thio analog of pentobarbital sodium, and differs only in that the number 2 carbon has a sulfur atom instead of an oxygen atom attached to it. Thiopental sodium is a yellow crystalline powder that is unstable in aqueous solution or when it is exposed to atmospheric air. For this reason, it is dispensed in sealed containers as a powder buffered with sodium carbonate. It is usually mixed with sterile water or saline to form 2.5%, 5.0%, or 10% solutions. Thiopental solutions should be stored in a refrigerator at 5° to 6°C (41° to 42°F) to retard deterioration. As solutions age, they become turbid and crystals precipitate, which results in progressive loss of activity, but does not increase its toxicity. Because the potency is decreased, larger quantities of solution must be used to produce the desired effect.⁴⁶

The metabolism of thiopental is exceedingly complex. Following injection with thiopental containing radioactive sulfur (³⁵S), monkeys produce at least 12 different metabolic products that are excreted in the urine. About 86% is found in the urine within 4 days after intravenous injection; small amounts are also found in the tissues and feces.⁴⁷

The initial toxic effect produced by thiopental is a marked depression of the respiratory centers. Both rate and amplitude are affected. By 5 min after administration of thiopental, heart rate, aortic pressure, peripheral vascular resistance, and left ventricular systolic and end-diastolic pressures increase.⁴⁸ Bigeminy is common. Cardiac arrhythmias associated with thiobarbiturate anesthesia can be accentuated by xylazine, halothane, methoxyflurane, and epinephrine.^{49–52} Observed arrhythmias include sinus tachycardia, bigeminy, extrasystoles, ventricular tachycardia, multifocal ventricular tachycardia, and ventricular fibrillation. Administration of a lidocaine bolus concurrently with thiopental (11 mg/kg) reduces the cardiopulmonary depressive effects of the latter and has been advocated for anesthetic induction of patients predisposed to cardiac arrhythmias.⁴⁸

Fig. 11.8. The average duration of anesthesia after successive hourly intravenous injections of equal doses of thiopental to dogs. From Wyngaarden et al.¹⁴¹

During prolonged thiopental anesthesia, there is a pronounced hyperglycemia, increased lactic acid and amino acids in blood, and decreased liver glycogen.⁵³ Insulin either prevents a decrease or favors increased storage of liver glycogen. Repeated doses of thiopental have a cumulative effect, as shown in Figure 11.8. Prolonged periods of anesthesia may result from this effect if numerous doses are administered.

Thiopental has an ultrashort action because it is rapidly redistributed (e.g., into muscle tissue) and becomes localized in body fat.⁵⁴ As concentrations in the plasma, muscle, and viscera fall, the thiopental concentration in fat continues to rise. On the other hand, an appreciable amount is metabolized by the liver, and this contributes to the early rapid reduction of arterial thiopental concentration.⁵⁵ The same effect occurs after a fatty meal. A high chylomicron level in the blood reduces sleeping time significantly because thiopental is in more intimate contact with chylomicrons and a smaller diffusion distance is present. Blood fat is more potent than depot fat in decreasing thiopental sleeping time.⁵⁶ Leukopenia, hyperglycemia, elevated arterial partial pressure of carbon dioxide, and decreased arterial partial pressure of oxygen have been observed in thiopental-anesthetized horses (Table 11.12) and are comparable to changes observed with the use of other barbiturates and in other species.

For small animals, 1.25%, 2.5%, and 5.0% solutions of thiopental are used, depending on the animal's size. Whenever convenient, the more dilute solutions should be used, because overdosing is less likely and irritation is less in the event of accidental perivascular injection. As in other species, thiopental may be used in dogs and cats as the sole anesthetic or for induction prior to inhalation anesthesia. For rapid induction of anesthesia of short duration, the dose is 10 to 12 mg/kg. Should 10 to 20 min of surgical anesthesia be required, the dose range is 20 to 30 mg/kg. One-third of the estimated dose is injected rapidly within 15 s, and the remainder is administered slowly to effect. Additional doses may be administered to prolong anesthesia when required. Following large-dose administration, recovery (to standing) usually requires 1 to 1.5 h. Large doses will saturate the

From Tyagi et al.¹³⁸

tissues and cause a prolonged emergence. When induction is preceded by preanesthetic sedation, a dose range of 8 to 15 mg/kg is used. As in other species, too large a dose prior to inhalation anesthesia depresses respiration and impairs the uptake of inhaled gases. The use of thiopental is contraindicated in neonates and in feline porphyria.

Thiopental was commonly used for rapid induction of anesthesia in horses during the 1950s and early 1960s. After preanesthetic sedation with a suitable tranquilizer (e.g., xylazine or acepromazine), 6 to 10 mg/kg of thiopental are injected IV. If injected as rapidly as possible, 6 to 9 mg/kg are adequate. The smaller dose is used prior to the use of inhalant anesthetics, whereas the larger dose is used when a short period of surgical anesthesia is required. Thiopental is more commonly mixed with 5% guaifenesin when used for equine anesthesia. Two or three grams of thiopental are added to 1 L of 5% guaifenesin and administered rapidly IV to effect. It is often preceded by tranquilization with xylazine, detomidine, or acetylpromazine. The time of induction can be decreased by administering an additional 1 g of thiopental as an adult horse (400 to 500 kg) begins to relax. Once the horse is recumbent, the anesthesia can be maintained by continuing the infusion of thiopental and guaifenesin at a slower rate or by intubating and administering an inhalant anesthetic. The induction dose alone will produce anesthesia lasting 10 to 20 min. Total anesthesia time should be limited to less than 1 h when the combination of thiopental and guaifenesin is used as the maintenance anesthetic or recovery can be very prolonged and of poor quality. To minimize the recovery time when thiopental and guaifenesin are used for anesthetic maintenance, the amount of thiopental should be decreased by 50% in subsequent liters of the mixture.

Similar doses of thiopental alone (4 to 6 mg/kg) or with 5% guaifenesin in 5% dextrose in water may be given to induce anesthesia in cows. Once anesthesia is induced in cattle, endotracheal intubation is essential to prevent possible aspiration of rumen contents. The possibility of this is reduced by positioning animals so that the anterior thoracic and caudal cervical region is higher than any other part of the body. As in newborn foals, use of thiopental is contraindicated in the neonatal calves. Thiopental is also used in doses of 8 to 15 mg/kg in small ruminants. Rapid intravenous induction can be achieved with 8 to 12 mg/kg, whereas larger doses are given by slow intravenous injection to effect. The latter technique provides 10 to 20 min of surgical anesthesia.

The dose of thiopental required to induce anesthesia in swine is variable. The minimal dose required ranges from 4.0 to 8.0 mg/kg. Half the dose is injected rapidly, and the remainder more slowly over the next several minutes. Even during light anesthesia, respiratory depression, irregular breathing, and apnea commonly occur in swine.

Thiamylal Sodium

This is the thio analog of the barbiturate secobarbital sodium. It differs from thiopental sodium in that the ethyl radical of the latter (on R₁) is replaced by an allyl radical.⁵⁷ In dogs, the anesthetic potency of thiamylal is about 1.5 times that of thiopental.⁵⁸

Administration

Barbiturates are administered by several routes, depending on the patient and the desired effect. For anesthesia, the intravenous route is preferable because the anesthetic can be given to effect. Because of wide variation in patient response, this type of dose

control is desirable. Intraperitoneal administration and intramuscular administration are not widely employed. The oral route is slow and unpredictable, and therefore is used chiefly when sedation is sought.

Care should be taken in selection of needles and syringes for administration. In large species of animals, 12- to 18-gauge 1.5- to 2.0-inch needles are used, depending on the quantity of anesthetic that must be injected rapidly to carry the patient through the excitement stage. When large quantities are to be injected, a vascular catheter is preferred. In smaller animals, 20- to 24-gauge needles aid in venipuncture and help slow the rate of injection. There is a careless tendency to use large syringes on very small animals. This is dangerous because the dose cannot be accurately controlled. A syringe size commensurate with the dose should always be employed; use of large syringes with small doses is an invitation to disaster.

In many practices, an indwelling venous catheter is inserted prior to anesthetic administration. This is used for anesthetic injection and subsequent fluid administration during surgery. It also helps ensure that inadvertent perivascular injection does not occur when animals are transported. In small animals (weighing less than 5 kg), it is advisable to dilute the anesthetic with sterile water. By making a 100% dilution, more accurate dose control is achieved.

When intravenous injection is to be made, hair over the vein may be removed with clippers and the skin prepared by swabbing with a suitable antiseptic. The latter procedure, in addition to cleaning the area, tends to distend the vein. For intravenous anesthesia, the cephalic vein on the anterior aspect of the forelimb is most commonly used in small animals. In dogs, the second choice is generally the saphenous vein on the lateral surface of the hind limb just proximal to the hock. In cats, the saphenous or femoral vein on the inner surface of the thigh is a good second choice. Other veins less frequently used are the jugular and the marginal vein of the ear. In large dogs already anesthetized, the lingual veins on the ventral surface of the tongue are easily accessible. These veins tend to bleed rather profusely, however. In horses, cattle, and sheep, the jugular vein is used almost exclusively. In swine, the marginal vein of the ear or the anterior vena cava is most commonly employed.

In dogs, if injection is to be made into the cephalic vein of the right foreleg, the assistant stands by the animal's left side with the left arm circling the dog's neck and the right arm extended over its back. The right hand grasps the right foreleg just below the elbow. The right index finger is extended over the dorsal surface of the limb, the thumb is held around the ventral surface of the leg, and, by compressing thumb and forefinger, the vein is occluded, causing it to distend with blood. The assistant turns his or her wrist slightly so that the skin covering the dorsal aspect of the foreleg and the cephalic vein is rotated outward. The veterinarian grasps the paw of the right foot with the left hand and, if the vein is not easily seen, by rapidly squeezing the paw several times, pumps blood from the paw to distend the vein. If the carpus is flexed acutely, the vein is stretched tightly over the underlying muscles and rolling is prevented. Good technique demands that the needle used for injection be threaded into the vein so that the

hub is at the site of venipuncture. The leg and syringe are both held in the veterinarian's left hand during injection so they will move as a unit if the animal moves. This prevents accidental retraction of the needle from the vein.

Persons experienced with administration of barbiturates to dogs and cats usually estimate the weight of the animal and draw an excess of solution into a syringe. The first one-third to one-half of the dose is rapidly injected while watching the animal's facial expression closely. As injection is made, the animal often licks its lips as though tasting the drug. Frequently, dogs move the head from side to side as the anesthetic effect begins. These movements are seen early in the administration and indicate more drug must be given. The eyes begin to lose their alert expression, and the animal then relaxes. As injection is continued, the veterinarian can, with thumb and forefinger placed behind the canine teeth, open the animal's jaw. If in a light state of anesthesia, the patient will further open the jaw, curl the tongue, and simulate a yawn. At this point, the cornea and pedal reflexes are still present, and the animal is not in a state of surgical anesthesia. Administration of anesthetic should be continued cautiously and in small amounts, with careful attention paid to respiration and reflexes. Surgical anesthesia is reached when the pedal reflex is abolished. At this point, further administration of drug is not necessary.

Intraperitoneal Injection

This has been employed extensively in the past, but has the disadvantage that the dose cannot be as accurately controlled as it can by intravenous administration. Usually with this method, the animal is restrained in a vertical position against the assistant's body with the animal's abdomen facing outward. An area just lateral to the umbilicus is clipped and a suitable antiseptic applied. The needle is passed through the abdominal wall and the injection made. The dose for intraperitoneal administration is calculated in the same manner as the intravenous dose. The peak concentration in the blood is reached more slowly, and drug absorbed into the portal system is subject to early metabolism.³⁴ This technique is not recommended in the clinical practice of veterinary anesthesia and may be quite painful to the animal.

Intramuscular and Intrathoracic Injection

Under unusual circumstances, such as when wild animals are anesthetized, intramuscular or subcutaneous injection of barbiturates may be indicated. Because of their high alkalinity, there is a tendency for tissue necrosis to develop following this procedure. For moderate anesthesia, 30 mg/kg, and for surgical anesthesia of 1 to 2 h, 40 mg/kg of pentobarbital can be administered. Induction requires about 15 min, and anesthesia reaches its peak effect about 30 min after injection.

Although pentobarbital has been given intrathoracically using the same dose as for intravenous anesthesia, veterinarians should strongly oppose intrathoracic administration of anesthetic because there is risk of puncture to the heart, pericardium, and lung, and barbiturates irritate the serosal surfaces. The latter fact can be confirmed on necropsy of animals destroyed with intrathoracic barbiturates. Pleural thickening, bronchitis, and coagulative

necrosis of the lung have been observed on examination of experimentally injected cats.

In general, thiobarbiturates produce more respiratory depression on induction than do oxybarbiturates: Often one-third of the calculated dose causes the patient to collapse and respiration to stop. This transient apnea is alarming to those not aware of this reaction. When it occurs, injection of anesthetic should be suspended until spontaneous rhythmic respirations resume. This usually occurs as soon as the blood carbon dioxide level rises to stimulate respiration and rapid redistribution decreases CNS concentration.

Barbiturate Slough

Occasionally, animals may struggle during induction of barbiturate anesthesia, and some of the drug may be administered perivascularly. This should be avoided if at all possible because a tissue slough may develop. Experienced anesthetists prevent barbiturate slough by threading the needle into the vein. This procedure makes it unlikely that the needle will come out of the vein if the syringe is jarred or the animal moves. Sloughs caused by anesthesia require 2 to 4 weeks to heal and leave an unsightly scar. Nothing can infuriate owners more than development of a slough in their animal.

If it is suspected that barbiturate solution has been injected perivascularly, the area should be infiltrated with 1 or 2 mL of 2% procaine solution.⁵⁹ Lidocaine can also be used for this purpose. Local anesthetics are effective for two reasons. First, they are vasodilators and prevent vasospasm in the area, and thus aid in dilution and absorption of the barbiturate. Second, they are broken down in an alkaline medium, and this reaction neutralizes the alkali (barbiturate). The use of hot packs or hydrotherapy may be beneficial, as is infiltration of the area with saline to dilute the barbiturate further. Additionally, systemic anti-inflammatory drugs may be of benefit.

Barbiturate Euthanasia

All of the euthanasia solutions that are commercially available in the United States contain pentobarbital as their active ingredient. Some include other drugs, but the additional ingredients do not make the product a more effective euthanasia agent. The combination products are schedule III controlled substances compared with the schedule II products that contain only pentobarbital. The usual dose of pentobarbital for euthanasia of dogs and cats is 120 mg/kg for the first 4.5 kg of body weight and 60 mg/kg for each additional 4.5 kg. Large animals usually require 10 to 15 mL per 45 kg of body weight. Pentobarbital should not be used for euthanasia of animals intended for consumption by people or other animals, and carcasses should be disposed of in a manner that prevents consumption by domestic or wild animals. Pentobarbital can be administered orally as a sedative prior to euthanasia. The dose is approximately 60 mg/kg, and the time to lateral recumbency is approximately 60 min.

Nonbarbiturate Drugs

Although the barbiturates have been the most commonly used short-acting anesthetics, many other injectable drugs have been

used to induce and maintain unconsciousness. Chloral hydrate alone and in combination with magnesium sulfate and pentobarbital sodium has been used for induction and maintenance of anesthesia in large domestic animals (i.e., horses and cows). Many drugs used to depress the CNS and immobilize laboratory animals do not find application in routine small animal clinical use. Among them are chloral hydrate, chloralose, urethan, metomidate, and magnesium sulfate. Newer drugs, such as etomidate and propofol, have been developed to provide short periods of unconsciousness from which recovery is rapid. These hypnotic drugs are most effective when given in combination with pre-anesthetics and analgesics to achieve anesthesia and analgesia. Several of these combinations have recently been developed and assessed for use in animal anesthesia.

Neurosteroids

This class of drugs was first evaluated as a combination of two steroids: alphaxalone and alphadolone acetate (Althesin or Saffan). The solubility of alphaxalone (9 mg/mL) is increased by alphadolone acetate (3 mg/mL) and by 20% wt/vol polyoxyethylated castor oil (Cremophor EL). The combination of the two steroids has an exceptionally high therapeutic index (30.6). It has little cumulative effect (Fig. 11.9), and the duration of anesthesia varies with species (Fig. 11.10). Administration of the combination before or after barbiturates is not advised, although adverse effects when used with other anesthetic drugs have not been reported. Evidence suggests the neurosteroid anesthetics work by enhancing GABA-mediated neurodepression.^{60,61} In addition, the activation of centrally located inhibitory glycine receptors may be involved.⁶¹

A new neurosteroid product has been developed that is a 10-mg/mL solution of alphaxalone in 2-hydroxypropyl- β -cyclodextrin (Alfaxan-CD; Jurox, Rutherford, Australia). This preparation does not appear to cause histamine release, which has been associated with the vehicle used in earlier neurosteroid preparations.⁶²

In cats, the dose of Althesin is 9 mg/kg for intravenous administration and 12 to 18 mg/kg for intramuscular administration. Intravenous injection produces relaxation in approximately 9 s and surgical anesthesia in about 25 s. Intramuscular administration produces variable results, but may be useful in fractious animals. The onset occurs in 6 to 12 min and lasts for approximately 15 min. A quiet area for induction is desirable. In fractious cats, when drugs must be administered intramuscularly, ketamine is the drug of choice because Althesin is less reliable by this route.⁶³

Althesin has a neutral pH and does not produce pain or inflammation when injected perivascularly or intramuscularly. Additional doses can be given to prolong anesthesia without cumulative effects, and recovery is rapid. In contrast to ketamine, Althesin produces good muscular relaxation. Althesin has a slightly protective effect against epinephrine-induced arrhythmias in cats.⁶⁴ Urination, defecation, muscle tremors, paddling, salivation, and hyperesthesia have been reported as side effects. Edema of the feet, ears, and muzzle occurs in approximately 25% of cats injected, but is usually transient and disappears within 2

Fig. 11.9. Duration of loss of righting reflex in mice given repeated intravenous doses of Althesin and other anesthetics (five mice per group). Second and subsequent doses were given 30 s after return of the righting reflex. After Child et al.⁶⁵

h. This condition apparently occurs in females more often than in males. Antihistamine administration reduces this occurrence.

In dogs and some other canidae, the use of polyoxyethylene derivatives of hexitol anhydride partial fatty acid esters produces an allergic response.⁶⁵ This response is manifested by a prolonged fall in blood pressure and a positive skin wheal if the drug is injected intradermally. Urticaria and erythema are believed to be caused by the release of histamine or histamine-like substances. Cremophor EL, a nonionic polyoxyethylated emulsifying agent used as the vehicle in Althesin, elicits the same response. Apparently, allergic reactions can be caused by the vehicle (polyoxyethylated castor oil). The reaction can be of the true-hypersensitivity type, which requires previous exposure to the drug, or of the complement-activation type, which requires no previous sensitization.⁶⁶

Horses anesthetized with Althesin can develop violent paddling and galloping movements during recovery, which can be prevented by prior administration of xylazine (1 mg/kg).⁶⁷ The minimum dose of Althesin for induction of anesthesia is approx-

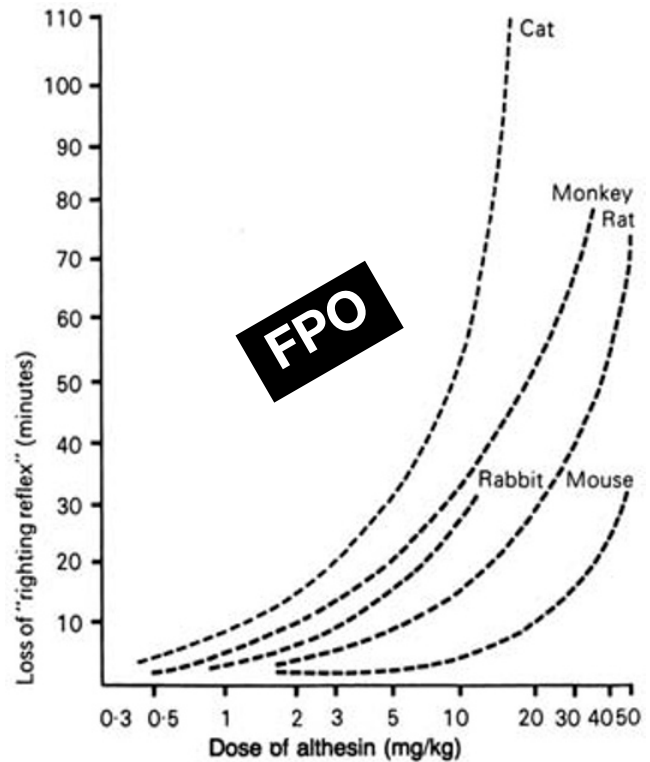

Fig. 11.10. Anesthetic activity of Althesin in different species. After Child et al.⁶⁵

imately 1.2 to 1.34 mg/kg in non-premedicated horses. Although xylazine administration lengthens the recovery time, its administration would appear prudent.

The dose of Althesin for sheep is approximately 2.2 mg/kg IV. This produces light surgical anesthesia for 8 to 15 min. The average maintenance dose to produce surgical anesthesia for a 3-h period is $0.23 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. Sheep given Althesin develop bradycardia, with a decrease in systolic and diastolic pressures of 20% to 35% of preinjection levels. Left ventricular end-diastolic pressure elevates, and cardiac output decreases. These parameters return to normal within 6 to 8 min of injection. Myocardial depression measured as a decrease in maximum dp/dt is produced.⁶⁷ Althesin has also been used to induce anesthesia prior to the administration of inhalants to maintain anesthesia in ruminants (goats, sheep, and young calves).⁶⁸ The dose of Althesin for pigs is approximately 6 mg/kg to produce 10 to 15 min of anesthesia. In pigs known to develop malignant hyperthermia under anesthesia, Althesin does not induce this reaction, and it has been used safely in animals known to be susceptible to this condition.⁶⁷

Althesin decreases cerebral blood flow accompanied by a fall in intracranial pressure in baboons.⁶⁹ Neither of the two steroids is extensively protein bound by the serum of rats, cats, horses, or people. Approximately 60% to 70% of a radioactive dose of alphaxalone or alphadolone acetate is excreted as metabolic products in the feces during the 5 days following intravenous injection; the other 20% to 30% appears in the urine within the same period.⁷⁰

Chloral Hydrate

Liebrich, who introduced chloral hydrate as a hypnotic in 1869, thought that, because it released chloroform *in vitro*, it would do the same *in vivo*. This has subsequently been proved a misconception. Chloral hydrate occurs as colorless translucent crystals that volatilize with an aromatic, penetrating odor on exposure to air. It has a bitter, caustic taste. One gram of the crystals dissolves in 0.25 mL of water. It may be administered orally, or solutions may be injected IV or intraperitoneally. It irritates the gastric mucosa and may cause vomiting if not diluted in water, but is readily absorbed from the gastrointestinal tract. A small amount of chloral hydrate is excreted unchanged in the urine. The greater portion is reduced to trichloroethyl alcohol, a less potent hypnotic, and this in turn is conjugated with glucuronic acid to form urochloralic (trichloroethylglucuronic) acid, which has no hypnotic property. The latter is excreted in the urine. In animals with liver damage, chloral hydrate may be found in larger quantities and urochloralic acid in smaller quantities in the urine.

Chloral hydrate depresses the cerebrum, with loss of reflex excitability. In subanesthetic doses, motor and sensory nerves are not affected. Chloral hydrate is a good hypnotic but a poor anesthetic; the amount needed to produce anesthesia approaches the minimal lethal dose, and it produces deep sleep that lasts for several hours. It has weak analgesic action. In hypnotic doses, the medullary centers are not affected. Anesthetic doses of chloral hydrate depress the vasomotor center severely, causing a fall in blood pressure. Hypnotic doses depress respiration, and anesthetic doses markedly depress the respiratory center. Death from chloral hydrate administration is caused by progressive depression of the respiratory center. The margin of safety is such that it is not a satisfactory surgical anesthetic.

Chloral hydrate is not used for small animal anesthesia and has lost most of its popularity as a general anesthetic in large animals. Its continued use in large animals depends on the simplicity of administration and on the duration of effect of the induction dose—an interval adequate for many routine procedures. It is relatively inexpensive and may be combined with barbiturates. It is an irritant when inadvertently injected outside the vein. Use of a vascular catheter obviates this hazard. The concentration of the chloral hydrate solution should not be too high: 7% to 12% wt/vol aqueous solutions are generally used.

Doses reported for intravenous chloral hydrate vary extensively, probably owing to the rate of administration and to varying interpretations of the depth of resulting anesthesia. The recommended intravenous dose for chloral hydrate in horses varies from 2 to 3 g/45 kg as a sedative and up to 10 g/45 kg when used alone for general anesthesia. When the drug is used to enhance xylazine or xylazine-butorphanol sedation, a dose of 0.6 to 1.2 g/45 kg is usually effective. A dose of 1.8 g/45 kg may be necessary. This mixture of drugs can be used to provide effective standing restraint during low epidural analgesia achieved with a local anesthetic in horses undergoing surgical correction of a rectovaginal fistula.

Chloral hydrate solution was once commonly administered at 15 to 30 g/min and was given until the horse was about to fall, at which time the intravenous tubing was disconnected and the ani-

mal restrained until recumbent. If necessary, additional solution was administered slowly until the desired degree of sedation or anesthesia was achieved. Because of conversion to trichloroethanol and slow passage across the blood-brain barrier, anesthetic depression increases for several minutes after initial induction. Therefore, additional doses should not be administered immediately. The chief disadvantage with chloral hydrate is that the dose required to induce general anesthesia prolongs recovery. For this reason, in modern practice, chloral hydrate is primarily used to induce a degree of narcosis or sedation, and analgesia is produced by means of local or regional anesthesia. Premedication with tranquilizers reduces the amount of chloral hydrate required, facilitates induction, and minimizes struggling during recovery.⁷¹

The time required for horses to stand after cessation of administration of anesthetic doses varies from 1 to 4 h and is similar in duration to that observed after chloral hydrate and magnesium sulfate administration. If anesthesia is maintained for a long period, recovery may also be prolonged. The nature of the recovery period can vary; if left undisturbed, horses often pass quietly into a hypnotic state, remaining thus until they are ready to stand. Excitement and struggling during recovery are not uncommon and can be minimized by use of tranquilizers.

Chloral hydrate is also occasionally used to induce narcosis or anesthesia in cattle and swine. In the former, it has been largely replaced by xylazine. The chloral hydrate dose required is similar to that for horses. In cattle, premedication with atropine sulfate and early intubation are indicated. Chloral hydrate may also be administered to horses and cattle by stomach tube to induce varying degrees of sedation or narcosis (3 to 6 g/45 kg of body weight).

Chloral hydrate has been combined with magnesium sulfate or with magnesium sulfate and pentobarbital sodium for anesthesia in horses and cattle (Fig. 11.11). Investigators claimed that these drug combinations produced a more rapid and excitement-free induction, an increased anesthetic depth, a smoother emergence, a wider margin of safety, and less irritation than does anesthesia achieved with chloral hydrate alone. Nevertheless, with the advent of rapid-onset, short-acting, and safer drugs, there seems to be little merit in the use of chloral hydrate alone or in combination with other drugs to induce and maintain anesthesia in any species.

Chloralose

This is prepared by heating anhydrous glucose and trichloroacetaldehyde (anhydrous chloral) in a water bath. Both α -chloralose and β -chloralose are formed, with the α form being active. Chloralose has been advocated for use in cardiovascular studies because it produces minimal depression and maintains more active reflexes than other anesthetics.⁷²

Chloralose is usually prepared as a 1.0% aqueous solution. Heat is necessary to dissolve the drug, but solutions should not be boiled. The intravenous anesthetic dose of α -chloralose is approximately 110 mg/kg in dogs and 80 mg/kg in adult cats.⁷³ α -Chloralose appears to depress neuronal function of the cortex and routes of afferent input less than pentobarbital. Many investigators still consider chloralose a valuable drug for maintenance of unconsciousness for long, nonsurvival, surgical experiments.⁷⁴

Fig. 11.11. Chloral hydrate and magnesium sulfate anesthesia (2:1) in horses: dose of chloral hydrate used and degree of anesthesia obtained in clinical cases.

Urethan

This is prepared by heating urea with alcohol under pressure or by warming urea nitrate with alcohol and sodium nitrite. The drug is marketed in the crystalline state. One gram dissolves in 0.5 mL of water, the aqueous solution being neutral. It is most often used as an anesthetic in laboratory animals and fish. The lethal intravenous dose for rabbits is 2.0 g/kg. The dose for dogs and cats is 0.6 to 2.0 g/kg. Up to 0.5 g/kg may be used as a hypnotic dose.

Urethan is mutagenic, carcinostatic, and carcinogenic.⁷⁵ Mice given urethan develop an exceptionally high incidence of lung tumors, regardless of the route of administration. Tumors also develop in treated rats and rabbits. Concern over the health of individuals in prolonged contact with urethan or its solutions is justified.⁷⁶ For this reason, urethan is no longer commonly used in any species.

Magnesium Sulfate

A saturated solution of magnesium sulfate has been used for euthanasia. However, it should be administered only after animals have been rendered unconscious with a barbiturate or another rapid-acting anesthetic. In small animals, anesthesia has been achieved with dilute solutions of magnesium sulfate; however, the CNS is globally depressed and respiratory arrest often occurs at anesthetic doses. Animals will become excited just prior to collapse. Respiratory arrest likely is caused by complete neuromuscular block and paralysis of the muscles of respiration rather than being a consequence of CNS depression. Therefore, one cannot be assured that magnesium sulfate administered alone is

a humane method for achieving anesthesia or euthanasia. Magnesium sulfate is better thought of as a muscle relaxant and CNS depressant than as a stand-alone anesthetic and is not recommended as such.

Metomidate

Metomidate hydrochloride is a hypnotic with muscle relaxant properties. Its hypnotic effect is exerted on mammals, birds, reptiles, and fish. Given alone, it induces sleep without analgesia. General anesthesia can be produced by combining it with neuroleptics or analgesics. It is available in powdered form, which dissolves readily in water to make 1% or 5% solutions. These solutions have a pH of 2.9 and 2.4, respectively. Combined with the butyrophenone tranquilizer azaperone, metomidate produces anesthesia in swine for approximately 2 h. Respiration slows and deepens. With rapid intravenous injection, apnea may occur. The cardiovascular system remains stable. It is often used as a sedative-anesthetic for fish.

Etomidate

This is an imidazole derivative that was synthesized in 1965 and first used for induction of anesthesia in people in 1975. It is a congener of metomidate and contains 2 mg/mL of the drug in 35% propylene glycol. Etomidate appears to work in a fashion similar to that of propofol and the barbiturates in that it enhances the action of the inhibitory neurotransmitter GABA.^{77,78} Single injections produce relatively brief hypnosis. In dogs, doses of 1.5 and 3.0 mg/kg last 8 ± 5 and 21 ± 9 min, respectively.⁷⁹ The duration of hypnosis is dose related. Etomidate is rapidly hy-

dolyzed in the liver and excreted in the urine. The pharmacokinetics of a 3-mg/kg intravenous dose of etomidate in cats are best described as a three-compartment open model similar to those determined in people and rats. Induction and recovery are rapid, with a brief period of myoclonus early in the recovery period.⁸⁰

Etomidate in powder and injectable forms has been used as an anesthetic for exotic species of animals. It was introduced in the United States as an induction agent for poor-risk human patients because it does not depress the cardiovascular and respiratory systems or release histamine. When used alone in dogs, it produces no change in heart rate, blood pressure, or myocardial performance.⁷⁹ Neonates born to mothers anesthetized with etomidate have minimal respiratory depression. Etomidate does not trigger malignant hyperthermia in susceptible swine.⁸¹ Etomidate qualifies as a good induction drug for neurosurgical procedures. It decreases cerebral metabolic rate of oxygen consumption (CMRO₂) and has anticonvulsant properties. It may have brain-protective properties following episodes of global ischemia associated with cardiac arrest.

Etomidate inhibits adrenal steroidogenesis in dogs, suppressing the usual increase in plasma cortisol observed during surgery. A single induction dose of etomidate may depress adrenal function for up to 3 h. However, the lack of a stress response to surgery does not have deleterious effects, and it has been argued that attenuation of metabolic and endocrine responses to surgery actually reduces morbidity and may make this unique action of etomidate beneficial to overall patient outcome. Attention has been given to the development of Addisonian crisis produced by etomidate-induced blockade of corticosteroid production during prolonged infusion to maintain sedation in intensive care patients. Consequently, long-term infusion is not recommended.^{82,83} Etomidate (2 mg/kg) can cause acute hemolysis. The mechanism of hemolysis appears to be propylene glycol, which causes a rapid osmolality increase that causes red cell rupture.⁸⁴

Etomidate is compatible with other common preanesthetic agents. Venous pain is common on injection in humans, and myoclonia may occur if premedication is not administered. Nausea and vomiting are troublesome, especially after the use of multiple doses, and can occur at recovery, as well as induction. For the most part, these side effects can be prevented by adequate preanesthetic sedation. In summary, etomidate may be one of the better induction drugs in traumatized patients and those with severe myocardial disease, cardiovascular instability, cirrhosis, or intracranial lesions, or in patients requiring cesarean section surgery.⁸¹

Propofol

Propofol (2,6-diisopropylphenol) is unrelated to barbiturates, euganols, or steroid anesthetics. It is only slightly soluble in water and is marketed as an aqueous emulsion containing 10 mg of propofol, 100 mg of soybean oil, 22.5 mg of glycerol, and 12 mg of egg lecithin/mL. Sodium hydroxide is added to adjust the pH. It is available in sterile glass ampules and contains no preservatives. Propofol emulsion can support microbial growth and endotoxin production.⁸⁵ Because of the potential for iatrogenic sepsis, unused propofol remaining in an open ampule should be

discarded and not be kept overnight for use the next day. Some formulations contain bacterial growth inhibitors to slow the growth rate of contaminants after a vial is opened, but these additives will not completely inhibit bacterial growth, so any unused propofol should still be discarded 6 h after a vial or ampule is opened. The growth inhibitors used are 0.005% disodium edentate or 0.025% sodium metabisulfite.

The pharmacokinetics of propofol in dogs fit a two-compartment open model. Rapid onset of action is caused by rapid uptake into the CNS. The short action and rapid smooth emergence result from rapid redistribution from the brain to other tissues and efficient elimination from plasma by metabolism.⁸⁶ Propofol has a large volume of distribution, as would be expected from its lipophilic nature. It is metabolized primarily by conjugation, but propofol's rapid disappearance from plasma is greater than hepatic blood flow, suggesting extra hepatic sites of metabolism.⁸⁷ The pharmacokinetics of propofol have not been reported in cats, but its anesthetic action is similar to that in dogs.⁸⁸ In general, after a single bolus injection, propofol induces a rapid, smooth induction followed by a short period of unconsciousness.⁸⁹ In people, recovery is rapid and free of emergence excitement after constant infusion or repeated bolus administration. In dogs, especially greyhounds, recoveries may be prolonged after continuous infusion of propofol exceeding 30 min.⁹⁰

Propofol is usually injected as a single bolus for induction of general anesthesia in dogs and cats to enable intubation and initiation of inhalation anesthesia.⁸⁹ It should be remembered that propofol is a sedative-hypnotic and has only minimal analgesic action at a subanesthetic dose. As with other hypnotics, even when an animal is rendered unconscious with propofol, it will respond to painful stimuli unless analgesic drugs such as the opioids or α_2 -agonists are administered concurrently. If administration is preceded by a preanesthetic such as morphine or medetomidine, the induction dose of propofol can be decreased substantially. The dose for induction of anesthesia in non-premedicated dogs ranges from 6 to 8 mg/kg IV, whereas the dose in sedated animals may be as low as 2 to 4 mg/kg IV.^{85,86} Following a single dose of 6 mg/kg IV, recovery in dogs is complete in approximately 20 min. A similar dose given to cats provides about 30 min of anesthesia to complete recovery. The incidence of postanesthetic side effects, such as vomiting, sneezing, or pawing, is about 15%, but can be decreased with acepromazine or α_2 -agonist premedication. When a patient is premedicated with 0.02 to 0.04 mg/kg of acepromazine, the induction dose of propofol is decreased by approximately 30% to 40%. Propofol can be used for maintenance of anesthesia in dogs either by intermittent bolus or continual infusion.^{91,92} The rate of administration depends on the adjunctive drugs administered and the degree of surgical stimulation.⁹² The continuous infusion rate ranges from 0.15 to 0.4 mg · kg⁻¹ · min⁻¹. When using an intermittent-bolus technique, doses of 0.5 to 2 mg/kg are administered as needed. If the bolus dose used is kept constant, the interval between bolus administrations will stabilize and remain constant after 1 to 2 boluses are administered.

Propofol induces depression by enhancing the effects of the inhibitory neurotransmitter GABA and decreasing the brain's

metabolic activity.⁹³ Propofol decreases intracranial and cerebral perfusion pressures. It transiently depresses arterial pressure and myocardial contractility similar to the ultra-short-acting thiobarbiturates. Hypotension is primarily the result of arterial and venous vasodilation.⁹⁴ Propofol enhances the arrhythmogenic effects of epinephrine, but is not inherently arrhythmogenic.⁹⁵

Propofol is a phenolic compound and, as such, can induce oxidative injury to feline red blood cells when administered repeatedly over several days. This toxicity is likely the result of the cat's reduced ability to conjugate phenol. Heinz bodies form, and clinical signs of anorexia, diarrhea, and malaise can result.⁹⁶ Brief apnea may occur after induction with propofol. Animals breathing spontaneously may experience hypercapnia for a short period after rapid bolus injection.⁹⁷ Propofol is primarily metabolized in the liver by conjugation pathways to form inactive metabolites, which are then excreted in the urine and, to a much lesser extent, in bile.⁹⁸ Evidence suggests a variability in the capacity of the hepatic cytochrome P-450 enzyme system involved in propofol metabolism among dog breeds.⁹⁹ This may explain some of the breed variability in recovery times seen after propofol administration (e.g., the slower recoveries seen in greyhounds). Propofol has been used for cesarean section surgery with generally good results.^{89,100} Because puppies have good conjugation enzyme activity, there is minimal fetal depression among neonates delivered from mothers anesthetized with propofol.

Complaints of pain by people injected with propofol IV are common. Pain likely occurs in small animals, but the prevalence appears to be much less. Pain can be minimized by premedication with an opioid or α_2 -agonist and/or injection into larger vessels. Propofol, unlike barbiturates, does not damage tissue when injected perivascularly or intra-arterially. When combined with an opioid, acepromazine, or an α_2 -agonist, propofol provides dependable short anesthesia for procedures such as castrations, ear flushes, exploration for foxtails, ultrasound examinations, biopsies, and suturing of small lacerations. Additionally, the advantage of rapid smooth recovery is beneficial in patients with chronic respiratory disease or those undergoing bronchoscopy or transtracheal aspiration procedures. Light propofol anesthesia has been advocated for patients undergoing upper-airway examination.¹⁰¹

Propofol is a satisfactory drug for immobilization of neonatal foals when given in combination with 0.5 mg/kg of xylazine IV. Immobilization is induced with 2 mg/kg propofol IV and maintained with $0.33 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ IV. Cardiovascular changes are characterized by decreased pressure and cardiac output, and a decrease in respiration rate.

Propofol anesthesia has been used in full-sized horses, as well. It is usually employed in conjunction with an α_2 -agonist such as detomidine or xylazine and can be used to maintain, as well as induce, general anesthesia. The induction dose of propofol is 2 to 4 mg/kg administered IV to premedicated horses.^{102–104} Limited data on maintenance of propofol anesthesia suggest an infusion rate of approximately 0.2 mg/kg/min is acceptable.¹⁰⁴ The quality of the induction and recovery seen with the use of propofol in horses is acceptable.^{102–105}

Alternative Methods of Anesthesia and Analgesia

Hypothermia

As the body temperature of warm-blooded animals falls, their metabolism is reduced, and therefore the need for oxygen is diminished. Oxygen uptake in dogs is reduced by approximately 50% at 30°C and 65% at 25°C.¹⁰⁶ The metabolic rate of isolated slices of rat heart is reduced 90% by lowering the temperature to 10°C.¹⁰⁷ The potassium-arrested heart at 37°C used four times as much glycogen and produced three times as much lactic acid as the heart at 17°C.¹⁰⁸ Thus, the heart, brain, liver, or other vital organs can survive at a low temperature for a considerably increased period when deprived of all or a portion of their blood supply. Hypothermia may be artificially produced in the entire body or in only a portion, such as the heart or head. It has found its greatest usefulness in surgery of the heart and CNS.¹⁰⁹

The colder an animal becomes, the less oxygen is required by a given organ. It has been shown, however, that the reduction of oxygen consumption varies for different organs. For example, the work done by the heart at 26° to 27°C is a little less than that at normal temperature, and while the general oxygen uptake by the body at this temperature is reduced to 40% of normal, that of the heart is still 50%. In monkeys, little change in cerebral oxygen uptake occurs until a temperature of 31°C is reached.¹¹⁰ At this point, it falls sharply, and through the next 4°C there is a drop of about 25%. Below 27°C, oxygen consumption continues to fall, but at a much slower rate. The relationship of cerebral oxygen consumption to temperature is sigmoid rather than linear (Fig. 11.12).

Several species of warm-blooded animals have been subjected to drastic hypothermia. Small laboratory animals can be cooled to 0°C, and even lower, and still recover. Between 80% and 100% of rats recovered after being cooled to temperatures just above the freezing point with cardiac and respiratory arrest for 1 h.¹¹¹ Golden hamsters have been kept on ice with circulatory arrest for up to 7 h. These animals even survived supercooling to -5° or -6°C .¹¹² When the circulation is maintained with a pump-oxygenator, dogs have survived cooling to 1.5°C.¹¹³

To induce the hypothermic state as quickly as possible, shivering must be controlled, because it is an important mechanism in protection against cold. Shivering is induced by an increased temperature gradient between cold receptors in the skin and centers in the hypothalamus.¹¹⁴ Even without visible shivering, there is general hypertonicity of the skeletal muscles, which results in increased metabolic, heart, and respiratory rates. Shivering can be prevented by deep anesthesia or by light anesthesia with curarization or tranquilization with a phenothiazine. The latter drugs exert their effect through a peripheral action on muscle fibers and on the hypothalamic temperature control center.

Moderate hypothermia produces a rectilinear decrease in anesthetic requirements (minimum alveolar concentration [MAC]) for cyclopropane, diethyl ether, fluroxene, halothane, and methoxyflurane (Fig. 11.13).¹¹⁵ Moderate hypothermia also reduces the concentration of anesthetic required to produce apnea. There is little difference between halothane, pentobarbital, and

Fig. 11.12. Relation of oxygen uptake by the brain to temperature. From Bering et al.¹¹⁰

chloralose in their effects on whole-body oxygen consumption during surface cooling in dogs (Fig. 11.14).¹¹⁶

Three methods of whole-body cooling have been used: surface, body cavity, and extracorporeal. *Surface cooling* is usually accomplished by directly immersing the unprotected body in ice water or by placing the body on a mattress through which ice water is circulated. Hyperventilation is maintained throughout the procedure to keep the blood pH on the alkaline side of normal. This has been shown to reduce cardiac arrhythmias and fibrillation. Below 28°C (82.4°F), no anesthetic is needed, and the patient is maintained on artificial ventilation alone. Active cooling is stopped when approximately two-thirds of the desired temperature fall has been accomplished. Otherwise, the temperature continues to drop once the desired degree of hypothermia has been reached.

Body cavity cooling is accomplished by pouring cold saline solution into the open thoracic cavity.¹¹⁷ This method has the disadvantage of being slow and requiring large volumes of saline solution.

Extracorporeal cooling can be accomplished by running blood from a cannulated artery through a heat exchanger using cold tap water as the cooling medium. A pump is required to force the blood through the system. Thrombosis is prevented by administration of heparin. Extracorporeal cooling has been used to lower the brain temperature below that of the general body temperature, but carries with it the dangers of hemolysis, interference with the blood coagulation mechanism, and thrombosis. The most obvious advantage is that it provides the best control over body temperature, and rewarming can be performed quickly and efficiently by running warm water through the heat exchanger. Warming also may be accomplished by covering the patient with electric blankets or by using warm-water baths. Microwave rewarming has been used experimentally.¹¹⁶

Since hypothermia is a form of general anesthesia, it carries the risks of profound depression of the CNS and vital organs. In addition, it has its own hazards for the circulatory system, skin and internal organs, and metabolism. Blood pressure falls during hypothermia, owing to decreased cardiac output, whereas periph-

Fig. 11.13. The percentage decline between 37° and 27°C of the minimum alveolar concentration (MAC) required for anesthesia. Cyclopropane, the least oil-soluble agent, declines least, and halothane and methoxyflurane, the most oil-soluble agents, decline most. From Regan and Eger.¹¹⁵

Fig. 11.14. Whole-body oxygen consumption compared with esophageal temperature during surface cooling in dogs. The least-squares best-fit lines are shown for three anesthetics: pentobarbital, halothane, and α -chloralose. Each point represents the mean, and each bar 1 SD. From Westenskow et al.¹¹⁶

eral vascular resistance increases. Occasionally, blood pressure may drop severely. The fall in heart rate seen with hypothermia is caused by depression of the sinoatrial node and the bundle of His. These conduction changes are manifested by a prolonging of the PR interval, spreading of the QRS complex, and lengthening of the ST interval. In dogs, a cardiac crisis occurs between 23° and 15°C. This is characterized by cessation of sinus rhythm, intense bradycardia, ventricular extrasystoles, and ventricular fibrillation or standstill. As expected, atropine does not relieve the bradycardia. Ventricular fibrillation has been shown to occur most often when the temperature of the heart muscle is below

28°C and when the heart is manipulated. Fibrillation rapidly depletes cardiac muscle energy stores. It occurs less frequently in young animals than in adults. Hypercapnia with acidemia, hyperkalemia, and myocardial hypoxia also appears to cause fibrillation. The incidence of spontaneous ventricular fibrillation has been shown to vary with the anesthetic used to initiate hypothermia. For example, administration of pentobarbital produces a higher incidence than does use of thiopental or ether.¹¹⁸

Several cardioplegic solutions have been used to stop the heart and to prevent fibrillation. Hypothermia plus cardioplegia is more protective of cardiac tissue than is hypothermia alone.^{119,120} Combined with deep hypothermia, cardioplegia solutions have provided 30 min of cardiac arrest without heart-lung bypass.

During hypothermia, clotting time is prolonged. In addition, the platelet count decreases, hemoconcentration occurs with sludging, and eosinophil and leukocyte counts decrease, accompanied by a fall in the mean corpuscular hemoglobin concentration.

Prolonged periods of hypothermia have detrimental effects on patients.^{121–123} In dogs held at 29°C for 24 h, cardiac output and whole-body oxygen consumption decreased progressively to 7% and 28% of control, respectively. Cerebral blood flow and cerebral oxygen consumption responded similarly. On rewarming, cardiovascular collapse with severe tissue hypoxia and metabolic acidosis occurs. Cerebral blood flow becomes grossly inadequate, with depletion of brain energy stores. Hypothermia severely damages the liver, kidneys, and adrenal glands in dogs when temperatures of around 25°C are maintained for several hours.¹²⁴ Short periods (1 to 2 h) of cooling, however, do not appear to cause demonstrable damage.

Hypothermia has been used for surgery of the heart and great vessels, brain, and spinal cord, and in some other surgical procedures. It also has been advocated in treatment of shock, stroke, and cerebral and spinal contusion, and in prevention of brain damage following a severe hypoxic episode. The chief factor limiting its use alone in heart surgery is the danger of hypoxic brain damage. For this reason, older patients and those with cardiac defects requiring extensive repair should be managed with heart-lung bypass. Hypothermia has also been used in dogs to remove heartworms and to repair cardiac anomalies, but its use is not widespread. This is probably because many veterinarians are unaware of the simplicity of the technique and do not appreciate its potential.

Induction

To produce hypothermia in dogs, a phenothiazine tranquilizer may be given IV as a preanesthetic agent. A thiobarbiturate is injected for general anesthesia, following which an endotracheal catheter is inserted and an inhalant anesthetic is used for maintenance. A slow intravenous drip of Ringer's lactate solution or 5% dextrose is started, and a muscle relaxant is given in the drip tubing to abolish respirations. Controlled ventilation is then initiated. Unless a cooling mattress is available, the animal is positioned in a sink, bathtub, or other container, with its head above water. Electronic thermometer probes are placed in the esophagus at heart level and in the rectum, and electrodes of an electrocardiograph are attached to the feet. From this point, constant

monitoring of the electrocardiogram on an oscilloscope is desirable, because cardiac fibrillation may occur at any time during the cooling period and requires immediate corrective measures.

Ice water is used for rapid cooling. It should be constantly agitated by hand or with a pump. The dog should be removed from the bath before the desired body temperature is reached, because temperature will continue to decline even after the dog's removal from the water.

After removal, the dog should be dried with towels and placed on an inactive heating pad during the operative period. Rewarming can then be started as soon as closure of the surgical wound is begun. As anesthesia is discontinued and shivering commences, the body temperature quickly begins to rise. If the operation is short, rewarming in a water bath may be necessary, along with administration of atropine and neostigmine to reverse the effects of the muscle relaxant.

Electronarcosis and Immobilization

Electric stimulation of the brain can activate either opioid or nonopioid pain-control pathways or both.¹²⁵ Passage of electricity through the brain to produce anesthesia has been investigated for many years. In the veterinary field, clinical trials were conducted by Sir Frederic Hobday in England as early as 1932. Despite extensive research, much remains to be learned about this technique. Early work documented the occurrence of respiratory depression, hyperthermia, convulsions, and fatalities. Electronarcosis may be of greatest use in situations where prolonged anesthesia is required for experimental purposes.

Most instruments deliver the current through needle electrodes applied to the head. Direct, pulsating direct, and alternating current have been used to produce electronarcosis. Alternating current of 700 cycles, 35 to 50 mA, and approximately 40 V has been employed.¹²⁶ Others have used combined direct and alternating current, modified to produce a rectangular wave for 1.0 to 1.4 ms, with a frequency of 100 waves/s.¹²⁷ Continuous electrode contact is important to maintain electronarcosis anesthesia. Individual variation among animals requires that the current be adjusted for each according to the response observed.

Electronarcosis is characterized by convulsions on induction unless a muscle relaxant is first administered. An exception to this is the method employing direct current for induction and then both direct and alternating current.¹²⁷ Profuse salivation develops on induction and continues throughout. This can be counteracted by using atropine. Endotracheal intubation should always be performed. Hyperthermia, probably caused by disturbance of the thermoregulatory center in the hypothalamus, is commonly seen. The electroencephalogram immediately following anesthesia is decreased in amplitude and increased in frequency, but returns to normal within 30 min. Brain lesions have been found following electronarcosis,¹²⁸ and skin burns from the electrodes have been reported.¹²⁹

Electronarcosis appears to produce severe stress, as evidenced by an increased plasma level of hydroxycorticoids, epinephrine, and norepinephrine (Fig. 11.15). The blood pressure rises sharply and then gradually falls to near normal levels (Fig. 11.16). The clotting time, sedimentation rate, hemoglobin, hematocrit, and

Fig. 11.15. Epinephrine secretion in response to a standard laparotomy: a comparison of different agents for anesthesia. The points on each curve represent the average values from seven dogs. Electronarcosis and laparotomy produced the greatest rise in epinephrine secretion, with response to procaine and to ether next in order, respectively. Nembutal (pentobarbital) depressed the epinephrine level of plasma despite the associated surgery. From Hardy et al.¹⁴²

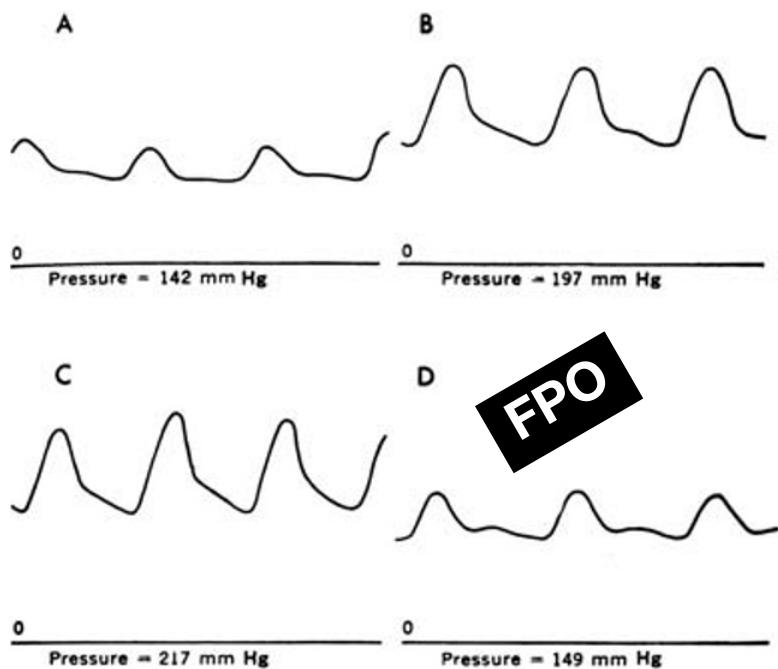

Fig. 11.16. Mean femoral artery blood pressure in a dog under electronarcosis: preinduction (A), induction (B), beginning surgical anesthesia (C), and 15 min after onset of surgical anesthesia (D). Courtesy of Dr. R.A. Herin, Colorado State University, Fort Collins, Colorado.

total and differential white blood cell counts do not differ from preinduction values.¹³⁰ There is little effect on arterial oxygen partial pressure; carbon dioxide content and pH decrease, whereas blood glucose rises. It was originally thought that electronarcosis, which produces an uninhibited response of the adrenal medullary and cortical systems, may be more desirable than drug-induced anesthesia, which usually depresses this response.¹³¹ This is in contrast to the modern concept of anesthesia, which endeavors to minimize sympathetic nervous system response associated with the production of general anesthesia. Consequently, there has been a loss of interest in electronarcosis and immobilization as humane alternatives for producing general anesthesia.

In addition to questionable humaneness, it is difficult to assess the depth of unconsciousness achieved by electronarcosis. Muscle relaxation varies from adequate to poor. Pain induced by surgery may cause body movements in animals that appear unconscious. The photomotor reflex is probably the best means of determining the depth of anesthesia if a large dose of atropine has not been used. Early investigators indicated that analgesia persists for several minutes after removal of the current and the animal often appears hypnotized. A slight stimulus may then cause complete arousal, and the patient resumes all normal activities.

In the mid-1980s, electroimmobilization was advocated and

used by sheep and cattle producers and some veterinarians for restraint and processing of food animals. This technique was recommended for minor surgery, although strong evidence exists that electroimmobilization is aversive and does not eliminate pain. Amnesia and unconsciousness are not achieved with the manufacturer's recommended electrode placement and electric current application, and this technique may induce pain and dysphoria. Consequently, electroimmobilization is no longer widely used, nor can it be recommended as a humane method of animal restraint.¹³²

Acupuncture

This technique has been advocated for providing analgesia during the operative and postoperative periods, to treat chronic pain, and even to treat selected disease states. Charts for people and farm animals (horses, cattle, and pigs) can be commonly found in the Oriental literature. Acupuncture points can be stimulated in many different ways, including needling, injection of saline, electric stimulation, and metal implantation. It has been shown that electroacupuncture minimally decreases halothane MAC in dogs. Although the mechanism of action of acupuncture has been suggested to be the activation of the endogenous opioid neurotransmitter system, the administration of opioid antagonists does not reverse acupuncture-induced decreases in halothane MAC. Some investigators have indicated that acupuncture induces surgical analgesia. However, there appear to be three reasons why acupuncture should not be solely relied upon for surgical anesthesia: lack of restraint, inadequate analgesia, and lack of adequate information on acupuncture points to be used for specific surgical sites. These factors—along with the disadvantages of unfamiliarity, time-consuming methods of application, and inconsistent effects—have made acupuncture an unreliable and nonviable method of producing general anesthesia. Acupuncture may be best used for treatment of chronic pain in animals. Treatment of laminitis and chronic back pain in horses has reportedly been effective.¹³³ See Chapter 24 for further discussion.

Physiological Hypnosis

Certain species of animals are highly susceptible to hypnosis (immobility reflex). These include arthropods, amphibians, reptiles, birds, guinea pigs, and rabbits. This modality is seldom used in animal anesthesia because of a lack of analgesia associated with the state of physiological hypnosis. Hypnosis should be viewed as a legitimate method of producing immobilization, not anesthesia.

Introduction

The term *dissociative anesthesia* is used to describe an anesthetic state induced by drugs that interrupt ascending transmission from the parts of the brain responsible for unconscious and conscious functions, rather than by generalized depression of all brain centers as seen with most other general anesthetics.¹ Dissociative anesthesia is characterized by a cataleptoid state in which the eyes remain open with a slow nystagmic gaze.² Varying degrees of hypertonus and purposeful or reflexive skeletal muscle movements often occur unrelated to surgical stimulation. Although somatic analgesia may be intense, it is relatively brief.

Phencyclidine, ketamine, and tiletamine are dissociative anesthetics that have been used clinically for immobilization and anesthesia.^{3,4} Phencyclidine was the first dissociative used in veterinary anesthesia, but it is no longer available for clinical use. Tiletamine is available for use only in combination with the benzodiazepine zolazepam. In a 1:1 ratio, this drug combination is marketed as Telazol in the United States and as Zoletil in Europe. In most respects, the pharmacodynamics of tiletamine are similar to those of ketamine (the most commonly used dissociative anesthetic), but tiletamine's potency and duration of action are intermediate between those of phencyclidine, the most potent, and ketamine, the least potent.

Pharmacology

Effects on the Nervous System

Dissociative anesthetics produce dose-related unconsciousness and analgesia. Because of their low molecular weight, a pK_a near

physiological pH, and high lipid solubility, dissociative anesthetics have a rapid onset of action. Classically, the mechanism of action has been described as selective depression of neuronal function of the neocorticothalamic axis and the central nucleus of the thalamus with concurrent stimulation of selected parts of the limbic system, including the hippocampus.^{5,6} More recently, antagonism of the *N*-methyl-D-aspartate (NMDA) receptor has been proposed as the most likely molecular mechanism responsible for most of the anesthetic, analgesic, psychotomimetic, and neuroprotective effects of the drug.⁷ Alternatively, effects could be mediated in part by one or more of the following: (a) action on voltage-dependent sodium, potassium, and calcium channels; (b) depression of acetylcholine receptors; (c) enhancement and prolongation of γ -aminobutyric acid (GABA) receptors that link to chloride channels (GABA_A receptors); and (d) depression of nociceptive cells in the medial medullary reticular formation and activity of cells in laminae I and V of the dorsal horn.⁸⁻¹⁰

Dissociative anesthetic administration to people with a history of seizures does not promote seizure activity despite the presence of thalamic and limbic epileptiform electroencephalogram patterns.^{11,12} In fact, low doses of ketamine may have anticonvulsant properties through antagonism of NMDA receptors.¹³⁻¹⁶ Nevertheless, ketamine-associated seizures have been reported in some animals, and use of ketamine, or any other dissociative anesthetic, in animals with a history of epilepsy or other seizure disorders should be avoided, if possible.¹⁷⁻²⁰

Analgesia produced by dissociative anesthetics occurs at sub-anesthetic doses. Elevated pain thresholds correlate with plasma ketamine concentrations of 0.1 $\mu\text{g/mL}$ or greater.²¹ The degree of analgesia appears to be greater for somatic pain than for visceral pain.²² In cats, visceral analgesia induced by ketamine (2, 4, and 8 mg/kg intravenously [IV]) is similar to that produced by butorphanol (0.1 mg/kg IV). With increasing doses of ketamine, or when ketamine and butorphanol are administered simultaneously, visceral analgesia is not increased.²³ At a high dose of ketamine (8 mg/kg), cats appear anesthetized but still respond to colonic nociceptor stimulation, suggesting limited visceral analgesia in cats and probably other species. Dissociative anesthetics appear to be more useful for anesthesia and postoperative analgesia related to integumentary and superficial musculoskeletal surgery.^{23,24} Furthermore, NMDA receptors appear to be involved in hyperalgesic responses after peripheral tissue injury and inflammation, suggesting that ketamine (and possibly other dissociatives) would be effective at reducing hyperalgesia following tissue trauma.²⁵⁻²⁹

Local infiltration of ketamine may produce a brief period of local anesthetic effect.^{30,31} When administered simultaneously with bupivacaine, ketamine doubles the duration of analgesic and local anesthetic effects of bupivacaine.³² This peripheral analgesic effect of ketamine may be attributed to one or all of the following mechanisms: (a) blockade of sodium and potassium currents in peripheral nerves, (b) blockade of NMDA, α -amino-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), and kainite receptors on unmyelinated axons, and (c) blockade of glutamate effects on C-fiber free-nerve endings.^{33–37}

Similar to systemic administration, epidural ketamine appears to produce profound somatic but poor visceral analgesia. Epidural administration produces a dose-dependent analgesic action.^{38,39} In rats, a dose of 6 mg/kg induces motor blockade lasting 5 to 15 min, whereas sensory blockade alone occurs with lower doses (4 mg/kg).⁴⁰ In horses, the caudal epidural injection of lower doses of ketamine (0.5, 1.0, or 2.0 mg/kg) prevents nociceptive responses initiated by surgical incision and is associated with dose-dependent perineal analgesia.^{41,42} In halothane-anesthetized ponies, epidural ketamine reduces the minimum alveolar concentration (MAC) of halothane between 14% (at a dose of 0.8 mg/kg) and 12% (at a dose of 1.2 mg/kg), which is similar to the reduction in MAC achieved with epidural morphine administration (14%).⁴³ When combined with epidural xylazine (0.5 mg/kg), ketamine (1 mg/kg) induces perineal analgesia lasting 20 min or longer. In some horses, analgesia is extended to the thigh and flank regions.⁴⁴ In another study, the subarachnoid administration of ketamine (1 to 2 mg/kg) at the L1-L2 intervertebral space of dogs produced analgesia of the hind limbs.⁴⁵

Tissue trauma produces continuous nociceptive stimulation of C fibers that activates NMDA receptors in the central nervous system (CNS). This activation of NMDA receptors decreases the threshold to glutamate, making them more responsive to stimuli. As a result, *windup* may develop, which is clinically manifested as an exaggerated response to subthreshold noxious stimuli following a primary injury and amplification of postoperative pain.^{46,47} These results have led to the concept of preemptively treating central sensitization as an important part of pain management. Consequently, the administration of ketamine at sub-anesthetic doses as a continuous-rate infusion in combination with other analgesics (e.g., opioids) has gained popularity in preventing or minimizing pain following surgery in both people and animals.^{48–53}

Dissociative anesthetics induce significant increases in cerebral blood flow (CBF), intracranial pressure (ICP), and cerebrospinal fluid pressure as a result of cerebral vasodilation and elevated systemic blood pressure.^{54–60} The mechanism of ketamine-induced elevated ICP remains controversial. Ketamine increases CBF and ICP in awake goats when arterial carbon dioxide partial pressure (PaCO₂) is allowed to rise but has no effect on CBF and ICP when PaCO₂ is maintained at a preketamine level, suggesting an indirect mechanism.^{61–63} In piglets with pre-existing intracranial hypertension, ketamine induced further increases in ICP, paralleling a rise in PaCO₂. When ventilation was controlled, no increase in ICP was observed in piglets with normal or elevated ICP.⁶² These studies suggest that initiating con-

trolled ventilation is prudent when dissociative anesthetics must be administered to patients with intracranial disease. Increased skeletal, thoracic, and abdominal muscle tone can also impede venous return from the head, increasing intracranial blood volume and pressure.^{62,63}

Dissociative anesthetics may not be contraindicated in all patients at risk for intracranial hypertension, particularly when administered in the presence of another anesthetic and/or when controlled ventilation is instituted. It has been hypothesized that when ketamine is administered in the presence of another anesthetic, the second anesthetic may suppress ketamine's excitatory effect on the CNS. Nevertheless, administration of ketamine should be avoided in spontaneously breathing patients with suspected intracranial hypertension or disease until scientific evidence to the contrary emerges.

Abnormal behavior, which may progress to delirium, may occur during emergence from dissociative anesthesia. Depression of the inferior colliculus and medial geniculate nucleus leading to misperception of auditory and visual stimuli may be responsible for this reaction.⁶⁴ Emergence reactions are characterized by ataxia, increased motor activity, hyperreflexia, sensitivity to touch, and sometimes violent recovery.^{16,65,66} These reactions usually disappear within several hours without recurrence. Pre-medication with or concurrent administration of α_2 -adrenergic agonists, acetylpromazine, or a benzodiazepine (e.g., diazepam, midazolam, or zolazepam), decreases the incidence and/or severity of emergence reactions.^{67–72}

Effects on the Cardiovascular System

The cardiovascular effects of dissociative anesthetics are characterized by indirect cardiovascular stimulation. Various effects on target organs include sympathomimetic effects mediated from within the CNS, inhibition of neuronal uptake of catecholamines by sympathetic nerve endings, direct vasodilation of vascular smooth muscle, and an inotropic effect on the myocardium.^{73–76} Heart rate and arterial blood pressure usually increase as a result of increased sympathetic efferent activity.⁷⁷ Plasma concentrations of epinephrine and norepinephrine can increase within 2 min of intravenous administration of ketamine and return to control levels 15 min later.⁷⁸ In dogs and cats anesthetized with ketamine, mean arterial pressure, heart rate, and cardiac output increase while peripheral vascular resistance remains mostly unchanged.^{22,79–84} Myocardial stimulation is associated with increased cardiac work and myocardial oxygen consumption. In healthy animals, increases in myocardial oxygen supply usually result from increased cardiac output and a decrease in coronary vascular resistance such that increases in coronary blood flow parallel the increase in oxygen consumption.^{85,86} However, some studies indicate that ketamine-induced increases in coronary blood flow may be insufficient to meet myocardial oxygen demand, especially if cardiovascular disease is present.^{87,88} The cardiovascular stimulating effects induced by dissociative anesthetics are blunted or prevented by prior administration of a benzodiazepine, droperidol, acetylpromazine, or α_2 -adrenergic agonists, or the concomitant administration of inhalation anesthetics, including nitrous oxide.^{89–93}

The direct effect of ketamine on the myocardium remains incompletely characterized. Positive inotropic effects have been demonstrated in patients whose heart rates were kept constant by atrial pacing and in isolated mammalian papillary muscle.^{76,94–97} However, in denervated hearts, ketamine (and presumably other dissociative anesthetics) induces direct myocardial depression in vivo and in vitro.^{97–102} Cook et al.⁹⁷ suggested that the predominant inotropic mechanism of ketamine is inhibition of catecholamine reuptake at the neuroeffector junction, leading to stimulation of β -adrenoceptors. The importance of an intact and normally functioning nervous system in stimulating cardiovascular function is underscored when ketamine is administered in the presence of other anesthetics. For example, when administered to dogs anesthetized with pentobarbital, ketamine induces a biphasic response in blood pressure, whereas in conscious dogs it induces only a pressor response.^{79,100}

A direct dose-dependent negative inotropic effect of ketamine on failing and nonfailing human myocardium has been demonstrated. The negative inotropic effect of ketamine cannot be attributed primarily to the absence of sympathetic tone but rather to other direct negative inotropic mechanisms. Therefore, ketamine administration for induction of anesthesia may induce an unanticipated decrease in myocardial contractility in patients with end-stage heart disease.¹⁰³

The survival rate of animals in shock is reportedly greater when they are anesthetized with ketamine versus halothane.¹⁰⁴ Ketamine has been shown to suppress activation of endotoxin-induced neuronal nuclear factor κ B, which regulates the production of proinflammatory cytokines, including tumor necrosis factor α in human glioma cells in vitro and intact mouse brain cells in vivo. Therefore, in theory, ketamine may offer some neuroprotective effects during endotoxemia.¹⁰⁵ Furthermore, intravenous administration of ketamine (10 mg/kg/h) prior to injection of endotoxin to rats completely inhibits the hemodynamic effects (profound hypotension), metabolic acidosis, and the release of cytokines associated with endotoxin shock. However, the hemodynamic effect and the release of cytokine are only modestly suppressed when ketamine is administered after exposure to endotoxin. Thus, ketamine may have protective effect in patients with endotoxemia, but only when given preemptively.¹⁰⁶ Critically ill patients occasionally respond to ketamine with an unexpected decrease in blood pressure and cardiac output.⁹⁴ This likely results from depletion of catecholamine stores and an uncovering of ketamine's direct myocardial depressant effects.¹⁰⁷

Effects on the Respiratory System

Dissociative anesthetics, when given alone, differ from most other anesthetics in that they do not depress ventilatory responses to hypoxia.¹⁰⁸ In dogs anesthetized with ketamine, respiratory rate and minute volume decrease initially, but both return to baseline values within 15 min.¹⁰⁹ In cats and sheep, ketamine induces a dose-dependent transient decrease in arterial oxygen partial pressure (PaO_2) in the presence of decreased or increased respiratory rate.^{22,110–114} At higher doses, respiration is characterized by an apneustic, shallow, and irregular pattern.^{3,19,84} Severe res-

piratory depression or arrest with an overdose of dissociative anesthetic has been reported in human patients and cats.^{84,115–117}

Dissociatives often cause increased salivation and respiratory-tract secretions, which can be partially controlled by administration of an antimuscarinic (e.g., atropine). Laryngeal and pharyngeal reflexes usually are partially or fully maintained during dissociative anesthesia. Nevertheless, swallowing reflexes may be somewhat obtunded because most species can be intubated when anesthetized with ketamine. Careful airway management and/or endotracheal intubation should always be performed to prevent aspiration.

Effects on the Hepatic and Renal Systems

Hepatic dysfunction following clinical use of ketamine, and other dissociatives, is not evident in either people or dogs.^{1,118} A significant increase in serum concentrations of liver enzymes has been observed in people anesthetized with a ketamine infusion and dogs given higher intramuscular doses (40 mg/kg daily for 6 weeks).^{1,118} In rats, ketamine induces hepatic microsomal enzymes but to a lesser extent than that seen with phenobarbital.¹¹⁹ The effect of ketamine-associated liver microsomal enzyme induction on drug interactions during anesthesia is largely uncharacterized.

Dissociative anesthetics generally undergo extensive hepatic biotransformation in dogs, horses, and people. Some hepatic metabolism occurs in cats, but normally the majority of drug is excreted via the kidney.^{113,120} Rapid recovery following intravenous bolus ketamine administration is by rapid redistribution of ketamine from the CNS to other tissues, primarily fat, lung, liver, and kidney.¹²¹ Clinically, animals with significant hepatic dysfunction do not metabolize ketamine as rapidly as do healthy animals. Animals with renal dysfunction or obstruction to urine flow also have prolonged sleep times when larger doses of ketamine are given.¹¹² Generally speaking, dissociative anesthetics should be given cautiously to animals that have significant hepatic or renal dysfunction.

Effects on Intraocular Pressure

In people, a slight increase in intraocular pressure (IOP) independent of changes in blood pressure has been observed during ketamine anesthesia.^{122,123} However, conflicting results have been reported. Intravenous or intramuscular administration of ketamine alone (2 to 8 mg/kg) reportedly did not affect IOP significantly.^{124,125} IOP increases during xylazine and ketamine anesthesia in dogs, whereas it tends to decrease in horses.^{126,127} Increases in extraocular muscle tone induced by ketamine may be responsible for the IOP increase.¹²⁸ With this in mind, ketamine should be used with caution in patients with corneal injuries where increased IOP may result in expulsion of intraocular contents.

Clinical Use

Dogs

Dissociatives can increase muscle tone and can induce spontaneous movement and rough recoveries, and occasionally convul-

sions, in dogs (Tables 12.1 and 12.2).^{66,109} To reduce these undesirable effects, dissociatives are often used in combination with adjunctive drugs. Benzodiazepines induce a central muscle relaxant effect that decreases the muscle hypertonus associated with ketamine.¹²⁹ In a comparative study, both midazolam-ketamine and diazepam-ketamine combinations induced minimal cardiovascular and respiratory effects. Time to intubation was significantly shorter with midazolam-ketamine, but recovery seemed to be smoother with diazepam-ketamine.¹³⁰ Zolazepam is combined with tiletamine in a fixed ratio in the proprietary mixture Telazol. This combination reduces the adverse effects of tileta-

mine when given alone, although the metabolism of zolazepam can vary among species and may result in a longer or shorter effect relative to tiletamine. Intravenous administration of acepromazine (0.11 mg/kg) and ketamine (11 mg/kg) induces anesthesia for 10 to 35 min, with good muscle relaxation and smooth recovery.⁶⁶

Xylazine (1.1 mg/kg intramuscularly [IM]) or medetomidine (10 to 30 µg/kg [IM]) is often used with ketamine (5 to 10 mg/kg IM) for short-term anesthesia of 25 to 40 min. The ketamine dose can be adjusted, depending on the desired duration of surgery.^{109,131} In high-strung small-breed dogs, small ketamine

Table 12.1. Use of ketamine alone or ketamine combinations in dogs.

Drug(s)	Dose(mg/kg) and Route	Duration (min)	Comment
Ketamine alone	10, IV	15±8	↑ Muscle tone Short duration Anesthesia inadequate for surgery
	1 or 2, intrathecally	—	Analgesia of the hind limbs
	10 µg/kg/min, CRI	—	↓ Isoflurane MAC by 25%
Ketamine Lidocaine Morphine	K 10 µg/kg/min; L 50 µg/kg/min; M 3.3 µg/kg/min, IV Simultaneously for CRI	—	↓ Isoflurane MAC by 45%
Acepromazine Ketamine Thiamylal	0.55, IM 11–22, IM To effect, IV	20–90	Occasional seizures
Acepromazine Ketamine	A 0.5, IV; K 10 IM A 0.2, IV; K 10 IV A 0.22, IM; K 11–18 IM	— 39±8 —	Good restraint Clinical anesthesia, less muscle rigidity Restraint, spastic movements, and prolonged recovery

Butorphanol	0.7, IM	—	Unsatisfactory sedation in vicious dogs
Telazol	10.6±1.3, IM	—	—
Acepromazine	1.8±1.2, IM	—	Adequate sedation in vicious dogs
Telazol	19.3±1.8, IM	—	—

IM, intramuscularly; IV, intravenously.

doses produce insufficient anesthesia and have a greater tendency to cause seizure. Dogs might salivate excessively during ketamine anesthesia, but this can be controlled with atropine or glycopyrrolate. α_2 -Adrenergic agonist–induced bradycardia and second-degree atrioventricular block may be minimized by ketamine’s sympathomimetic effect. However, atropine should be given if cardiac slowing is pronounced. An advantage of α_2 -adrenergic agonist–ketamine combinations is the reversibility of CNS and cardiopulmonary depression. Antagonism should not be initiated for at least 20 min after ketamine administration unless required to treat severe adverse effects. Earlier antagonism may cause ketamine-induced hyperexcitability and seizures.¹³²

In dogs, intravenous continuous-rate infusion of a low dose of ketamine (10 μ g/kg/min) reduces the isoflurane MAC by 25%, whereas the continuous-rate infusion of a combination of morphine (3.3 μ g/kg/min), lidocaine (50 μ g/kg/min), and ketamine (10 μ g/kg/min) has reduced the isoflurane requirement as much as 45%.¹³³ Concurrent administration of either morphine-lidocaine or morphine-ketamine combinations reportedly reduces CNS hypersensitivity in people suffering inflammatory or

neuropathic pain.^{134–137} Tables 12.1 and 12.2 further summarize the use of ketamine and Telazol either alone or in combination with various other classes of drugs when employed as anesthetics in dogs.

Cats

In cats, dissociatives have been used as primary anesthetic agents. Diazepam (0.3 mg/kg) is commonly mixed in the same syringe with ketamine (5.5 mg/kg) and given slowly IV for short-term anesthesia. This has proven to be a safe combination in cats with compromised cardiovascular function. Diazepam (0.22 mg/kg IV or 0.44 mg/kg IM) followed by ketamine (1 to 5 mg/kg IM) has also been used successfully in geriatric cats.¹³⁸ Administration of butorphanol prior to diazepam-ketamine may increase analgesia and enable diagnostic or surgical procedures to be performed when endotracheal intubation and delivery of an inhalant anesthetic are not feasible.¹³² When various doses of midazolam (0.05, 0.5, 1.0, 2.0, or 5.0 mg/kg IV) are combined with ketamine (3 mg/kg IV), the duration of anesthesia increases slightly. However, increasing the intravenous midazolam dose (5

mg/kg) will often prolong objectionable behavioral signs (restlessness, vocalization, and changes in ability to approach and restrain).¹³⁹ Telazol has been used alone or in combination in cats. Zolazepam appears to be metabolized at a slower rate than tiletamine in this species, resulting in residual muscle relaxation and sedation, which often prolongs complete recovery. Xylazine and ketamine have been combined with Telazol to alter the dissociative anesthetic–benzodiazepine ratio, improving recovery characteristics, as well as facilitating possible antagonism with an α_2 -adrenergic antagonist. This combination, which has been called *TKX* (Telazol-ketamine-xylazine), is made by reconstituting 500 mg of Telazol powder with 100 mg (1 mL of 100 mg/mL) of xylazine and 400 mg (4 mL) of ketamine. The resulting solution is very potent and, by using an insulin syringe, is more accurately dosed at 0.1 mL/5 kg of body weight.

Phenothiazine tranquilizers such as acepromazine have been combined with ketamine for better muscle relaxation and a smoother recovery. However, phenothiazine derivatives are α -adrenoceptor antagonists, and hypotension, prolonged recovery, and hypothermia may occur if they are used in higher doses.

α_2 -Adrenergic agonist–ketamine combinations have often been used in cats. Xylazine (0.5 to 1.1 mg/kg IM), with or without atropine, is administered 20 min before ketamine (11 to 22 mg/kg IM).^{68,140} Emesis is a common side effect of xylazine in cats, and it has been suggested that this should be allowed to occur prior to ketamine administration so as to prevent aspiration of stomach contents.⁶⁶ When compared with acepromazine (0.11 mg/kg IM)-ketamine (4.6 mg/kg IM), the simultaneous administration of xylazine (0.23 mg/kg IM)-ketamine (4.6 mg/kg IM) produces a longer anesthetic action. However, xylazine-ketamine anesthesia is also accompanied by longer-lasting cardiopulmonary depression.¹⁴¹

Medetomidine (10 to 80 μ g/kg IM) has been combined with several different doses of ketamine (2.5, 5, 7.5, and 10 mg/kg IM) in cats undergoing ovariohysterectomy. The dose of ketamine is usually reduced as the medetomidine dose increases. Apnea may occur when the ketamine dose approaches 10 mg/kg. Good muscle relaxation and profound analgesia are comparable to that achieved with xylazine (1 mg/kg IM)-ketamine (10 mg/kg IM), and anesthesia lasts longer than it typically does with the acepromazine (1 mg/kg IM)-ketamine (10 mg/kg IM) combination.^{142,143} Specific α_2 -adrenergic antagonists such as atipamezole have been used to reverse medetomidine-ketamine anesthesia. Atipamezole dosed at two- to threefold the medetomidine dose is effective in antagonizing most of the anesthetic and analgesic effects of the medetomidine-ketamine combination.^{144,145} Recovery to sternal recumbency usually occurs within 10 to 12 min after injection.¹⁴⁶ Bradycardia, vomiting, and excessive salivation, not unlike those seen with xylazine-ketamine, are the most common side effects following (2 to 5 min) medetomidine-ketamine administration.¹⁴⁷

The use of oxymorphone, morphine, meperidine, and butorphanol has been assessed in combination with ketamine in cats.^{148,149} When administered at oxymorphone's peak effect, the ketamine requirement is decreased by 2.5% to 10%.¹⁴⁸ Apparently, the administration of morphine or meperidine neither im-

proves nor reduces the anesthetic effects of ketamine.¹⁴⁹ Adding butorphanol (0.1 mg/kg IV) to ketamine (8 mg/kg IV) appears to increase the intensity and duration of analgesia for a variety of procedures. The most effective dose of butorphanol ranges from 0.05 to 0.2 mg/kg IV. Some clinicians' experiences suggest that doses below and above this range provide less analgesia. It is important to realize that butorphanol is an opioid agonist-antagonist that has a *ceiling effect* on analgesia as well as undesirable opioid actions (e.g., respiratory depression). Doses above 0.2 mg/kg may cause CNS stimulation that is unaccompanied by an increased analgesic action. Tables 12.3 and 12.4 further summarize the use of ketamine and Telazol either alone or in combination with other drugs for use as anesthetics in cats.

Horses

Dissociatives should not be used as a monoanesthetics in horses because of the potential for dangerous and uncontrollable behavior and muscle incoordination. Preanesthetic sedation and tranquilization must be present before ketamine is administered. α_2 -Adrenergic agonists (xylazine, detomidine, or romifidine) are most commonly used for this purpose. Xylazine (1.1 mg/kg IV), followed in 5 to 10 min by ketamine (2.2 to 3.0 mg/kg IV), induces a short period of anesthesia in horses. Higher doses of ketamine (2.75 to 3.0 mg/kg IV) are usually required for ponies, young "high-strung" Arabians, Hackneys, and thoroughbreds.¹⁵⁰ Ketamine should not be administered if xylazine fails to produce adequate sedation, and an alternative anesthetic technique (e.g., guaifenesin-thiobarbiturate mixture) should be considered.¹⁵⁰ It is not uncommon for heart and respiratory rates to decrease by one-third after xylazine administration.¹⁵¹ After ketamine injection, heart rate may remain decreased while respiratory rate returns to prexylazine values.¹⁵¹ Cardiac output and systemic arterial, pulmonary, and central venous pressures remain within normal ranges during xylazine-ketamine anesthesia.¹⁵¹ Duration of anesthesia (15 to 20 min) is related to redistribution of ketamine to other body tissues and hepatic metabolism. In horses, approximately 60% of ketamine is metabolized by the liver, with the remainder excreted unchanged in the urine.¹⁵² Anesthesia can be extended by administering one-third to one-half of the original dose of each drug.

In horses, the addition of butorphanol (0.01 or 0.02 mg/kg) enhances muscle relaxation and analgesia when using a xylazine-ketamine combination.¹⁵³ Behavioral changes caused by butorphanol may be breed dependent. CNS stimulation characterized by hyperresponsiveness and spasmodic lip movements has been reported in high-strung individuals after butorphanol intravenous administration, whereas deep sedation and ataxia were observed at the same dose when given to a Belgian stallion.¹⁵⁴ For extremely painful procedures, methadone with and without acepromazine has been administered to enhance analgesia during xylazine-ketamine anesthesia.^{155,156}

Ketamine (1.5 to 2.0 mg/mL) can be added directly to a 5% solution of guaifenesin and the mixture administered as a rapid infusion, or ketamine can be administered as a bolus (1.5 to 2.2 mg/kg IV) after administration of enough guaifenesin to produce limb weakness (e.g., 1 to 2 mL/kg of a 5% solution). Less cardiovascular depression occurs with this combination, as compared

Table 12.3. Use of ketamine alone or ketamine combinations in cats.

Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment
Ketamine alone	2, 4, or 8, IV 4–30, IM	105–115 20–45 (11–40, IM)	Visceral analgesia Incomplete immobilization and chemical restraint Little analgesia, better muscle relaxation, and minor surgical procedures

with thiopental-guaifenesin or thiamylal-guaifenesin anesthetic induction.^{150,157} Bolus administration of ketamine plus guaifenesin in foals rapidly induces anesthesia with good muscle relaxation and analgesia followed by a smooth recovery.¹⁵⁸

Continuous infusion of a guaifenesin-ketamine-xylazine combination is safe and effective for extending anesthesia in adult horses after xylazine (1.1 mg/kg IV) and ketamine (2.2 to 3.0 mg/kg IV) induction. This drug combination is prepared by adding 500 mg of xylazine and 2000 mg of ketamine to 1 L of 5% guaifenesin.^{159–161} In ponies anesthetized for 2 h with this mixture, arterial blood pressure and left ventricular stroke work index were transiently decreased for the first 15 to 30 min after induction.¹⁶⁰ Cardiac index and arterial pH were also decreased for 15 min after induction. Hypoventilation with mild hypercapnia was noted throughout the study. These changes are transient and comparable to those reported for other injectable anesthetic drugs or drug combinations. In ponies and foals, anesthesia can be induced with a rapid intravenous injection of 1.1 mL/kg of the guaifenesin-ketamine-xylazine mixture. Anesthesia may be maintained by continuous intravenous infusion of 2 to 4 mL · kg⁻¹ ·

h⁻¹, depending on anesthetic requirement. Standing recovery usually occurs within 25 to 45 min of discontinuation of the mixture.^{150–162} An α_2 -adrenergic antagonist such as tolazoline (2 to 4 mg/kg) can be administered IV to hasten recovery. When diazepam (0.1 mg/kg) is combined with xylazine (0.3 mg/kg) and ketamine (2 mg/kg), muscle relaxation is improved when compared with the administration of xylazine-ketamine alone. Diazepam provides practical advantages over guaifenesin in commercial preparation, small volume, and ease of administration.¹⁶³

Detomidine is approved for use in horses in the United States as a sedative-analgesic for colic. Short-term anesthesia in horses can be achieved with detomidine (20 μ g/kg IV) sedation followed in 6 to 8 min by ketamine (2.2 mg/kg IV). Mean arterial blood pressure increases after detomidine-ketamine injection.^{164,165} When compared with xylazine, detomidine may induce better muscle relaxation when combined with ketamine. Recovery can be somewhat unpredictable. Occasionally, horses and ponies experience a rough recovery.¹⁶⁶ This may result from the longer sedation and muscle relaxation achieved with detomidine in some animals.^{164–166}

Romifidine (100 µg/kg IV) has also been used in combination with ketamine (2.0 to 2.2 mg/kg IV) for short-term anesthesia or for induction prior to inhalation anesthesia in horses. The anesthesia duration produced by this combination is 10 to 25 min, similar to that of xylazine-ketamine.^{167–169} Tables 12.5 and 12.6 further summarize ketamine and Telazol combination anesthesia in horses.

Ruminants

Xylazine (0.1 to 0.2 mg/kg IV) is commonly administered prior to, or concomitantly with, ketamine (2.2 to 3.0 mg/kg IV) for short-term anesthesia of ruminants. Tracheal intubation is easily achieved in cattle anesthetized with this combination.^{170,171} Anesthesia may be safely prolonged by administering ketamine (1 to 2 mg/kg) slowly to effect. Alternatively, anesthesia can be

maintained in adult cattle with a continuous infusion of ketamine in saline or 5% dextrose solution (2 mg/mL) at a rate of 10 mL/min.¹⁷² Clinical experience shows that guaifenesin-ketamine-xylazine mixture is an effective anesthetic combination in ruminants. The concentration of each drug in the mixture is 50 mg/mL, 2 mg/mL, and 0.1 mg/mL for guaifenesin, ketamine, and xylazine, respectively. Anesthesia can be induced with 0.55 to 1.1 mL/kg initially and maintained with adjustment for surgical stimulation with 2.2 mL · kg⁻¹ · h⁻¹ in adult cattle and 1.65 mL

· kg⁻¹ · h⁻¹ in calves, kids, and lambs. Anesthesia onset is gradual but smooth. Muscle relaxation is excellent, easily enabling tracheal intubation. Supplementation with oxygen (5 to 10 L/min) during procedures may help prevent hypoxemia. Mild hypoventilation is induced by the anesthetic mixture. Surgical procedures that can be performed in cattle anesthetized with guaifenesin-ketamine-xylazine include femoral fracture plating and pinning, penile surgery, umbilical hernia repair, cesarean section, and celiotomy.¹⁷² Tables 12.7 and 12.8 further summa-

^aSuppl, supplemental dose.

alize the use of ketamine combinations and Telazol for anesthesia in ruminants.

In llamas, xylazine (0.25 mg/kg IM) followed in 15 min by ketamine (5 mg/kg IM) induces 30 to 60 min of anesthesia and restraint sufficient for minor procedures such as suturing lacerations, abscess drainage, or cast application.¹⁷³ If tracheal intubation is desired, xylazine (0.25 mg/kg IV) with ketamine (2.5 mg/kg IV) can be used. Changes in heart rate and blood pressure are similar to those observed in other species. A recent study compared the anesthetic effects of two combinations of xy-

lazine (0.4 and 0.8 mg/kg IM) and ketamine (4 and 8 mg/IM) in llamas. The low-dose combination induced sternal recumbency, but analgesia-anesthesia was observed in only two llamas. The high-dose combination produced longer recumbency (87 vs. 19 min) and analgesia (73 vs. 18 min). Severe hypoxemia was observed in llamas receiving the high-dose combination, as evidenced by low saturation of peripheral oxygen measured by pulse oximeter and low PaO₂ measured from arterial blood gas. Hypoxemia can be treated effectively with nasal insufflation of 100% oxygen.¹⁷⁴

Swine

Ketamine has been used extensively in pigs premedicated with atropine (0.04 mg/kg IM) for minor surgical and diagnostic procedures. At intramuscular doses of 11 to 20 mg/kg, muscle relaxation is poor and analgesia is brief. Green et al.¹⁷⁵ reported that pigs react violently to intramuscular injections of ketamine and then exhibit muscle tremor, extensor rigidity, panting respiration, and erythema. These responses can be minimized by combining diazepam (1 mg/kg IM) or xylazine (2 mg/kg IM) with ketamine (10 to 20 mg/kg IM). Deep sedation and good muscle relaxation occur with these drug combinations, but pigs may still respond to noxious stimuli such as incision of the abdominal wall.^{175,176} Alternatively, a combination of oxymorphone (0.075 mg/kg), xylazine (2 mg/kg), and ketamine (2 mg/kg) mixed in the same syringe and given IV induces surgical anesthesia. When given IM, satisfactory anesthesia can be achieved by doubling the dose of each drug.^{171,177}

Short-term anesthesia in pigs can also be achieved with at-

ropine (0.025 mg/kg IM)-butorphanol (0.2 mg/kg IM)-xylazine (2 mg/kg IM)-ketamine (10 mg/kg IM) (ABXK) or with atropine (0.025 mg/kg IM)-butorphanol (0.2 mg/kg IM)-medetomidine (80 µg/kg IM)-ketamine (10 mg/kg IM) (ABMK). Anesthesia is induced rapidly with both combinations, but ABMK appears to induce more effective anesthesia for major surgery, which is characterized by good muscle relaxation enabling endotracheal intubation for over 1.5 h. Atipamezole (240 µg/kg IV or IM) can be administered to shorten the anesthesia.¹⁷⁸ Medetomidine-ketamine appears to produce longer periods of muscle relaxation (43.6 vs. 12.7 min vs. 21.0 vs. 14 min) and anesthesia (49.4 vs. 13.5 min vs. 34.6 vs. 17.2 min) than does xylazine-ketamine in pigs. Slight cardiovascular stimulation with minimal respiratory effect occurs during medetomidine-ketamine anesthesia.¹⁷⁹ Tables 12.9 and 12.10 further summarize the use of ketamine combinations and the use of Telazol for anesthesia in swine.

Table 12.9. Use of ketamine alone or ketamine combinations in swine.

Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment
Atropine Ketamine	0.044, IM 20, IM	10–30	Poor muscle relaxation and analgesia
Xylazine Ketamine	2, IM 20, IM	—	Required supplemental dose for intubation
Innovar-Vet Ketamine	1 mL/13.6 kg, IM 11, IM	41.75	Good muscle relaxation
Acepromazine Ketamine	0.5, IM 15, IM	18.25	Strong, sharp muscle activity
Xylazine Ketamine	0.2, IM 11, IM	24.5	Strong, sharp muscle activity
Ketamine alone	10–20, IM	—	Violent reaction, muscle tremor, extensor rigidity, ↑ heart rate and respiratory rate, panting respiration, and erythema
Diazepam Ketamine	1, IM 10, IM	40	Deep sedation and response to incision Good muscle relaxation
Xylazine Ketamine	2, IM 15, IM	40	Deep sedation Good analgesia Excellent muscle relaxation
Xylazine Ketamine Oxymorphone	2, IV 2, IV 0.075, IV	20–30	Good analgesia and muscle relaxation Smooth recovery, which can be shortened by naloxone
Xylazine Ketamine	1, IV 10, IV	25	Good analgesia
Guaifenesin Xylazine Ketamine	50 mg/mL 1 mg/mL 1 mg/mL Induction, 0.67–1.1 mL/kg, IV Maintenance, 2.2 mL/kg/h, IV	120	Good muscle relaxation and analgesia Minimal cardiovascular changes
Atropine Butorphanol Xylazine Ketamine	0.025, IM 0.2, IM 2, IM 10, IM	—	Rapid induction of anesthesia

Wolf (<i>Canis lupus L.</i>)	Xylazine Ketamine	30 mg total, IM 400 mg total, IM	148.0±52.7	—	205
	Xylazine Ketamine	2–3, IM 5–6, IM	35–40	—	206
Order Carnivora, family Felidae					
Bobcat (<i>Lynx rufus</i>)	Acepromazine Ketamine	0.66–1.1, IM 17.6, IM (11.9–34.9)	—	Immobilization	200
	Ketamine alone	33.4, IM (22.4–60.3)	—	—	200
California bobcat (<i>Felis rufus californicus</i>)	Ketamine alone	5.5–17.0, IM	—	—	207
Fishing cat (<i>Felis viverrina</i>)	Ketamine alone	19–25, IM	—	—	208
Flat-headed cat (<i>Felis planiceps</i>)	Ketamine alone	8, IM	—	—	208
Jungle cat (<i>Felis chaus</i>)	Medetomidine Ketamine	0.1, IM 2.5, IM	—	Immobilization	192 (<i>continued</i>)

Table 12.11. Use of ketamine alone or ketamine combinations in exotic and wildlife animals (continued).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Leopard cat (<i>Felis bengalensis</i>)	Ketamine alone	8–25, IM	—	—	209
Cheetah	Ketamine alone	8–12, IM	—	—	209
(<i>Acinonyx jubatus</i>)	Ketamine alone	10	—	—	208
	Medetomidine	0.06–0.07, IM	—	Immobilization	292
	Ketamine	2.5–3.0, IM	—	—	209
Jaguar (<i>Panthera onca</i>)	Ketamine alone	13–18, IM	—	—	192
	Medetomidine	0.05, IM	—	Immobilization	192
	Ketamine	1.5–2.0, IM	—	—	192
Leopard (<i>Panthera pardus</i>)	Medetomidine	0.07–0.08, IM	—	Immobilization	209
	Ketamine	2.5–3.0, IM	—	—	207
Black leopard (<i>Panthera pardus</i>)	Ketamine alone	15, IM	—	Occasional convulsion Inadequate muscle relaxation	210
	Ketamine alone	11 (5.5–17.0 range), IM	—	—	209
	Ketamine alone	7.5, IM	—	—	209
Chinese leopard (<i>Panthera pardus japonensis</i>)	Ketamine alone	15, IM	—	Occasional convulsion Inadequate muscle relaxation	209
Clouded leopard (<i>Neofelis nebulosa</i>)	Ketamine alone	8.6, IM	—	Occasional convulsion Inadequate muscle relaxation	208
	Ketamine alone	7, IM	—	—	208
Snow leopard (<i>Panthera uncia</i>)	Ketamine alone	10, IM	—	—	192
	Medetomidine	0.06–0.08, IM	—	Complete immobilization	193
	Ketamine	2.5–3.0, IM	—	—	193
	Medetomidine	0.067±0.016, IM	45	Complete immobilization	211
	Ketamine	(0.038–0.107 range)	—	Allowed tracheal intubation	(continued)
		2.7±0.8, IM	—	—	
		(1.3–5.7 range)	—	—	
	Xylazine	2.2±0.2, IM	30–45	Immobilization	
	Ketamine	(1.9–2.6 range)	—	Moderate to good muscle relaxation	
		10.9±1.0, IM	—	—	
		(9.6–12.8 range)	—	—	

Table 12.11. Use of ketamine alone or ketamine combinations in exotic and wildlife animals (*continued*).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Snow leopard (<i>Panthera uncia</i>)	Medetomidine	0.067±0.014, IM (0.038–0.109 range)	30–60	Immobilization	211
	Ketamine	2.9±0.8, IM (1.6–5.7 range)		Shorter recovery compared with xylazine-ketamine Good to excellent muscle relaxation	
Lion (<i>Panthera leo</i>)	Medetomidine	0.03, IM	—	Immobilization	192
	Ketamine	1.0–1.5, IM	—		
	Ketamine alone	10–20, IM	—	Rapid immobilization	209
		5–7, IM	—	—	212
		5.0–7.5, IM	—	—	210
	Xylazine	110 total, IM	240	Immobilization	190
	Ketamine	450 total, IM			
	Xylazine	3.2, IM	—	—	213
	Ketamine	8, IM			
Mountain lion, puma (<i>Felis concolor</i>)	Xylazine	0.88–0.99, IM	—	Immobilization	200
	Ketamine	7.3–7.7, IM			
		Suppl. ^b 4.4–8.8, IM			
	Ketamine alone	11–25, IM	—	—	209
	Xylazine	1.8, IM	—	—	214
	Ketamine	11, IM			
Margay (<i>Felis wiedii</i>)	Ketamine alone	15, IM	—	Occasional convulsion Inadequate muscle relaxation	209
Tiger (<i>Panthera tigris</i>)	Ketamine alone	7–14, IM	—	—	209
	Medetomidine	0.03, IM	—	Immobilization	192
	Ketamine	1.0–1.5, IM			
Order Carnivora, family Mustelidae					
Badger (<i>Taxidea taxus</i>)	Ketamine alone	11–33, IM	—	Immobilization	200
Beaver (<i>Castor canadensis</i>)	Ketamine alone	22, IM	—	Immobilization	215
	Acepromazine	0.22, IM	—	Immobilization	200
	Ketamine	11, IM			
	Diazepam	0.1, IM	—	Smooth induction	216
	Ketamine	25, IM			(<i>continued</i>)

Table 12.11. Use of ketamine alone or ketamine combinations in exotic and wildlife animals (*continued*).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Ferret (<i>Mustela putorius furo</i>)	Ketamine alone	20–25, IM	—	—	217
	Xylazine Ketamine	2, IM 25, IM	80.0±11.4	—	218
	Ketamine alone	60, IM	—	Muscle rigidity Incomplete analgesia	219
	Diazepam Ketamine	3, IM 35, IM	—	Muscle rigidity Incomplete analgesia	219
	Xylazine Ketamine	2, IM 25, IM	—	Acceptable analgesia Muscle relaxation	219
	Ketamine alone	25, IM	—	Excessive salivation Muscle tremor Paddling motions	220
	Xylazine Ketamine	2, IM 25, IM	—	Good muscle relaxation	220
Fisher (<i>Martes pennanti</i>)	Ketamine or with acepromazine	7.5, IM (11.0–24.2) 1.1, IM	—	Immobilization	200
	Ketamine alone	5–20, IM	—	—	217
Mink (<i>Mustela vison</i>)	10–15, IM	—	—	Suitable for electroejaculation Surgical anesthesia	217
	100, IM 15.4–22.0, IM	—	—	Immobilization	217 217
Pine marten (<i>Marten americana</i>)	Ketamine alone	11–22, IM	—	Immobilization	200
European otter (<i>Lutra lutra</i>)	Diazepam Ketamine	0.5, IM 18, IM	—	Good muscle relaxation Smooth recovery	221
	Medetomidine Ketamine	0.1–0.12, IM 4–5, IM	—	Good muscle relaxation Immobilization	222
Asian small-clawed otter (<i>Aonyx cinerea</i>)	Ketamine alone	22, IM	—	—	200
River otter (<i>Lutra canadensis</i>)	Ketamine alone	1, IM	—	Immobilization	200 (<i>continued</i>)

Table 12.11. Use of ketamine alone or ketamine combinations in exotic and wildlife animals (*continued*).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Australian skink and bobtail skink (<i>Tiliqua rugosa</i>)	Ketamine alone	170–230 mg total, IM	—	Good muscle relaxation	223
King's skink (<i>Egernia kingii</i>)	Ketamine alone	170–230 mg total, IM	—	Good muscle relaxation	223
Common skunk (<i>Mephitis mephitis nigra</i>)	Ketamine alone	10–20, IM	—	—	224
Spotted skunk (<i>Spilogale gracilis</i>)	Ketamine alone	30.1, IM	—	Immobilization	200
Striped skunk (<i>Mephitis mephitis</i>)	Ketamine alone	4.5–60.0, IM 26.8, IM	— 44	Immobilization Immobilization	225 200
Weasel (<i>Mustela frenata</i>)	Ketamine alone	15.4–22.0, IM	—	Immobilization	200
Order Carnivora, family Ursidae					
American black bear (<i>Ursus americana</i>)	Medetomidine Ketamine	0.03–0.04, IM 1.0–1.5, IM	—	Immobilization	192
	Xylazine Ketamine	2.0–4.5, IM 5–9, IM	—	Good chemical restraint	180

Thomson's gazelle (<i>Gazella thomsoni</i>)	Telazol	—	—	—	183
		—	—	—	183
Thomson's gazelle (<i>Gazella thomsoni</i>)	Acepromazine	—	—	—	183
		—	—	—	183
Telazol	Telazol	—	—	—	183
		—	—	—	183

Table 12.13. Use of Telazol alone or Telazol combinations in exotic and wildlife animals (continued).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Gemsbok (<i>Oryx gazella</i>)	Telazol	31, IM	—	Immobilization	184
Blue-bearded gnu (<i>Connochaetes taurinus taurinus</i>)	Telazol	5.5, IM	—	—	183
Brindled gnu (<i>Connochaetes taurinus</i>)	Telazol	6.6, IM	—	—	183
Impala (<i>Aepyceros melampus</i>)	Telazol	4.4, IM	—	—	183
Greater kudu (<i>Tragelaphus strepsiceros</i>)	Telazol	4.85, IM	—	—	183
Alaskan moose (<i>Alces alces gigas</i>)	Telazol	4.4–7.9, IM	—	Chemical restraint Lower dose produces ataxia	184
		2.4–5.3, IM	0–103	Unpredictable response Prolonged ataxia during recovery	268
Nyala (<i>Tragelaphus angasi</i>)	Telazol	6.6–11.0, IM	—	—	183
Siberian reindeer (<i>Rangifer tarandus</i>)	Telazol	4.4–5.3, IM	—	Immobilization	184
Springbok (<i>Antidorcas marsupialis</i>)	Telazol	10.6, IM	—	—	183
Wapiti (<i>Cervus canadensis</i>)	Telazol	9.2, IM	—	Immobilization	184
Zebu (<i>Bos indicus</i>)	Telazol	3.6, IM	—	—	183
Order Carnivora, family Canidae					
Cacomistle (<i>Bassariscus astutus</i>)	Telazol	3.3–16.5, IM	—	Desirable immobilization	184
Coyote (<i>Canis latrans</i>)	Telazol	11, IM	—	Desirable immobilization	184
Cape hunting dog (<i>Lycan pictus</i>)	Telazol	8.8–10.0, IM	—	Desirable immobilization	184
Raccoon dog (<i>Nyctereutes procyonoides</i>)	Telazol	6.6, IM	—	Desirable immobilization	184
Red fox (<i>Vulpes vulpes</i>)	Telazol	10, IM	25.1±2.5	Good cardiovascular and respiratory support Desirable immobilization	269 (continued)

Table 12.13. Use of Telazol alone or Telazol combinations in exotic and wildlife animals (*continued*).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Red fox (<i>Vulpes vulpes</i>)	Telazol	8.8, IM	—	Excellent immobilization	184
		4, IM	34	—	185
Fennec fox (<i>Fennecus zerda</i>)	Telazol	13, IM (12–16 range)	53 (32–65 range)	Excellent immobilization	185
Gray wolf (<i>Urocyon cinereoargenteus</i>)	Telazol	5.3, IM (2.6–14.1 range)	63 (12–135 range)	Surgical anesthesia	185
		8.8, IM	—	Desirable immobilization	184
Iranian wolf	Telazol	3.6, IM (2.1–5.5 range)	(15–78 range)	Excellent immobilization	185
Timber wolf (<i>Canis lupis</i>)	Telazol	2.2–6.6, IM	—	Needed physical restraint	184
Order Carnivora, family Felidae					
Caracal (<i>Felis caracal</i>)	Telazol	3.3–5.5, IM	—	Needed some restraint	184
		6.6–7.3, IM	—	—	183
African wildcat (<i>Felis libyca</i> Forster)	Telazol	4.4, IM	—	Desirable immobilization	184
Bobcat (<i>Lynx rufus</i>)	Telazol	13.3, IM	99	Additional dose for maintenance	185
Dusky jungle cat (<i>Felis chaus</i>)	Telazol	1.1–5.5, IM	—	Desirable immobilization	184
Geoffrey cat (<i>Felis geoffreyi</i>)	Telazol	4, IM	—	Desirable immobilization	184
		4, IM (4.0–4.1 range)	31 (26–37 range)	Excellent immobilization	185
Fishing cat (<i>Felis viverrina</i>)	Telazol	2.0–4.4	—	Desirable immobilization	184
		2.2–4.4, IM	—	Desirable immobilization	184
Jungle cat (<i>Felis chaus</i>)	Telazol	4.2, IM	58	Surgical anesthesia	185
		1.1–5.5, IM	—	—	184
Leopard (<i>Felis bengalensis</i>)	Telazol	7, IM (5–10 range)	61 (25–87 range)	Excellent immobilization	185
		2.2–6.6, IM	—	Desirable immobilization	184
Pampas cat (<i>Felis manul</i>)	Telazol	2.2–5.5, IM	—	Desirable immobilization	184 (<i>continued</i>)

Table 12.13. Use of Telazol alone or Telazol combinations in exotic and wildlife animals (continued).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Cheetah (<i>Acinonyx jubatus</i>)	Telazol	1.6–3.5, IM	60–90	Light anesthesia Moderate muscle relaxation Muscle rigidity and voluntary movement with low dose	270
		4.6, IM (2.9–9.2 range)	117 (39–395 range)	Surgical anesthesia Salivation	185
		2.2–2.75, IM	—	Desirable immobilization	184
		2.2–8.8, IM	—	—	183
		4.2, IM (3.5–4.4 range)	60 (40–115 range)	Excellent immobilization	185
Jaguar (<i>Panthera onca</i>)	Telazol	2–4, IM	—	Desirable immobilization	184
		6.6, IM	—	Desirable immobilization	184
Black leopard (African spotted leopard) (<i>Panthera pardus</i>)	Telazol	5.0–6.25, IM	<180	Desirable immobilization	271
		6.6, IM (1.4–11.5 range)	141 (23–228 range)	Surgical anesthesia at higher dose Lowest dose did not produce immobilization	185
		3.4–11.0, IM	—	—	183
		3.6–6.0, IM	—	—	272
		4–5, IM	—	—	184
Clouded leopard (<i>Panthera nebulosa</i>)	Telazol	4.7, IM (1.5–8.3 range)	121 (23–293 range)	Excellent immobilization	185
		4, IM (3.9–4.0 range)	65 (56–75 range)	Good immobilization	185
Lion (<i>Panthera leo</i>)	Telazol	3.76±0.48, IM	—	Rapid induction time Good muscle relaxation No convulsions	273
		1.6–2.9, IM	—	Sufficient muscle relaxation Licking movement	184
		2.2–3.0, IM	—	Desirable immobilization	183
		2.2–8.4, IM	—	—	185
		5, IM (3.2–8.9 range)	69 (21–139 range)	Good immobilization	185
		<2.2, IM	—	Some immobilization	184 (continued)

Table 12.13. Use of Telazol alone or Telazol combinations in exotic and wildlife animals (*continued*).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Mountain lion, puma (<i>Felis concolor</i>)	Telazol	8.2, IM (2.7–16 range)	96 (20–280 range)	Poor muscle relaxation at lower dose Repeated doses for root canal and tooth capping Needed a little physical restraint	185
		2.2–3.3, IM	—	—	184
		8.3, IM (4.5–12.2 range)	42 (30–55 range)	Surgical anesthesia	185
		4.4, IM	—	—	183
		4.4–5.5, IM	—	Desirable immobilization	184
Serval (<i>Felis serval</i>)	Telazol	2.2–12.2, IM	—	—	183
		2.0–2.8, IM	—	Slight physical restraint needed	184
Tiger (<i>Panthera tigris</i>)	Telazol	4, IM	—	Anesthesia	184
		3.5–4.0, IM	180–300	Desirable immobilization	271
		2.3–11.7, IM	—	Minimum dose of 4.6 mg/kg for female and 4 mg/kg for male	274
		4.4–19.3, IM	—	—	183
Order Carnivora, family Ursidae					
American black bear (<i>Ursus americana</i>)	Telazol	4.7±0.8, IM	—	—	275
		0.6–0.73, IV 3.3–7.0, IM	—	—	183
		2.8–4.4, IM	—	—	183
Asiatic bear (<i>Selenarctos thibetanus</i>)	Telazol	3.5±1.8, IM	—	—	275
Brown bear (<i>Ursus arctos syriacus</i>)	Telazol	7–9, IM	45–75	Rapid induction Predictable recovery Wide safety margin Few adverse side effects	276
		2.4–6.3, IM	—	—	183
Kamchacka bear (<i>Ursus arctos beringianus</i>)	Telazol	4.3, IM (3.1–5.2 range)	41 (26–75 range)	Surgical anesthesia Additional half dose can be given for prolonged procedures	185
		5.5, IM	20	Good anesthesia	184 (<i>continued</i>)

Table 12.13. Use of Telazol alone or Telazol combinations in exotic and wildlife animals (continued).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Polar bear (<i>Ursus maritimus</i>)	Telazol	4.9, IM (3.5–7.0 range)	83 (15–230 range)	Surgical anesthesia Additional IM or IV dose may be necessary to maintain anesthesia	185
		5, IM	—	Immobilization Inadequate analgesia	277
		8–9, IM	—	Immobilization Satisfactory analgesia Fast recovery	278
		3.5–7.0, IM	—	—	185
Sloth bear (<i>Melursus ursinus</i>)	Telazol	5.5–6.6, IM	—	—	183
Spectacled bear (<i>Tremartos ornatus</i>)	Telazol	5.7, IM (3.2–11.1 range)	35 (23–45 range)	Excellent immobilization	185
		2.8±0.5, IM	—	—	275
Sun bear (<i>Helarctos malaynus</i>)	Telazol	4.0–5.5, IM	—	—	185
		2.8–4.7, IM Suppl. ^a 29%–75% of original dose	15–180	Adequate immobilization Rapid induction Smooth recovery Free of convulsions	275
		4.8, IM (4.0–5.5 range)	35 (30–45 range)	Surgical anesthesia	185
Order Carnivora, family Viverridae					
Binturong (<i>Arctictis binturong</i>)	Telazol	1.1, IM	—	A litter but able to handle	184
African palm civet (<i>Nandinia binotata</i>)	Telazol	5.5–8.8, IM	—	Needed higher dose	184
Banded palm civet (<i>Hemigalus derbyanus</i>)	Telazol	6.6, IM	—	Desirable immobilization	184
Formosan masked civet (<i>Paguma larvata</i>)	Telazol	<2–4, IM	—	Manual restraint needed	184
Palm civet (<i>Paradoxurus hermaphroditus</i>)	Telazol	2.2–4.9, IM	—	Needed some restraint	184
Lesser oriental civet (<i>Viverricula indica</i>)	Telazol	4.4, IM	—	Desirable immobilization	184 (continued)

Table 12.13. Use of Telazol alone or Telazol combinations in exotic and wildlife animals (*continued*).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Fanaloka (<i>Cryptoprocta fosse</i>)	Telazol	2-8, IM	—	Needed some physical restraint	184
Genet (<i>Genetta tigrina</i>)	Telazol	2.2, IM	—	Desirable immobilization	184
Linsang (<i>Prionodon linsang</i>)	Telazol	4.4, IM	—	Desirable immobilization	184
African water mongoose (<i>Atilax paludinosus</i>)	Telazol	5.5, IM	—	Desirable immobilization	184
Ring-tail mongoose (<i>Gallidia elegans</i>)	Telazol	4.4, IM	—	Desirable immobilization	184
Black-footed mongoose <i>Bdeogale</i> species	Telazol	4.4, IM	—	Desirable immobilization	184
Ratel (<i>Mellivora capensis</i>)	Telazol	2.2, IM	—	Awakened fast	184
Other species					
Acouchi (<i>Myoprocta pratti</i>)	Telazol	4.4-6.6, IM	—	—	184
Badger (<i>Taxidea taxus</i>)	Telazol	4.4, IM	—	Surgical anesthesia	185
Chimpanzee (<i>Pan troglodytes</i>)	Telazol	16, orally Suppl. ^a 2.5, IM	40	Immobilization Analgesia <40	279
Chinchilla (<i>Chinchilla villidera laniger</i>)	Telazol	11-44, IM	115-431	Surgical anesthesia	280
		4.4, IM	—	—	183
		5.5-44, IM	—	—	184
African elephant (<i>Loxodonta africana</i>)	Telazol	3, IM	—	—	184
Ferret (<i>Mustela putorius</i>)	Telazol	12, IM	31 (15-51 range)	Poor analgesia Immobilization	281
		22, IM	73 (45-165 range)	Immobilization Good muscle relaxation Adequate analgesia	281
		19.8, IM	—	—	183
		5.8, IM (1.5-10.0 range)	32 (17-58 range)	Excellent immobilization Halothane can be used for prolonged anesthesia	185 (<i>continued</i>)

Table 12.13. Use of Telazol alone or Telazol combinations in exotic and wildlife animals (continued).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Gerbil (<i>Meriones unguiculatus</i>)	Telazol	60, IM	Male, 5.7±0.37 Female, 4.3±1.18 1.58–4.03	Surgical anesthesia	282
		20–40, IM		Immobilization	282
Guinea pig (<i>Cavia porcellus</i>)	Telazol	52, IM	122 (70–163 range)	Unsatisfactory anesthesia Useful for procedures requiring prolonged recumbency without manipulation	283
Hamster Outbred Syrian	Telazol	20–80, IP	7–27	Immobilization Inadequate analgesia	284
		60–80, IM	19–32	Immobilization Inadequate analgesia	
European hedgehog (<i>Erinaceus europaeus</i>)	Telazol	0.75–10.0, IM	—	—	183
Feral horse (<i>Equus equus</i>)	Telazol Butorphanol Xylazine	3.5, IM	88	Immobilization	285
		0.07, IM	(16–210 range)		
		3, IM			
Hutia (<i>Plagiodontia aedium</i>)	Telazol	6.6, IM	—	—	185
Spotted hyena (<i>Crocuta crocuta</i>)	Telazol	1.8, IM	—	Desirable immobilization	185
Long-nose rat kangaroo (<i>Potorous tridactylus</i>)	Telazol	14.7, IM	—	—	286
Red kangaroo (<i>Macropus rufus</i>)	Telazol	4.1, IM (2.8–6.9 range)	107 (30–217 range)	Desirable anesthesia Salivation	287
		<4, IM	—	Poor muscle relaxation	287
		>4, IM	—	Good muscle relaxation	
		6–8, IM	20–30	Prolonged procedures	287
		1.8–6.2, IM Suppl. ^a 25%–60% of original IM dose	60–120	Sufficient anesthesia	286
Tree kangaroo (<i>Dendrolagus matschiei</i>)	Telazol	1.6–4.9, IM	20	Minor muscle rigidity Adequate immobilization	286
Kinkajou (<i>Potos flavus</i>)	Telazol	0.7–7.7, IM	—	Desirable immobilization Higher dose may be necessary for surgery	185 (continued)

Table 12.13. Use of Telazol alone or Telazol combinations in exotic and wildlife animals (continued).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Koala (<i>Phascolarctos cinereus</i>)	Telazol	7, IM	30-45	Anesthesia	288
		(5.0-7.7 range) Suppl. ^a 2.5	90	Mild salivation	
Mice Outbred or inbred	Telazol	6.9, IM	86.3±1.1 (80-98 range)	Surgical anesthesia	289
		100-160, IP or IM	4-119	Respiratory depression	284
Mink (<i>Mustela vison</i>)	Telazol	30, IM	27	Surgical anesthesia	185
		1.2-2.6, IM	—	Good immobilization	184
Monkeys	Telazol	3.6-7.5, IM	5-35	Surgical anesthesia	
		12-16, IM	36-57	Surgical anesthesia	290
Red howler monkey (<i>Alouatta senicullus</i>)	Telazol	5-10, IM	30-55	Excellent muscle relaxation Absence of ocular movement Gradual emergence	291
		23.3, IM (13.0-37.5)	45	Good muscle relaxation Immobilization	185
River otter (<i>Lutra canadensis</i>)	Telazol	5.4, IM	38 (20-57)	Surgical anesthesia	184
		(4.1-6.7 range)	10	Chemical restraint	185
Sea otter (<i>Enhydra lutris</i>)	Telazol	2.2, IM	—	—	183
		4.1-6.7, IM	—	—	292
Pacarana (<i>Dinomys branickii</i>)	Telazol	0.66-11.0, IM	—	—	292
		1.2, IM	40	Unable to resist handling	292
Lesser panda (<i>Ailuurus fulgens</i>)	Telazol	1.4-2.9, IM	25-45	Surgical anesthesia	292
		9.3, IM	360	Surgical anesthesia but with apnea	200
Muscle tremors (continued)	Telazol	1-2, IM	—	Immobilization	184
		4.4, IM	—	—	255
		4.1, IM (1.8-6.3)	25-40	Moderate muscle relaxation Mild salivation Increased salivation Muscle tremors	(continued)

Table 12.13. Use of Telazol alone or Telazol combinations in exotic and wildlife animals (continued).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Collared peccary (<i>Tayassu tajacu sonoriensis</i>)	Telazol	4.6–32.3, IM >19, IM	—	Good immobilization Surgical anesthesia	184
Phalanger (<i>Trichosurus vulpecula</i>)	Telazol	7.7–11.5, IM	—	—	286
Nonhuman primates	Telazol	0.6–10.0, IM 2–22, IM	—	Chemical immobilization Surgical anesthesia	293
Rabbits (<i>Sylvilagus floridanus</i>)	Telazol Xylazine	15, IM 5, IM	72±8	Surgical anesthesia Profound visceral analgesia	237
Raccoon (<i>Procyon lotor</i>)	Telazol	23.6, IM (13–40 range) 8.8–23.4, IM	68 (20–120 range) —	Unsatisfactory surgical anesthesia Immobilization —	283 183
	Telazol	11.8, IM (4.3–225.0 range)	45 (17–65 range)	Surgical anesthesia with higher dose Poor muscle relaxation with lower dose Desirable immobilization	185
		5.9–13.7, IM	—	Lower dose given IV	184
		0.8–7.0, IM	—	—	184
		6.6–14.8, IM	—	—	183
Rat Sprague-Dawley	Telazol	20–30, IP	68 (41–110 range)	Satisfactory anesthesia Good muscle relaxation	283
Outbred or inbred	Telazol	20–40, IP or IM	6 to >300	Satisfactory anesthesia	284
Rhesus monkey (<i>Macaca mulatta</i>)	Telazol	3–5, IM	—	—	294
Hoffman's sloth (<i>Choloepus hoffmanni</i>)	Telazol	2.2–4.4, IM	—	—	184
Striped skunk (<i>Mephitis mephitis</i>)	Telazol	9.3, IM (3–14 range) 5.5–11.0, IM 17.6–54.2, IM	42 (10–102 range) — —	Surgical anesthesia — Desirable immobilization —	185 184 183
Gray squirrel (<i>Sciurus carolinensis</i>)	Telazol	4.4–6.6, IM	—	—	183
Formosan tree squirrel (<i>Callosciurus erythraeus</i>)	Telazol	8.3–17.0, IM	—	—	184 (continued)

Table 12.13. Use of Telazol alone or Telazol combinations in exotic and wildlife animals (continued).

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Tayra (<i>Eira barbara</i>)	Telazol	3.3, IM	—	—	184
Mainland wombat (<i>Phascolomis hirsutus</i>)	Telazol	2.0–2.2, IM	—	—	286
Gray seal (<i>Halichoerus grypus</i>)	Telazol	1, IM	—	—	295
Elephant seal (<i>Mirounga anquistrostris</i>)	Telazol	0.7–1.6, IM	—	Lower dose not sufficient for good restraint	184
		1–2, IM	—	Satisfactory immobilization	184
Southern elephant seal (<i>Mirouba leonina</i>)	Telazol	1, IM	—	—	285
Tasmanian devil (<i>Sarcophilus harrisi</i>)	Telazol	2.8–5.5, IM	—	Higher dose may be necessary	184
Northern sea lion (<i>Eumetopias jubatus</i>)	Telazol	1.8–2.5, IM	—	Smooth recovery	296
Tapir (<i>Tapirus terrestris</i>)	Telazol	2.8, IM	—	Immobilization	184

IM, intramuscularly; IP, intraperitoneally; IV, intravenously.

^aSuppl. supplemental dose.

Table 12.14. Use of Telazol alone or Telazol combinations in reptiles.

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Alligator (<i>Alligator Mississippiensis</i>)	Telazol	15, IM	183.8±33.8	Long induction time Painful on injection Incomplete loss of response	297
Boa constrictor (<i>Boa constrictor</i>)	Telazol	15–29, IM	—	Adequate for minor procedures	184
Crocodile (<i>Crocodylus noloticus</i>)	Telazol Acepromazine	5–10, IM 1, IM	—	Sedation	298
Common iguana (<i>Iguana iguana</i>)	Telazol	10, IM	—	Desirable immobilization	184
Indian python (<i>Python molurus</i>)	Telazol	26.5, IM	—	—	183
Rattlesnake (<i>Crotalus atrox</i>)	Telazol	15.4, IM	—	—	183
Timber rattlesnake (<i>Crotalus horridus</i>)	Telazol	35–210, IM	—	Long duration of sedation	184
Tortoise <i>Testudo</i> species	Telazol	75, IM	—	Prolonged recovery	184
	Telazol	1.1–22.0, IM	—	—	183

Table 12.15. Use of Telazol alone or Telazol combinations in birds.

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Mynah bird (<i>Acridotheres tristis</i>)	Telazol	26.5, IM	—	—	183
Sulfur-crested cockatoo (<i>Cacatua galerita</i>)	Telazol	2.64–25.2, IM	—	—	183
Ring-necked dove (<i>Streptopelia risoria</i>)	Telazol	50–75, IM	—	—	184
Rock dove (<i>Columba livia</i>)	Telazol	10–70, IM	—	—	283
Muscovy duck (<i>Cairina moschate</i>)	Telazol	5.9–15.6, IM	—	5.9 and 8.4 mg/kg did not produce sufficient analgesia	184
		13.2–22.0, IM	—	—	183
Bald eagle (<i>Haliaeetus leucocephalus</i>)	Telazol	13.2–22.0, IM	—	—	183
Emu (<i>Dromaius novaehollandiae</i>)	Telazol	15, IM	—	Needed some physical restraint	183
		22, IM	—	—	
Flamingo <i>Phoenicopteri</i> species	Telazol	22, IM	—	—	183
Chilean flamingo (<i>Phoenicopterus ruber chilensis</i>)	Telazol	6.6, IM	—	Desirable immobilization	184
Egyptian goose (<i>Alopochen aegyptiacus</i>)	Telazol	22.0–24.5, IM	—	—	183
Lesser Magellian goose (<i>Choenphaga picta</i>)	Telazol	6.6–8.8, IM	—	Desirable immobilization	184
White-fronted goose (<i>Anser albifrons frontalis</i>)	Telazol	2.7, IM	—	Desirable immobilization	184
Roadside hawk (<i>Buteo magnirostris</i>)	Telazol	16–33, IM	—	Desirable immobilization	184
Pea hen (<i>Pavo cristatus</i>)	Telazol	11.3, IM	—	—	183
Green heron (<i>Butorides virescens</i>)	Telazol	75, IM	—	Excellent anesthesia	184
Rhinoceros hornbill (<i>Buceros rhinoceros</i>)	Telazol	28.7, IM	—	—	183
Blue-gold macaw (<i>Ara ararauna</i>)	Telazol	12.1–22.0, IM	—	—	183 (continued)

Table 12.15. Use of Telazol alone or Telazol combinations in birds. (continued)

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Scarlet macaw (<i>Ara macao</i>)	Telazol	4.4–11.0, IM	—	—	184
		5.5–19.8, IM	—	—	183
Mallard (<i>Anas platyrhynchos</i>)	Telazol	44.1–55.1, IM	—	—	183
Osprey (<i>Pardion haliaetus</i>)	Telazol	9.26–17.6, IM	—	—	183
Ostrich (<i>Sruthio camelus</i>)	Telazol	4–5, IM	—	Desirable immobilization	184
		3.7, IV	—	Good induction Poor recovery	262
Barn owl (<i>Tyto alba</i>)	Telazol	8.8–30.2, IM	—	—	183
African ring-neck parakeet (<i>Psittacula krameri</i>)	Telazol	26, IM	—	Desirable immobilization	184
Parakeet (<i>Melopsittacus undulatus</i>)	Telazol	20–22, IM	—	—	183
Patagonian parrot (<i>Cyrulophus patagonus</i>)	Telazol	11, IM	—	Excellent immobilization	184
Crested green wood partridge (<i>Rollulus roulroul</i>)	Telazol	10, IM	—	Good immobilization	184
Pigeon (<i>Columbia livia</i>)	Telazol	30.6, IM (20–48 range)	41.4 (25–70 range)	Immobilization Poor relaxation	283
		40–60, IM	—	Good anesthesia	184
Plover Charadriidae species	Telazol	17.6, IM	—	—	183
Rhea (<i>Rhea americana</i>)	Telazol	2–5, IM	—	Tranquilized, resisted handling	184
Greater thea (<i>Rhea americana</i>)	Telazol	2–22, IM	—	—	184
		35.8	—	—	183
Yellow-bellied sapsucker (<i>Sphyrapicus varius</i>)	Telazol	33–100, IM	—	Good immobilization	184
Black swan (<i>Cygnus atratus</i>)	Telazol	6.6, IM	—	—	184
Black-neck swan (<i>Cygnus malanocoryphus</i>)	Telazol	4.4–6.6, IM	—	Some physical restraint needed	184 (continued)

Table 12.15. Use of Telazol alone or Telazol combinations in birds. (continued)

Common Names (Genus and Species)	Drug(s)	Dose and Route (mg/kg)	Duration (min)	Comment	Reference
Wood stork (<i>Mycteria americana</i>)	Telazol	11, IM	—	—	183
Blue-wing teal (<i>Anas discors</i>)	Telazol	22-35, IM	—	Prolonged recovery with higher dose	184
Green-wing teal (<i>Anas crecca carolinensis</i>)	Telazol	35, IM	—	Prolonged recovery with higher dose	184
Woodcock (<i>Philohela minor</i>)	Telazol	44, IM	—	Desirable immobilization	184

IM, intramuscularly; IV, intravenously.

Nondomestic Animals

Ketamine and Telazol have both been used extensively in various combinations for the immobilization of captured and wild animals. Ketamine usage has been somewhat limited because of its relatively low concentration, requiring a large volume be delivered to many larger species. Ketamine can be lyophilized and reconstituted to a smaller volume to create a higher concentration when a larger dose is required via a remote delivery device (e.g., darts).^{180–182} In contrast, Telazol has the advantage of being reconstituted to a small volume with potent sedatives or adjunctive analgesic drugs to increase overall potency. Both anesthetics have been used alone or in combination in many wild and exotic species.^{183–186} Tables 12.11 through 12.15 further summarize the use of ketamine and Telazol, alone and in combination with other drugs, in nondomesticated species.

Introduction

Inhalation anesthetics are used widely for the anesthetic management of animals. They are unique among the anesthetic drugs because they are administered, and in large part removed from the body, via the lungs. Their popularity arises in part because their pharmacokinetic characteristics favor predictable and rapid adjustment of anesthetic depth. In addition, a special apparatus is usually used to deliver the inhaled agents. This apparatus includes a source of oxygen (O₂) and a patient breathing circuit that in turn usually includes an endotracheal tube or face mask, a means of eliminating carbon dioxide (CO₂), and a compliant gas reservoir. These components help minimize patient morbidity or mortality because they facilitate lung ventilation and improved arterial oxygenation. In addition, inhalation anesthetics in gas samples can now be readily and affordably measured almost instantaneously. Measurement of inhalation anesthetic concentration enhances the precision and safety of anesthetic management beyond the extent commonly possible with injectable anesthetic agents.

Over the nearly 150 years that inhalation anesthesia has been used in clinical practice, fewer than 20 agents have actually been

introduced and approved for general use with patients (Fig. 13.1).¹ Fewer than ten of these have had any history of widespread clinical use in veterinary medicine, and only 5 are of current clinical veterinary importance in North America. It is this group of anesthetics that are the focus of this chapter. Isoflurane is generally considered the most widely used inhalation anesthetic in veterinary medicine, having replaced halothane in this regard. The gaseous agent nitrous oxide (N₂O) and the newest volatile agent sevoflurane, along with halothane, enjoy varying degrees of popularity and are grouped in an intermediary category. It is important to note that, at the time of updating this chapter, suppliers are considering no longer making and distributing halothane, at least in North America. However, because the decision at this time is not final, for purposes of this chapter, the author will continue to include information on halothane. The other newer volatile anesthetic, desflurane, is presently only of limited use in veterinary medicine but is grouped among the five contemporary agents. Two additional volatile agents receive brief attention for different reasons. Methoxyflurane, an agent popular during the period of about 1960 to 1990, is no longer commercially available in North America. However, because of some of its physical-chemical characteristics, mention here has value to the reader in comparing agents of more current interest. Enflurane, introduced for use in human patients in 1972 and still commercially available, has little or no use in veterinary practice in the United States but remains in limited use elsewhere for management of small companion animal patients or laboratory animals. Although of investigational interest, a review of xenon is not included in this clinically focused chapter.

In this edition, information on agents of largely historical interest has not been included. Readers interested in aspects of these formally used agents are referred to the earlier editions of this and other textbooks.²⁻⁶ Such agents include diethyl ether, chloroform, and others noted in Fig. 13.1.

Physiochemical Characteristics

The chemical structure of inhalation anesthetics and their physical properties determine their actions and safety of administration. An in-depth analysis of the impact of agent chemical structure and physical properties is beyond the scope of this chapter. However, brief discussion of aspects of Fig. 13.2 and Table 13.1 is appropriate because the physiochemical characteristics summarized determine and/or influence practical considerations of

Inhalation Anesthetics in Clinical Practice

Fig. 13.1. Inhalation anesthetics introduced for widespread clinical use. Adapted from Eger¹ and Karzai et al.³²³

their clinical use. For example, they determine the form in which the agents are supplied by the manufacturer (i.e., as a gas or liquid) and account for the resistance of the anesthetic molecule to degradation by physical factors (e.g., heat and light) and substances it contacts during use (e.g., metal components of the anesthetic-delivery apparatus and the CO₂ absorbents such as soda lime). The equipment necessary to deliver the agent safely to patients (e.g., vaporizer and breathing circuit) is influenced by some of these properties, as are the agent's uptake, distribution within, and elimination (including potential for metabolic breakdown) from the patient. In summary, a knowledge and understanding of fundamental properties enable more intelligent use of contemporary anesthetics.

Chemical Characteristics

All contemporary inhalation anesthetics are organic compounds except N₂O (Fig. 13.2) (cyclopropane and xenon are other no-

table inorganic anesthetics). Agents of current interest are further classified as either aliphatic (i.e., straight or branch chained) hydrocarbons or ethers (i.e., two organic radicals attached to an atom of O₂; the general structure is ROR). In the continued search for a less reactive, more potent, nonflammable inhalation anesthetic, focus on halogenation (i.e., addition of fluorine, chlorine, or bromine; iodine is least useful) of these compounds has predominated. Chlorine and bromine especially convert many compounds of low anesthetic potency into more potent drugs. Historically, interest in fluorinated derivatives was delayed until the 1940s because of difficulties in synthesis, and thus quantities available for study were limited. Methods of synthesis, although difficult, have improved considerably and facilitated new agent discovery (Fig. 13.2). It is interesting that organic fluorinated compounds are a group of extreme contrasts—some are toxic, others are not; some are extremely inert, others are highly reactive. In some anesthetics, fluorine is substituted for chlorine or

Table 13.1. Some physical and chemical properties of inhalation anesthetics in current clinical use for animals

Property	Desflurane	Enflurane	Halothane	Isoflurane	Methoxyflurane ^a	N ₂ O	Sevoflurane

^aMethoxyflurane is no longer available.

bromine to improve stability but at the expense of reduced anesthetic potency and solubility.

Halothane (Fig. 13.2) is a halogenated, aliphatic saturated hydrocarbon (ethane). Predictions that halogenated structure would provide nonflammability and molecular stability encouraged the development of halothane in the early 1950s. However, soon after clinical introduction it was observed that the concurrent presence of halothane and catecholamines increased the incidence of cardiac arrhythmias, especially in human patients. An ether linkage in the molecule favors a reduced incidence of cardiac arrhythmias. Consequently, this chemical structure is a predominant characteristic of all agents developed or proposed for clinical use since the introduction of halothane (Fig. 13.2).

Despite many favorable characteristics and improvements over earlier anesthetics (Fig. 13.1) that included improved chemical stability, halothane is susceptible to decomposition. Accordingly, halothane is stored in dark bottles, and a very small amount of a preservative, thymol, is added to it to retard breakdown. Thymol is much less volatile than halothane and over time collects within the devices used to control delivery of the volatile anesthetic (i.e., vaporizers) and causes them to malfunction. To accomplish greater molecular stability, fluorine is substituted for chlorine or bromine in the anesthetic molecule. This chemical manipulation added shelf life to the substance and negated the need for additives such as thymol. Unfortunately, the fluorine ion is also toxic to some tissues (e.g., kidneys), which is of clinical concern if the parent compound (e.g., sevoflurane and, historically, most notably methoxyflurane) is not resistant to metabolism (Fig. 13.2).

Physical Characteristics

There is a constant interchange of respiratory gases (O₂ and CO₂) between cells and the external environment via blood. Inhalation anesthesia involves additional considerations whereby an anesthetic must be transferred under control from a container to sites of action in the central nervous system (CNS). Early in this process the agent is diluted to an appropriate amount (concentration) and supplied to the respiratory system in a gas mixture that contains enough O₂ to support life. The chain of events that en-

sues is influenced by many physical and chemical characteristics that can be quantitatively described (Tables 13.1 to 13.4). The practical clinical applications of these quantitative descriptions are reviewed here. Limited space does not permit in-depth review of all underlying principles, and readers interested in further background information are referred elsewhere.^{7,8}

The physical characteristics of importance to our understanding of the action of inhalation anesthetics can be conveniently divided into two general categories: those that determine the means by which the agents are administered and those that help determine their kinetics in the body. This information is applied in the clinical manipulation of anesthetic induction and recovery and in facilitating changes in anesthetic-induced CNS depression in a timely fashion.

Properties Determining Methods of Administration

A variety of physical and chemical properties determine the means by which inhalation anesthetics are administered. These include characteristics such as molecular weight, boiling point, liquid density (specific gravity), and vapor pressure.

General Principles: A Brief Review Molecules are in a constant state of motion and exhibit a force of mutual attraction. The degree of attraction is evident by the state in which the substance exists (i.e., solid, liquid, or gas). Molecular motion increases as energy (e.g., in the form of heat) is added to the molecular aggregate and decreases as energy is removed. With increased motion the intermolecular forces are reduced; if conditions are extreme enough, a change in physical state may ensue. All substances exist naturally in a particular state but can be made to exist (at least in theory) in any or all phases by altering conditions. Water, as an example, exists as ice (mutual molecular attraction is great), liquid water, or water vapor (attraction considerably reduced), depending on conditions.

Gas versus Vapor Inhalation anesthetics are either gases or vapors. In relation to inhalation anesthetics the term *gas* refers to an agent, such as N₂O, that exists in its gaseous form at room tem-

perature and sea level pressure. The term *vapor* indicates the gaseous state of a substance that at ambient temperature and pressure is a liquid. With the exception of N_2O , all the contemporary anesthetics fall into this category. Desflurane (Table 13.1) is one of the new volatile liquids that comes close to the transition stage and offers some unique (among the inhalation anesthetics) considerations to be discussed later in this chapter.

Whether inhalation agents are supplied as a gas or volatile liquid under ambient conditions, the same physical principles apply to each agent when it is in the gaseous state. Molecules move about haphazardly at high speeds and collide with each other (more frequently in liquid than in gas) or the walls of the containing vessel. The force of the bombardment is measurable and referred to as pressure. In the case of gases, if the space or volume in which the gas is enclosed is increased, the number of bombardments decreases (i.e., a smaller number of molecular collisions per unit time) and then the pressure decreases. The behavior of gases is predictably described by various gas laws. Relationships such as those described by Boyle's law (volume vs. pressure), Charles's law (volume vs. temperature), Gay-Lussac's law (temperature vs. pressure), and Dalton's Law of Partial Pressure (the total pressure of a mixture of gases is equal to the sum of the partial pressures of all of the gaseous substances present), among others, are important to our overall understanding of aspects of respiratory and anesthetic gases and vapors. However, in-depth descriptions of these principles are beyond the scope of this chapter, and readers are referred elsewhere for this information.⁸

Methods of Description Quantities of inhalation anesthetic agent are usually characterized by one of three methods: pressure (i.e., in millimeters of mercury [mm Hg]), concentration (in volume percent [vol%]) or mass (in milligrams [mg] or grams [g]). The form most familiar to clinicians is that of concentration (e.g., X% of agent A in relation to the whole gas mixture). Modern monitoring equipment samples inspired and expired gases and provides concentration readings for inhalation anesthetics. Precision vaporizers used to control delivery of inhalation anesthetics are calibrated in percentage of agent, and effective doses are almost always reported in percentages.

Pressure is also an important way of describing inhalation anesthetics and is further discussed as a measure of anesthetic potency. A mixture of gases in a closed container will exert a pressure on the walls of the container. The individual pressure of each gas in a mixture of gases is referred to as its *partial pressure*. As noted earlier, this expression of the behavior of a mixture of gases is known as Dalton's law, and its use in understanding inhalation anesthesia is inescapable. Use of the concept of partial pressure is important in understanding inhalation anesthetic action in a multiphase biological system because, unlike concentration, the partial pressure of an agent is the same in different compartments that are in equilibrium with each other. That is, in contradistinction to concentration or volume percent, an expression of the relative ratio of gas molecules in a mixture, partial pressure is an expression of the absolute value.

Molecular weight and agent density are used in many calculations to convert from liquid to vapor volumes and mass. Briefly

Table 13.2. Partition coefficients (solvent and gas) of inhalation anesthetics at 37°C

Solvent	Desflurane	Enflurane	Halothane	Isoflurane	Methoxyflurane	N ₂ O	Sevoflurane
Water	—	0.78	0.82	0.62	4.50	0.47	0.60
Blood	0.42	2.00	2.54	1.46	15.00	0.47	0.68

Tissue samples are derived from human sources. Data are from sources referenced in the immediate past edition of this text and chapter. N₂O, nitrous oxide.

Table 13.3. Solvent-gas partition coefficients for halothane at 37°C in a variety of species³²⁷

Solvent	Dog	Horse	Ox	Rabbit
Blood	3.51	1.77	2.40	4.02
Brain	6.03	5.42	4.80	6.22
Liver	6.64	8.51	5.10	9.17
Kidney	4.95	3.21	3.80	6.96
Muscle	5.45	3.55	5.40	3.67

Table 13.4. Rubber or plastic-gas partition coefficients at room temperature

Solvent	Desflurane	Enflurane	Halothane	Isoflurane	Methoxyflurane	N ₂ O	Sevoflurane	Reference
Rubber	—	74	120	62	630	1.2	—	Eger ¹
	19	—	190	49	—	—	29	Targ et al. ³²⁸
Polyvinyl chloride	—	120	190	110	—	—	—	Eger ¹
	35	—	233	114	—	—	69	Targ et al. ³²⁸
Polyethylene	—	~2	26	~2	118	—	—	Eger ¹
	16	—	128	58	—	—	31	Targ et al. ³²⁸

These data are summarized from multiple sources as reported in Eger,¹ with some differences in methods of determination. The data from Targ et al.³²⁸ indicate more recently derived data that, unlike earlier data, were recorded following complete equilibration with these materials. Where there is overlap, the ranking of partition coefficients is consistent with halothane > isoflurane > sevoflurane > desflurane. Combining both groupings yields methoxyflurane > halothane > enflurane > isoflurane > sevoflurane > desflurane > nitrous oxide.

(and in simplified fashion), Avogadro's principle is that equal volumes of all gases under the same conditions of temperature and pressure contain the same number of molecules (6.0226×10^{23} [Avogadro's number] per gram molecular weight). Furthermore, under standard conditions the number of gas molecules in a gram molecular weight of a substance occupies 22.4 L. To compare properties of different substances of similar state, it is necessary to do so under comparable conditions; with respect to gases and liquids this usually means with reference to pressure and temperature. Physical scientists have arbitrarily selected *standard conditions* as being 0°C (273 K in absolute scale) and 760 mm Hg pressure (1 atmosphere at sea level). If conditions differ, appropriate temperature and/or pressure corrections must be applied to resultant data.

The weight of a given volume of liquid, gas, or vapor may be

expressed in terms of its density or specific gravity. The density is an absolute value of mass (usually grams) per unit volume (for liquids, volume = 1 mL; for gases, 1 L at standard conditions). The specific gravity is a relative value; that is, the ratio of the weight of a unit volume of one substance to a similar volume of water in the case of liquids or air in the case of gases (or vapors) under similar conditions. The value of both air and water is 1. At least for clinical purposes, the value for density and specific gravity for an inhalation anesthetic is the same. Thus, for example, we can determine the volume of isoflurane gas (vapor) at 20°C from a mL of isoflurane liquid according to the scheme given in Fig. 13.3. This type of calculation has practical applications. For example, to determine the savings in isoflurane liquid afforded by reducing the fresh gas (e.g., O₂) inflow rate, a series of calculations as presented in Fig. 13.4 can be made.

- a. Isoflurane specific gravity = 1.49 g/mL, therefore:
1 mL liquid isoflurane = 1 mL x 1.49 g/mL = 1.49 g
- b. Since molecular weight of isoflurane = 185 g (from Table 13-1, then:
1.49 g ÷ 185 g = 0.0081 mol of liquid
- c. Since 1 mol of gas = 22.4 L, then:
0.0081 mol x 22,400 mL/mol = 181.4 mL of isoflurane vapor at 0C, 1 atm
- d. But vapor is at 20C not 0C (i.e., 273 K),
So, 181.4 x 293/273 = 194.7 mL vapor/mL liquid isoflurane at 20C and at sea level pressure

For substantial variation in ambient pressure, the final figure noted above would have to be further “corrected” by a factor of: 760/ambient barometric pressure

Fig. 13.3. Example of calculations to determine the volume of isoflurane vapor at 20°C from 1 mL of isoflurane liquid.

- a. Total isoflurane vapor delivered over 2 hours (120 min) estimated at:
 $3\%/100 \times 6 \text{ LPM} = 0.18 \text{ LPM} \times 120 \text{ min} = 21.60 \text{ L}/120 \text{ min} = 21,600 \text{ mL}/120 \text{ min}$
vs
 $3\%/100 \times 4 \text{ LPM} = 0.12 \text{ LPM} \times 120 \text{ min} = 14.4 \text{ L}/120 \text{ min} = 14,400 \text{ mL}/120 \text{ min}$
- b. Total vapor volume saved:
 $21,600 \text{ mL}/120 \text{ min} - 14,400 \text{ mL}/120 \text{ min} = 7,200 \text{ mL vapor}/120 \text{ min saved}$
- c. Total liquid isoflurane volume saved/2 hours
 $7,200 \text{ mL vapor} \div 194.7 \text{ mL vapor/mL liquid} = 36.98 \text{ mL of isoflurane liquid}$
(194.7 mL vapor/mL liquid can be calculated as in Fig. 13.4 or taken from Table 13-1)

The economic value of reducing isoflurane consumption can then be determined by calculating the product of the liquid volume saved and the purchase cost/mL of isoflurane liquid

Fig. 13.4. Problem: Determine the savings in isoflurane liquid afforded by reducing the fresh gas (e.g., O₂) inflow rate from 6 Lpm (L/min) to 4 Lpm, given that the average delivered (vaporizer setting) concentration for 2 h is 3%.

Vapor Pressure Molecules of liquids are in constant random motion. Some of those in the surface layer gain sufficient velocity to overcome the attractive forces of neighboring molecules and in escaping from the surface enter the vapor phase. The

change in state from a liquid to a gas phase is known as *vaporization* or *evaporation*. This process is dynamic and in a closed container that is kept at a constant temperature eventually reaches an equilibrium whereby there is no further net loss of

Vapor Pressure - Temperature Relationship

Fig. 13.5. Vapor pressure as a function of temperature for six volatile anesthetics. Curves are generated from Antoine equations.^{324,325}

molecules to the gas phase (i.e., the numbers of molecules leaving and returning to the liquid phase are equal). The gas phase at this point is saturated.

Molecules of a vapor exert a force per unit area or pressure in exactly the same manner as do molecules of a gas. The pressure (mm Hg) that the vapor molecules exert when the liquid and vapor phases are in equilibrium is known as the *vapor pressure*. Thus, the vapor pressure of an anesthetic is a measure of its ability to evaporate; that is, it is a measure of the tendency for molecules in the liquid state to enter the gaseous (vapor) phase. The vapor pressure of a volatile anesthetic must be at least sufficient to provide enough molecules of anesthetic in the vapor state to produce anesthesia at ambient conditions. The *saturated vapor pressure* represents a maximum concentration of molecules in the vapor state that exists for a given liquid at each temperature. Herein lies a practical difference between substances classified as a gas or vapor: A gas can be administered over a range of concentrations from 0 to 100%, whereas the vapor has a ceiling that is dictated by its vapor pressure. The saturated vapor concentration can be easily determined by relating the vapor pressure to the ambient pressure. For example, in the case of halothane (Table 13.1), a maximal concentration of 32% halothane is possible under usual conditions (i.e., $[244/760] \times 100 = 32\%$, where 760 mm Hg is the barometric pressure at sea level). With other variables considered constant, the greater the vapor pressure, the

greater is the concentration of the drug deliverable to a patient. Therefore, again from Table 13.1, halothane, for example, is more volatile than methoxyflurane under similar conditions. The barometric pressure also influences the final concentration of an agent. For example, in locations such as Denver, Colorado, where the altitude is about 5000 feet above sea level and the barometric pressure is only about 635 mm Hg, the saturated vapor concentration of halothane at 20°C is now $(243/635) \times 100 = 38.3\%$.

It is important to recognize that the saturated vapor pressure at 1 atmosphere is unique for each volatile anesthetic agent and depends only on its temperature. In this case, the effect of barometric pressure can be neglected over ranges normally encountered in the practice of anesthesia. Thus, for a given agent, the graph of the saturated vapor pressure versus temperature is a curve as shown in Fig. 13.5. From this graph it can be seen that if the temperature of the liquid is increased, more molecules escape the liquid phase and enter the gaseous phase. The greater number of molecules in the vapor phase produces a greater vapor pressure and vapor concentration. Conversely, if the liquid is cooled, the reverse occurs and vapor concentration decreases. Liquid cooling may occur not only because of changing ambient conditions but also as a natural consequence of the vaporization process. For example, during vaporization the “fastest” molecules at the surface escape first. With depletion of these “high energy” molecules, the average kinetic energy of those left behind is reduced, and there

is a tendency for the temperature of the remaining liquid to fall if this process is not compensated for externally. As the temperature decreases, the vapor pressure, and thus the vapor concentration, also decreases.

Boiling Point The *boiling point* of a liquid is defined as the temperature at which the vapor pressure of the liquid is equal to the atmospheric pressure. Customarily, the boiling temperature is stated at the standard atmospheric pressure of 760 mm Hg. The boiling point decreases with increasing altitude because the vapor pressure does not change, but the barometric pressure decreases. The boiling point of N₂O is −89°C (Table 13.1) at 1 atmosphere pressure at sea level. It is thus a gas under operating-room conditions. Because of this, it is distributed for clinical purposes in steel tanks compressed to the liquid state at about 750 psi (pounds per square inch; 750 psi/14.9 psi [1 atmosphere] = 50 atmospheres). As the N₂O gas is drawn from the tanks, liquid N₂O is vaporized, and the overriding gas pressure remains constant until no further liquid remains in the tank. At that point, only N₂O gas remains, and the gas pressure decreases from this point as remaining gas is vented from the tank. Consequently, the weight of the N₂O minus the weight of the tank, rather than the gas pressure within the tank, is a more accurate guide to the remaining amount of N₂O in the tank.⁹

Desflurane, the newest clinically available volatile anesthetic, also possesses an interesting consideration because its boiling point (Table 13.1) is near room temperature. This characteristic accounted for an interesting engineering challenge in developing an administration device (i.e., a vaporizer) for routine use in the relatively constant environment of the operating room and limits further consideration of its use in all but a narrow range of circumstances commonly encountered in veterinary medical applications. For example, because of its low boiling point, even evaporative cooling has large influences on vapor pressure and thus the vapor concentration of gas mixtures delivered to patients.

Calculation of Anesthetic Concentration Delivered by a Vaporizer

The saturated vapor pressure of most volatile anesthetics is of such magnitude that the maximal concentration of anesthetic attainable at usual operating-room conditions is above the range of concentrations that are commonly necessary for safe clinical anesthetic management. Therefore, some control of the delivered concentration is necessary and usually provided by a device known as a *vaporizer*. The purpose of the vaporizer is to dilute the vapor generated from the liquid anesthetic with O₂ (or an O₂ and N₂O mixture) to produce a more satisfactory inspired-anesthetic concentration. This anesthetic dilution is usually accomplished as indicated in the Fig. 13.6 model by diverting the gas entering the vaporizer into two streams, one that enters the vaporizing chamber (anesthetic chamber volume: V_{anes}) and the other that bypasses the vaporizing chamber (dilution volume or V_{dilution}). If the vaporizer is efficient, the carrier gas passing through the vaporizing chamber becomes completely saturated to an anesthetic concentration (%) reflected by (anesthetic-agent vapor pressure/atmospheric pressure) × 100, at the vaporizer chamber temperature. The resultant anesthetic concentration then

is decreased (diluted) downstream by the second gas stream to a “working” concentration. In modern, precision, agent-specific vaporizers no mental effort is required—just set the dial; the manufacturers have precalibrated the vaporizer for accurate delivery of the dialed concentration. Nevertheless, it is helpful to our overall understanding to know the principles underlying this convenience and how to apply these principles in the use of older noncompensated measured-flow vaporizers.

To calculate the anesthetic concentration from the vaporizer, one must know the vapor pressure of the agent (at the temperature of use), the atmospheric pressure, the fresh gas flow entering the vaporizing chamber, and the diluent gas flow. Then,

$$\% \text{ anesthetic} = \frac{\text{flow of anesthetic from the vaporizing chamber}}{\text{total gas flow}}$$

More detail for interested readers is presented in Fig. 13.6.

Properties Influencing Drug Kinetics: Solubility

Anesthetic gases and vapors dissolve in liquids and solids. The solubility of an anesthetic is a major characteristic of the agent and has important clinical ramifications. For example, anesthetic solubility in blood and body tissues is a primary factor in the rate of uptake and its distribution within the body. It is therefore a primary determinant of the speed of anesthetic induction and recovery. Solubility in lipid bears a strong relationship to anesthetic potency, and its tendency to dissolve in anesthetic-delivery components such as rubber goods influences equipment selection and other aspects of anesthetic management.

Solubility of Gases As previously mentioned, molecules of a gas that overlie a liquid surface are in random motion, and some penetrate the liquid surface. After entering the liquid they intermingle with the molecules of the liquid (i.e., the gas dissolves in the liquid). There is a net movement of the gas into the liquid until equilibrium is established between the dissolved gas in the liquid and the undissolved portion above the liquid. At this time there is no further net gain of gas molecules by the liquid, and the number of gas molecules entering the liquid equals the number leaving. The gas molecules within the liquid exert the same pressure or tension that they exert in the gas phase. If the pressure (i.e., the number of gas molecules overlying the liquid) is increased, more molecules pass into the liquid, and the pressure within the liquid is increased. This net inward movement of gas molecules continues until a new equilibrium is established between the pressure of the gas in the liquid and that overlying the liquid. Alternatively, if the pressure of gas overlying the liquid is somehow decreased below that in the liquid, gas molecules escape from the liquid. This net outward movement of gas molecules from the liquid phase continues until equilibrium between the two phases is reestablished.

The amount, that is, the total number of molecules of a given gas dissolving in a solvent depends on the chemical nature of the gas itself, the partial pressure of the gas, the nature of the solvent, and the temperature. This relationship is described by Henry’s law,

$$V = S \times P$$

Steps:

1. The saturated *concentration* of anesthetic in the anesthetic vaporizing chamber and leaving it (ideally at A above) is calculated knowing the saturated vapor pressure (P_{VP}) (from Table 2) and barometric pressure (P_B).

For example:

$$\text{Halothane\%} = \frac{243}{760} \times 100 = 32.0\%$$

2. The *volume* of anesthetic leaving the vaporizing chamber is the original volume of the carrier gas (O_2) entering the anesthetic vaporizing chamber ($V_{carrier}$) and the volume of anesthetic (V_{halo}) added to it.

$$\text{Halothane\%} = \frac{V_{halo}}{V_{carrier} + V_{halo}} \times 100 \quad (b)$$

Halothane% is known from (a) above and $V_{carrier}$ is known from control of a flowmeter (e.g., a measured flow vaporizer) or via the design characteristics of a commercial, agent-specific, vaporizer that automatically “splits” the fresh gas flow from a single flow meter. In the first case, two gas flow controls are necessary, one for $V_{carrier}$ and one for a larger gas dilution flow ($V_{dilution}$). In either the case of manual or automatic fresh gas flow alteration, the equation is then solved for V_{halo} (expressed in ml of halothane vapor).

For example, if $V_{carrier} = 100 \text{ mL } O_2$, then

$$32\% = \frac{V_{halo}}{100 + V_{halo}} \times 100$$

$$3200 + 32V_{halo} = 100V_{halo}$$

$$3200 = 68V_{halo}$$

$$V_{halo} = 47.1 \text{ mL halothane vapor}$$

3. V_{halo} is then contained in a total gas volume at B of

$$V_{total \text{ gas}} = V_{halo} + V_{carrier} + V_{diluent} \quad (c)$$

Where $V_{diluent}$ is set by the anesthetist using a second gas control e.g., flowmeter; units here of mL/min) or by the vaporizer design and dial setting.

Then in our example for a $V_{diluent}$ of 1000 mL (in 1 minute)

$$\begin{aligned} V_{total} &= 47.1 + 100 + 1000 \\ &= 1147 \text{ ml (rounded off)} \end{aligned}$$

4. So the final halothane vapor concentration is determined by

$$\text{halothane \%} = \frac{V_{halo}}{V_{Total}} \times 100$$

Again, in our example,

$$\text{halothane \%} = \frac{47.1}{1147} = 4.1\%$$

Alternatively, with some basic algebraic work with equations given above, the same numbers can be applied to the resultant formula given below to arrive at the anesthetic concentration. The condensed formula is:

$$\text{Anesthetic concentration (\%)} = \frac{V_{carrier} \cdot P_{VP} \cdot 100}{V_{diluent} \cdot (P_B - P_{VP}) + (V_{carrier} \cdot P_B)}$$

Fig. 13.6. An anesthetic vaporizer model to assist in illustrating the principles associated with the calculation of the vapor concentration of an inhalation anesthetic emerging from a vaporizer. Conditions associated with halothane delivery in San Francisco (i.e., at sea level; barometric pressure = 760 mm Hg) at 20°C are used as an example of general principles.

where V is the volume of gas, P is the partial pressure of the gas, and S is the solubility coefficient for the gas in the solvent at a given temperature. Henry’s law applies to gases that do not combine chemically with the solvent to form compounds.

Before leaving this basic information, a brief focus on a number of variations may be helpful. First, it is important to recognize that if the atmosphere that overlies the solvent is made up of a mixture of gases, then each gas dissolves in the solvent in proportion to the partial pressure of the individual gases. The total pressure exerted by the molecules of all gases within the solvent equals the total gas pressure lying above the solvent.

Within the body there is a partition of anesthetic gases between blood and body tissues in accordance with Henry’s law. This process can be perhaps better understood by visualizing a system composed of three compartments (e.g., gas, water, and oil) contained in a closed container (Fig. 13.7). In such a system the gas overlies the oil, which in turn overlies the water. Because

there is a passive gradient from the gas phase to the oil, gas molecules move into the oil compartment. This movement in turn develops a gradient for the gas molecules in oil relative to water. If gas is continually added above the oil, there will be a continual net movement of the gas molecules from the gas phase into both the oil and, in turn, the water. At a given temperature, when no more gas dissolves in the solvent, the solvent is said to be *fully saturated*. At this point the pressure of the gas molecules within the three compartments will be equal, but the amount (i.e., the number of molecules or volume of gas) partitioned between the two liquids will vary with the nature of the liquid and gas. Finally, it is important to understand that the amount of gas that goes into solution depends on the temperature of the solvent. Less gas dissolves in a solvent as temperature increases, and more gas is taken up as solvent temperature decreases. For example, as water is heated, air bubbles appear inside the container as a result of the decreasing solubility of the air in water.

Fig. 13.7. Diagrammatic representation of an anesthetic gas distributing itself among three compartments (gas, oil, and water). At equilibrium, the number of anesthetic molecules in the three compartments differs, but the pressure exerted by the anesthetic molecules is the same in each compartment.

Conversely, as blood is cooled from a normal body temperature (e.g., hypothermia), gases become more soluble in blood.

The extent to which a gas will dissolve in a given solvent is usually expressed in terms of its solubility coefficient (Table 13.2). With inhalation anesthetics, solubility is most commonly measured and expressed as a *partition coefficient* (PC). Other measurements of solubility include the Bunsen and Ostwald solubility coefficients.^{8,10}

The PC is the concentration ratio of an anesthetic in the solvent and gas phases (e.g., blood and gas) (Fig. 13.8) or between two tissue solvents (e.g., brain and blood) (Table 13.2). It thus describes the capacity of a given solvent to dissolve the anesthetic gas; that is, how the anesthetic will *partition* itself between the gas and the liquid solvent phases after equilibrium has been reached. Remember, anesthetic gas movement occurs because of a partial pressure difference in the gas and liquid solvent phases, so when there is no longer any anesthetic partial pressure difference there is no longer any net movement of anesthetic, and equilibrium has been achieved. Solvent-gas PCs are summarized in Table 13.2. The values noted in this table are for human tissues because these values are most widely available in the anesthesia literature. Comparative data for halothane with some species of clinical interest in veterinary medicine is listed in Table 13.3. Regardless of the species, it is important to emphasize that many factors can alter anesthetic-agent solubility.¹⁰⁻¹³ Perhaps the most notable after the nature of the solvent is temperature.

Of all the PCs that have been described or are of interest, two are of particular importance in the practical understanding of anesthetic action. They are the blood-gas and the oil-gas solubility coefficients.

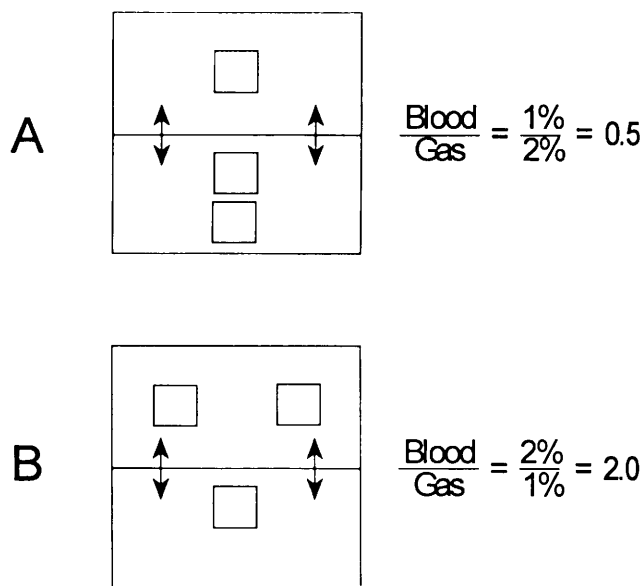

Fig. 13.8. Blood-gas partition coefficient illustration. Adapted from Eger.¹⁰

Blood-Gas Partition Coefficient Blood-gas solubility coefficients (Tables 13.2 and 13.3) provide a means for predicting the speed of anesthetic induction, recovery, and change of anesthetic depth. Assume, for example, that anesthetic A has a blood-gas PC value of 15. This means that the concentration of the anesthetic in blood will be 15 times greater at equilibrium than that in alveolar gas. Expressed differently, the same volume of blood, say 1 mL, will hold 15 times more of anesthetic A than 1 mL of alveolar gas despite an equal partial pressure. Alternatively, consider anesthetic B with a PC of 1.4. This PC indicates that, at equilibrium, the amount of anesthetic B is only 1.4 times greater in blood than it is in alveolar air. Comparing the PC of anesthetic A with that of anesthetic B indicates that anesthetic A is much more soluble in blood than B (nearly 11 times more soluble: 15/1.4). From this, and assuming other conditions are equal, anesthetic A will require a longer time of administration to attain a partial pressure in the body for a particular end point (say, anesthetic induction) than will anesthetic B. Also, since there is more of anesthetic A contained in blood and other body tissues under similar conditions, elimination (and therefore anesthetic recovery) will be prolonged when compared with anesthetic B.

Oil-Gas Partition Coefficient The oil-gas PC is another solubility characteristic of clinical importance (Table 13.2). This PC describes the ratio of the concentration of an anesthetic in oil (olive oil is the standard) and gas phases at equilibrium. The oil-gas PC correlates directly with anesthetic potency (see the section Anesthetic Dose: The Minimum Alveolar Concentration) and describes the capacity of lipids for anesthetic.

Other Partition Coefficients Solubility characteristics for various tissues (Tables 13.2 and 13.3) and other media, such as rubber

and plastic (Table 13.4), are also important. For example, the solubility of a tissue determines in part the quantity of anesthetic removed from the blood to which it is exposed. The higher the tissue solubility, the longer it will take to saturate the tissue with anesthetic agent. Thus, other things considered equal, anesthetics that are very soluble in tissues will require a longer period for induction and recovery. If the amount of rubber goods in the apparatus used to deliver the anesthetic to a patient is substantial, and the anesthetic-agent solubility in rubber is large, the amount of uptake of anesthetic agent by the rubber may be of clinical significance.

Pharmacokinetics: Uptake and Elimination of Inhalation Anesthetics

The aim in administering an inhalation anesthetic to a patient is to achieve an adequate partial pressure or tension of anesthetic (P_{anes}) in the CNS (e.g., brain; for purposes of this discussion, considerations of anesthetic delivery to spinal cord sites of action are considered similar to those of the brain) to cause a desired level of CNS depression commensurate with the definition of general anesthesia. Anesthetic depth varies directly with P_{anes} in brain tissue. The rate of change of anesthetic depth is of obvious clinical importance and depends directly on the rate of change in anesthetic tensions in the various media in which it is contained before reaching the brain. Thus, knowledge of the factors that govern these relationships is of fundamental importance to skillful control of general inhalation anesthesia.

Inhalation anesthetics are unique among the classes of drugs that are used to produce general anesthesia because they are administered via the lungs. The pharmacokinetics of the inhaled anesthetics describe the rate of their uptake by blood from the lungs, distribution in the body, and eventual elimination by the lungs and other routes. Readers seeking more in-depth coverage are directed to reviews by Eger,^{10,14} Eger et al.,¹⁵ and Mapleson.¹⁶

Inhalation anesthetics, similar to the gases of respiration (i.e., O_2 and CO_2), move down a series of partial pressure gradients from regions of higher tension to those of lower tension until equilibrium (i.e., equal pressure throughout the apparatus and body tissues) is established. Thus on induction, the P_{anes} at its source in a vaporizer is high, as is dictated by the vapor pressure, and progressively decreases as anesthetic travels from vaporizer to patient breathing circuit, from circuit to lungs, from lungs to arterial blood, and, finally, from arterial blood to body tissues (e.g., the brain) (Fig. 13.9). Of these the alveolar partial pressure (P_A) of anesthetic is pivotal. The brain has a rich blood supply, and the anesthetic in arterial blood (P_{aAnes}) rapidly equilibrates with brain tissue ($P_{\text{brainAnes}}$). Usually gas exchange at the alveolar level is sufficiently efficient that the P_{aAnes} is close to P_A . Thus, the $P_{\text{brainAnes}}$ closely follows P_A , and by controlling the P_A there is a reliable indirect way for controlling $P_{\text{brainAnes}}$ and anesthetic depth.

At this point it may be also helpful to recall that although the partial pressure of anesthetic is of primary importance, we frequently define clinical dose of an inhaled anesthetic in terms of concentration (C; i.e., vol%). As previously noted this is because it is common practice for clinicians to regulate and/or measure

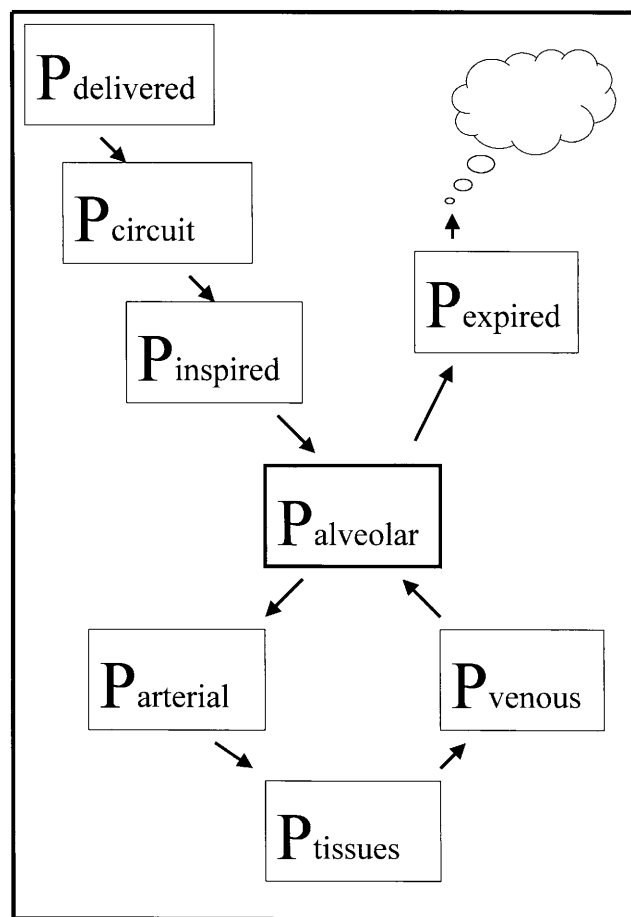

Fig. 13.9. The flow pattern of inhalation anesthetic agents during anesthetic induction and recovery. Inhalation anesthesia may be viewed as the development of a series of partial pressure (tension) gradients. During induction there is a high anesthetic tension in the vaporizer that decreases progressively as the flow of anesthetic gas moves from its source to the brain. Some of these gradients are easily manipulated by the anesthetist; others are not or are done so with difficulty.

respiratory and anesthetic gases in volume percent. In addition, in the gaseous phase, the relationship between the P_{anes} and the C_{anes} is a simple one:

$$P_{\text{anes}} = \text{fractional anesthetic concentration} \times \text{total ambient pressure}$$

The fractional anesthetic concentration is of course $C_{\text{anes}}/100$. However, as reviewed in the preceding section, in blood or tissues the actual *quantity* of anesthetic depends on both the P_{anes} and the anesthetic solubility (as measured by PC) within the solvent (e.g., blood or oil). Consequently, at equilibrium, the *partial pressure* of the gas in the alveoli and among tissue compartments will be equal although *concentrations* will vary within these tissues.

Anesthetic Uptake

The P_A of anesthetic is a balance between anesthetic input (i.e., delivery to the alveoli) and loss (uptake by blood and body tissues) from the lungs. A rapid rise in the P_A of anesthetic is asso-

- A. Increased alveolar delivery
 - 1. Increased inspired anesthetic concentration
 - a. Increased vaporization of agent
 - b. Increased vaporizer dial setting
 - c. Increased fresh gas flow
 - d. Decreased gas volume of patient breathing circuit
 - 2. Increased alveolar ventilation
 - a. Increased respiratory rate
 - b. Decreased dead space ventilation
- B. Decreased removal from the alveoli
 - 1. Decreased blood solubility of anesthetic
 - 2. Decreased cardiac output
 - 3. Decreased alveolar-venous anesthetic gradient

Fig. 13.10. Factors related to a change in alveolar anesthetic tension (P_A , alveolar partial pressure).

ciated with a rapid anesthetic induction or change in anesthetic depth. Factors that contribute to a rapid change in the P_A of anesthetic are summarized in Fig. 13.10.

Delivery to the Alveoli

Delivery of anesthetic to the alveoli and therefore the rate of rise of the alveolar concentration or fraction (F_A) toward the inspired concentration or fraction (F_I) depends on the inspired-anesthetic concentration itself and the magnitude of alveolar ventilation. Increasing either one of these or both increases the rate of rise of the P_A of anesthetic; that is, with other things considered equal there is an increase in speed of anesthetic induction or change in anesthetic level.

Inspired Concentration The inspired concentration has a number of variables controlling it. First of all, the upper limit of inspired concentration is dictated by the agent vapor pressure, which in turn depends on temperature. This may be especially important considering the breadth of veterinary medical application of inhaled anesthesia and methods of vaporizing volatile

anesthetics under widely diverse conditions (some environmental conditions are quite hostile).

Characteristics of the patient breathing system can also be a major factor in generating a suitable inspired concentration under usual operating-room conditions. Characteristics of special importance include the volume of the system, the amount of rubber or plastic components of the system, the position of the vaporizer relative to the breathing circuit (i.e., within or outside of the circuit), and the fresh gas inflow to the patient breathing circuit. The patient breathing circuit contains a gas volume that must be replaced with gas containing the desired anesthetic concentration. Thus, the volume of the breathing circuit serves as a buffer to delay the rise of anesthetic concentration. In the management of small animals (i.e., animals weighing less than 10 kg) a non-rebreathing patient circuit and/or a relatively high fresh gas inflow into the patient breathing circuit is usually used, so there should *not* be a clinically important difference between the delivered (e.g., vaporizer dial setting) and the inspired concentrations. That is, when the vaporizer dial setting is adjusted to the desired concentration setting, the fresh gas plus anesthetic flowing from the vaporizer almost immediately contains the dialed anesthetic vapor concentration. In addition, the total gas flow is high relative to the volume of the delivery circuit, so the anesthetic concentration in the inspired breath is rapidly increased. However, with animals weighing more than 10 kg, a circle, CO_2 absorber (i.e., rebreathing), patient breathing circuit is most commonly used for inhalation anesthesia. The volume of this breathing circuit may be very large compared with fresh gas inflow. This volume markedly delays the rate of rise of inspired-anesthetic concentration because the residual gas volume must be “washed out” and replaced by anesthetic containing fresh gas in order for the inspired concentration to increase to that delivered from the vaporizer (Fig. 13.11). In addition, exhaled gas (minus CO_2) is rebreathed to varying degrees with these circuits. The inspired gas is composed of exhaled and fresh gases. Because the expired gas contains less anesthetic than does the fresh gas, the inspired-anesthetic gas concentration

Fig. 13.11. A comparison of the rate of increase of inspired-halothane concentration toward a constant-delivered concentration $F_{\text{insp}}/F_{\text{del}}$ in a 7-L small animal anesthetic breathing circuit (SAAM) at fresh gas flow rates of 1, 3, 6, and 12 L/min (LPM).¹⁷

Table 13.5. Vaporizer positioning within or outside of a circle patient rebreathing circuit influences inspired anesthetic concentration

Factor	Vaporizer Positioning	
	Out of Circuit	In Circuit
Increase ventilation	Decrease	Increase
Increase fresh gas (O_2) inflow to circuit	Increase	Decrease

will be less than that of the fresh gas leaving the vaporizer.

In veterinary applications, the delaying influence of the circle circuit is most notable with anesthetic management of very large animals such as horses¹⁷ and cattle and/or when using a closed-circuit fresh gas flow rate (i.e., where O_2 is the fresh gas, and its inflow [plus anesthetic] to the circuit just meets the metabolic needs of the patient). With closed-circuit delivery, the fresh gas inflow is very low relative to the circuit volume.^{7,10,17}

The high solubility of some older anesthetics (e.g., methoxyflurane) (Table 13.4) in rubber and plastic also delays development of an appropriate inspired-anesthetic concentration. The loss of anesthetic to these equipment “sinks” serves to increase the apparent volume of the anesthetic circuitry and may, in some cases, be clinically important (e.g., the use of rubber hoses and a large rubber rebreathing bag on circuits designed for anesthetic management of horses). With the newest inhalation anesthetics and more modern anesthetic-delivery equipment this issue is of minor or no clinical importance.

Positioning the vaporizer in relation to the patient breathing circuit will influence inspired-anesthetic concentration.^{16,18} For example, with the vaporizer positioned within a circle rebreathing circuit, a decrease in inspired concentration will follow an increase in fresh gas inflow to the circuit, whereas an increase in inspired concentration will result if the vaporizer is positioned outside the circuit (Table 13.5). With the loss of methoxyflurane to clinical practice most vaporizers in use, at least in North America, are agent-specific, precision vaporizers. This style of vaporizer is always placed upstream and outside of the patient breathing circuit.

Alveolar Ventilation An increase in alveolar ventilation increases the rate of delivery of inhalation anesthetic to the alveolus (Fig. 13.12). If unopposed by blood and tissue uptake of anesthetic, alveolar ventilation would rapidly increase the alveolar concentration of anesthetic so that within minutes the alveolar concentration would equal the inspired concentration. However, in reality the input created by alveolar ventilation is countered by absorption of anesthetic into blood. Predictably, hypoventilation decreases the rate at which the alveolar concentration increases over time compared with the inspired concentration (i.e., anesthetic induction is slowed). Alveolar ventilation is altered by changes in anesthetic depth (increased depth usually means de-

Fig. 13.12. The effect of ventilation on the rise of the alveolar concentration (F_A) of halothane toward the inspired (F_I) concentration. As noted, the F_A/F_I ratio increases more rapidly as ventilation is increased from 2 to 8 L/min. Redrawn from Eger,¹⁰ with permission.

creased ventilation), mechanical ventilation (usually increased ventilation), and dead-space ventilation (i.e., for any constant minute ventilation, a decrease in dead-space ventilation results in an increase in alveolar ventilation).

Alveolar ventilation and thus the alveolar anesthetic concentration can also be influenced by administering a potent inhalation anesthetic like halothane in conjunction with N_2O . Very early in the administration of N_2O (during the period of large volume uptake; the first 5 to 10 min of delivery) the rate of rise of the alveolar concentration of the concurrently administered inhalation anesthetic is increased. This is commonly referred to as the *second gas effect*, and this phenomenon can be applied clinically to speed anesthetic induction.^{10,14,19}

Removal from Alveoli: Uptake by Blood

As noted by Eger,¹⁰ anesthetic uptake is the product of three factors: solubility (S , the blood-gas solubility [Table 13.4]), cardiac output (CO), and the difference in the anesthetic partial pressure between the alveolus and venous blood returning to the lungs ($P_A - P_I$), expressed in mm Hg:

$$\text{uptake} = S \times CO(P_A - P_I/P_{\text{bar}})$$

where P_{bar} = barometric pressure in mm Hg. Note that if any of these three factors equals zero there is no further uptake of anesthetic by blood.

Solubility As previously discussed the solubility of an inhalation anesthetic in blood and tissues is characterized by its PC (Tables 13.2 and 13.3). Remember that a PC describes how an in-

Fig. 13.13. The rise in the alveolar anesthetic concentration (F_A) toward the inspired concentration (F_I). Note that the rise is most rapid with the least soluble anesthetic, nitrous oxide, and slowest with the most soluble anesthetic, methoxyflurane. All data are from studies in people. The curves are redrawn from Eger.^{1,326}

halation anesthetic distributes itself between two phases or two solvents (e.g., the quantity of agent in blood and alveoli [gas] or blood and muscle, respectively) once equilibrium is established (i.e., when the anesthetic partial pressure is equal). Based on blood-gas PCs, inhalation anesthetics range from highly soluble (methoxyflurane) to poorly soluble (N_2O , desflurane, and sevoflurane). Agents such as halothane and isoflurane are intermediary.

Compared with an anesthetic with high blood solubility (PC), an agent with low blood solubility is associated with a more rapid equilibration because a smaller amount of anesthetic must be dissolved in the blood before equilibrium is reached with the gas phase. In the case of the agent with a high blood-gas PC the blood acts like a large “sink” into which the anesthetic is poured, and accordingly blood is “reluctant” to give up the agent to other tissues (such as the brain). The blood serves as a conduit for drug delivery to the brain and as such can be visualized as a pharmacologically inactive reservoir that is interposed between the lungs and the agent’s site of desired pharmacological activity (i.e., brain). Therefore, an anesthetic agent with a low blood-gas PC is usually more desirable than a highly soluble agent, because it is associated with (a) a more rapid anesthetic induction (i.e., more rapid rate of rise in alveolar concentration during induction [Fig. 13.13]); (b) a more precise control of anesthetic depth (i.e., alveolar concentration during the anesthetic maintenance); and (c) a more rapid elimination of anesthetic and recovery (i.e., a rapid decrease in alveolar concentration during recovery).

Fig. 13.14. The effect of cardiac output on the rise of the alveolar concentration (F_A) of halothane toward the inspired concentration (F_I). As noted, the F_A/F_I ratio increases more rapidly as cardiac output is decreased from 18 to 2 L/min. Redrawn from Eger.¹⁰

Cardiac Output The amount of blood flowing through the lungs and into body tissues also influences anesthetic uptake from the lungs. The greater the CO, the more blood is passing through the lungs carrying away anesthetic from the alveoli. Thus, a large CO, like increased anesthetic-agent blood solubility, delays the alveolar rise of P_{anes} (Fig. 13.14). Patient excitement is an example in which a relatively large CO is anticipated. Conversely, a reduced CO should be anticipated with a patient in shock. Such a situation would be associated with an increase in the rate of the P_A increase of the anesthetic, and this, along with other factors, make the anesthetic induction more rapid and risky.

Alveolar to Venous Anesthetic Partial Pressure Difference The magnitude of difference in anesthetic partial pressure between the alveoli and mixed venous blood is related to the amount of uptake of anesthetic by tissues. It is not surprising that the largest gradient occurs during induction. Once the tissues no longer absorb anesthetic (i.e., equilibrium is reached), there is no longer any uptake of anesthetic from the lungs because $P_I = P_A$ (i.e., the mixed venous blood returning to the lungs contains as much anesthetic as when it left the lungs). The changes in gradient between the initiation of induction and equilibration result in part from the relative distribution of CO. In this regard it is important to recognize that roughly 70% to 80% of the CO is normally directed to only a small volume of body tissues in a lean individual.^{20,21} Tissues such as the brain, heart, hepatoportal system, and kidneys represent only about 10% of the body mass but normally receive about 75% of the total blood flow each minute. As a result these highly perfused tissues equilibrate rapidly with arterial anesthetic partial pressure when compared with other body

Fig. 13.15. The fall in alveolar concentration (F_A) relative to the alveolar concentration at the end of anesthesia (F_{A0}). Note that the newest, most insoluble volatile anesthetic, desflurane, is eliminated in humans more rapidly than are the other contemporary potent anesthetics. Not shown is information for methoxyflurane. If present, the curve for methoxyflurane would appear above that for halothane. From Eger,³²⁶ with permission.

tissues (actual timing is influenced by agent solubility). Since the venous anesthetic pressure or tension equals that in the tissue within 10 or 15 min, about 75% of the blood returning to the lungs is the same as the alveolar tension. This presumes there has been no change in arterial anesthetic partial pressure during this time and thus uptake is reduced. Skin and muscle comprise the major bulk of the body (about 50% in humans) but at rest receive only about 15% to 20% of the CO, so saturation of these tissues requires several hours. Fat is a variable component of body bulk and receives only a small proportion of blood flow. Consequently, anesthetic saturation of this tissue is very slow because all anesthetics are considerably more soluble in fat than in other tissue groups (Table 13.2).

Other factors can influence the magnitude of the alveolar to arterial anesthetic partial pressure gradient. For example, abnormalities of ventilation-perfusion cause an alveolar-arterial gradient proportional to the degree of abnormality.^{10,22,23} Others include loss of anesthetic via the skin²⁴⁻²⁶ and into closed gas spaces^{10,14,19} and metabolism.^{10,14}

Overview

The rate with which the alveolar anesthetic concentration increases relative to the inspired concentration (i.e., the rate of change in anesthetic level) is often summarized as a plot of the ratio of F_A/F_I versus time. The position of individual curves representing different anesthetics on a plot is related to the solubility characteristics of the anesthetics (Fig. 13.13). The shape of the graph of F_A/F_I versus time is similar for all anesthetics (Fig. 13.13). A rapid initial rise results from the effect of alveolar ventilation bringing anesthetic into the lung. The rate of rise of the curve then decreases as uptake by the blood occurs. With time the highly perfused tissues of the body equilibrate with incoming blood so that eventually about three-quarters of the total blood flow returning to the heart has the same anesthetic partial pres-

sure as it had when it left the lungs. Thus, further uptake from the lung is decreased, and the rate of approach of the F_A to F_I over time is further decreased.

Anesthetic Elimination

Recovery from inhalation anesthesia results from the elimination of anesthetic from the CNS. This requires a decrease in alveolar anesthetic partial pressure (concentration), which in turn fosters a decrease in arterial and then CNS anesthetic partial pressure (Fig. 13.9). Prominent factors accounting for recovery are the same as those for anesthetic induction. Therefore, factors such as alveolar ventilation, CO, and especially agent solubility greatly influence recovery from inhalation anesthesia. Indeed, the graphic curves representing the washout of anesthetic from alveoli versus time (Fig. 13.15) are essentially inverses of the wash-in curves. That is, the washout of the less soluble anesthetics is high at first (i.e., rapid washout by ventilation of the lung functional residual capacity) and then rapidly declines to a lower output level that continues to decrease but at a slower rate. The washout of more soluble agents is also high at first, but the magnitude of decrease in alveolar anesthetic concentration is less and decreases more gradually with time (Fig. 13.15).

An important factor during the washout period is the duration of anesthesia. This effect and a comparison of this effect between three agents spanning a range of blood solubilities is summarized in Fig. 13.16.²⁷ If a patient rebreathing anesthetic circuit (e.g., circle system) is in use and the patient is not disconnected from the circuit at the end of anesthesia, the circuit itself may also reduce the rate of recovery, just as the circuit was shown to decrease the rate of rise of anesthetic during induction. This influence of rebreathing circuits can be reduced by directing high flow rates of anesthetic-free O₂ into the anesthetic circuit (i.e., applying principles of a non-rebreathing circuit).

Other factors that are important to varying degrees to inhala-

Fig. 13.16. The decrease in the alveolar anesthetic concentration (F_E) from the concentration at the time of breathing circuit disconnect (i.e., the beginning of recovery from anesthesia; F_{EO}) is influenced by both the solubility (λ) of anesthetic and the duration of anesthesia. From Stoelting and Eger,²⁷ with permission.

tion anesthetic elimination from the body include percutaneous loss, intertissue diffusion of agents, and metabolism. Transcutaneous movement of inhalation agent occurs, but the amount under consideration is small.^{24–26,28} Intertissue diffusion is of theoretical interest, but its clinical importance is limited.^{29–31} Metabolism may also play a small role with some inhalation anesthetics (e.g., methoxyflurane and perhaps even halothane), especially when associated with prolonged anesthesia.^{29,32–34}

A special consideration associated with recovery after use of N_2O also deserves comment. *Diffusion hypoxia* is a possibility at the end of N_2O administration when the patient breathes air immediately rather than O_2 for at least a brief transition period (i.e., 5 to 10 min).^{35–37} In this case a large volume of N_2O enters the lung from the blood. This early rapid inflow of N_2O to the lung displaces other gases within the lung. If at this time the patient is breathing air (only about 21% O_2) rather than 100% O_2 , N_2O dilutes alveolar O_2 , further reducing O_2 tension from levels found in ambient air. This action may cause life-threatening reductions in arterial oxygenation. Since the major effect is in the first few minutes after discontinuing N_2O , the condition can be prevented by administering pure O_2 at the conclusion of N_2O administration rather than allowing the patient to breathe ambient air immediately.

Biotransformation

Inhalation anesthetics are not chemically inert.³⁸ They undergo varying degrees of metabolism primarily in the liver but also to lesser degrees in the lung, kidney, and intestinal tract.^{32,39–42} The importance of this is twofold. First, in a very limited way with older anesthetics, metabolism may facilitate anesthetic recovery. Second and more important is the potential for acute and chronic toxicities by intermediary or end metabolites of inhalation agents, especially on kidneys, liver, and reproductive organs.^{32,42}

The magnitude of metabolism of inhalation anesthetic agents is determined by a variety of factors, including the chemical structure, hepatic enzyme activity (cytochrome P-450 enzymes located in the endoplasmic reticulum of the hepatocyte), the blood concentration of the anesthetic,⁴³ disease states, and ge-

Table 13.6. Biotransformation of inhalation anesthetics in humans

Anesthetic	% Anesthetic Metabolized	References

netic factors (i.e., some species and individuals are more active metabolizers of these drugs than are others, e.g., humans compared with rats).

An indication of the extent of biotransformation of contemporary inhalation anesthetics is presented in Table 13.6. Sevoflurane degrades *in vivo* to about the same extent as isoflurane and as indicated by transient postanesthetic increases in blood and urinary fluoride levels in rats,^{44–48} dogs,⁴⁷ horses,^{49–51} swine,⁵² and people.⁵³ The peak serum fluoride concentrations observed in people during and after sevoflurane anesthesia are low, and nephrotoxicity is not expected.^{53,54} Desflurane resists degradation *in vivo*.^{52,55,56} The increase in serum inorganic fluoride is much smaller than that found with isoflurane.^{52,55,56}

For further information on the biotransformation of inhalation anesthetics in general and for specific details regarding individual anesthetic agents, readers are referred to reviews by Baden and Rice³² and Mazze and Fujinaga.⁴²

Anesthetic Dose: The Minimum Alveolar Concentration

In 1963 Merkel and Eger described what has become the standard index of anesthetic potency for inhalation anesthetics: the

minimum alveolar concentration (MAC).⁵⁷ The MAC is defined as the minimum alveolar concentration of an anesthetic at 1 atmosphere that produces immobility in 50% of subjects exposed to a supramaximal noxious stimulus. Thus, the MAC corresponds to the median effective dose (ED₅₀): Half of the subjects are anesthetized and half have not yet reached that “level.” The dose that corresponds to the ED₉₅ (95% of the individuals are anesthetized), at least in people, is 20% to 40% greater than the MAC.⁵⁸ Anesthetic potency of an inhaled anesthetic is inversely related to the MAC (i.e., potency = 1/MAC). From information presented earlier, it also follows that the MAC is inversely related to the oil-gas PC. Thus, a very potent anesthetic like the formally available agent methoxyflurane, which has a high oil-gas PC, has a lower MAC, whereas an agent with a low oil-gas PC has a higher MAC.

A number of characteristics of the MAC deserve emphasis.¹⁰ First, the A in MAC represents *alveolar* concentration, not inspired or delivered (e.g., as from a vaporizer). This is important because the alveolar concentration is easily monitored with contemporary technology. Also, as we reviewed earlier, after sufficient time for equilibration (minutes), alveolar partial pressure will more closely approximate arterial and brain anesthetic partial pressures.

Second, the MAC is defined in terms of volume percent of 1 atmosphere and therefore represents an anesthetic partial pressure (P) at the anesthetic site of action; that is, remember, $P_x = (C/100) \cdot P_{\text{bar}}$, where P_x stands for the partial pressure of the anesthetic in the gas mixture, C is the anesthetic concentration in volume percent, and P_{bar} is the barometric or total pressure of the gas mixture. Thus, although the concentration at the MAC for a given agent may vary depending on ambient pressure conditions (e.g., sea level vs. high altitude), the anesthetic partial pressure always remains the same. For example, the MAC for isoflurane in healthy dogs is reported as 1.63 vol%. The study reporting this value was conducted at near sea level conditions at Davis, California (i.e., $P_{\text{bar}} = 760$ mm Hg). Based on the foregoing discussion, a MAC of 1.63 vol% represents an alveolar isoflurane partial pressure (P_{iso}) of 11.6 mm Hg. In comparison, for the same dog at Mexico City (elevation, 2240 m above sea level; $P_{\text{bar}} = 584$ mm Hg) the alveolar P_{iso} at the MAC is expected to be the same as determined at Davis (i.e., 11.6 mm Hg), whereas the MAC (i.e., the alveolar concentration) would be about 2.17 vol%.

Finally, it is important to note that the MAC is determined in healthy animals under laboratory conditions in the *absence* of other drugs and circumstances common to clinical use that may modify the requirements for anesthesia. General techniques for determining the MAC in animals are given elsewhere.^{10,59–62} In determining the MAC in people the initial surgical skin incision has been the standard noxious stimulus used.¹⁰ For the determination of the MAC in smaller animals (mice to dogs and pigs)^{10,63,64} the standard stimulus has been application of a forceps or other surgical clamp to the base of the tail or the base of the dewclaw of the limb (e.g., pigs⁶²), whereas electrical stimulus applied beneath the oral mucous membranes is most commonly used in larger species such as horses.⁶⁰

The MAC values for contemporary inhalation anesthetics for a

variety of animals commonly encountered in veterinary medicine are summarized in Table 13.7a and b. Values for humans are also listed for comparison. For values of agents of historical interest such as methoxyflurane, enflurane, or diethyl ether, readers are referred to the review in an earlier edition of this book or elsewhere.^{10,64}

Since its original introduction, the MAC concept has been extended to other stimulus end points in an effort to better define and understand the anesthetic state. For example, Stoelting and coworkers⁶⁵ determined the value for the MAC of an anesthetic at which people opened their eyes on verbal command during emergence from anesthesia; this has been termed *MAC-awake*. The verbal stimulus is of course less intense than the surgical incision in people and thus the response occurs at a lower concentration of anesthetic than movement following incision. The end-tidal concentration preventing movement in response to tracheal intubation (the MAC for intubation) is more stimulating to people than is surgical incision and was described by Yakaitis and colleagues.^{66,67} Roizen and colleagues⁶⁸ reported an even greater alveolar concentration necessary to prevent adrenergic response (rise in endogenous catecholamines) to skin incision (also in human patients) compared with the concentration necessary to just prevent movement; this is known as *MAC-BAR*. Thus, a group of response curves is possible and depends on the chosen strength of the stimulus applied.

In a single species the variability in the MAC (response to a noxious stimulus) is generally small and not substantially influenced by gender, duration of anesthesia, variation in arterial CO₂ partial pressure (PaCO₂) (from 10 to 90 mm Hg), metabolic alkalosis or acidosis, variation in arterial oxygen partial pressure (PaO₂) (from 40 to 500 mm Hg), moderate anemia, or moderate hypotension^{10,64,69} (Table 13.8). Even between species the variability in the MAC for a given agent is usually not large. However, there is at least one notable exception (Table 13.7a). In humans, the MAC for N₂O is 104%, making it the least potent of the inhalation anesthetics currently used in this species. Its potency in other species is less than half that in humans (i.e., around 200%). Because the N₂O MAC is above 100% it cannot be used by itself at 1 atmosphere pressure in any species and still provide adequate amounts of O₂. Consequently, and assuming that the MAC values for combinations of inhaled anesthetics are additive, N₂O is usually administered with another more potent inhalant agent to thereby reduce the concentration of the second agent necessary for anesthesia (Fig. 13.17). However, because of the potency difference between animals and people, the amount of reduction differs in an important way. For example, administration of 60% N₂O with halothane reduces the amount of halothane needed to produce the MAC by about 55% in healthy people (Fig. 13.17) but reduces it only by about 20% to 30% in dogs. As noted in Fig. 13.17, the response of other animals most closely resembles that of dogs. Some physiological factors and drugs that influence the MAC are listed in Table 13.8.

Equipotent doses (i.e., equivalent concentrations of different anesthetics at the MAC) are useful for comparing effects of inhalation anesthetics on vital organs. In this regard anesthetic dose is commonly defined in terms of multiples of the MAC (i.e., 1.5

or 2.0 times the MAC or simply 1.5 MAC or 2.0 MAC). From the preceding discussion, therefore, the ED₅₀ equals the MAC or 1.0 MAC and represents a light level of anesthesia (clearly inadequate in 50% of otherwise unmedicated, healthy animals). The ED₉₅ is 1.2 to 1.4 MAC, and 2.0 MAC represents a deep level of anesthesia, in some cases even an anesthetic overdose. The concept of MAC multiples can be used to compare drug effects and contrast pharmacodynamics of multiple doses of a specific drug.

Pharmacodynamics: Actions and Toxicity of the Volatile Anesthetics

All contemporary inhalation anesthetic agents in one way or another influence vital organ function. Some actions are inevitable and accompany the use of all agents, whereas other actions are a special or prominent feature of one or a number of the agents. In addition, dose-response relationships of inhalation anesthetics are not necessarily parallel. Differences in action, and especially

undesirable action, of specific anesthetic agents form the basis for selecting one agent over another for a particular patient and/or procedure. Undesirable actions also provide primary impetus for development of new agents and/or anesthetic techniques.

Data from healthy animals exposed to equipotent alveolar concentrations of these drugs under controlled circumstances provide foundation information for this review. In other cases, results of studies of human volunteers form the basis of our understanding of some drug actions. Because animals are com-

monly allowed to breathe spontaneously during clinical management of general anesthesia (versus controlled mechanical ventilation) investigational results obtained from spontaneously breathing test animals are often considered baseline by veterinarians. In the broader anesthesiology and pharmacology literature, however, results of studies from human volunteers or animals administered precise amounts of inhalation anesthetics during controlled ventilation (and normocapnia) most commonly form the basis of comparison of pharmacodynamic differences. It is important to stress that many variables other than mode of ventila-

Fig. 13.17. When nitrous oxide (N_2O) is combined with halothane the alveolar concentration of halothane at minimum alveolar concentration is decreased. However, the halothane sparing imposed by nitrous oxide (N_2O) is less in animals compared with humans. From Steffey and Eger,²¹⁶ with permission.

tion commonly accompany anesthetic management of animals in both clinical and laboratory settings. These variables influence drug pharmacodynamics and may cause individuals to respond differently than test subjects that were studied under standardized conditions. Such confounding variables include species, duration of anesthesia, noxious (painful) stimulation, coexisting disease, concurrent medications, variation in body temperature, and extremes of age as examples.

Central Nervous System

Inhalation anesthetics affect the CNS in many ways. Mostly these agents are selected because they induce a reversible, dose-related state of CNS (somatic and motor), but also hemodynamic and endocrine, unresponsiveness to noxious stimulation: that is, a state of *general anesthesia*. Interestingly, although clinical anesthesia was introduced more than 150 years ago, the sites and mechanisms by which general anesthetics (including the inhalation anesthetics) cause unresponsiveness to surgical or other forms of noxious stimulation remain unknown. Traditionally, this summary state we refer to as general anesthesia was assumed to result from a focus in the brain. However, mounting evidence is causing a shift in thinking such that this state we know as general anesthesia is likely the collection of a number of end points that are distinct and site specific, and include supraspinal and spinal events. For example, actions focused in the brain (especially the cerebral cortex and thalamus) mediate such centrally recognized components of general anesthesia as amnesia (at least in humans) and hypnosis (sleep), whereas the spinal cord appears to be a critical site of anesthetic action that suppresses noxious-evoked movement.^{70–72} In-depth review of known neural effects and theories of mechanism of action of inhalation anesthetics is beyond

the scope of this clinically focused review. Accordingly, readers with further interest in these subjects are referred to recent reviews by investigators currently active in this work.^{73,74}

Inhalation anesthetics influence electrical activity of the brain, cerebral metabolism, cerebral perfusion, intracranial pressure, and analgesia—issues of critical importance to anesthetic management of animals.

Electroencephalographic Effects

The electroencephalograph (EEG) is used to help identify pathological brain disorders and to predict the outcome of brain insults. Studies have also shown that general anesthesia alters EEG parameters, and we apply this knowledge to better understand anesthetic circumstances. The EEG signal (wave) contains two basic parameters within a time frame (i.e., continues or an epoch): amplitude and frequency. *Amplitude* is the electrical height of the waves in volts, and *frequency* is the number of times per second the wave crosses the zero voltage reference point. The signal from an alert, attentive brain is usually low amplitude and high frequency. When events that lead the brain to produce higher frequencies occur, the EEG is described as *activated*, and it is considered *depressed* when slower frequencies are noted. General characteristics of the normal EEG are that it is symmetrical, the patterns are predictable, and spike waveforms are not present. All anesthetics do not produce exactly the same changes in EEG pattern as dose (anesthetic depth) increases, so the generic correlation of the raw EEG pattern with anesthetic dose is not precise. Indeed, despite some weak correlations and its usefulness as an indication of changing anesthetic depth, no parameter has had sensitivity and specificity sufficient to justify use of the EEG alone as a reliable index of anesthetic depth.⁷⁵ With technological advances of recent years, research has focused on use of processed EEG parameters (e.g., the bispectral index) as improved descriptions of anesthetic states. However, this subject is beyond the scope of this chapter and therefore is explored elsewhere (see Chapter 38).

In general, as the depth of anesthesia increases from awake states, the electrical activity of the cerebral cortex becomes desynchronized. Using isoflurane as an example of the general EEG response to volatile anesthetics,¹ the frequency of the EEG activity (alveolar concentrations of <0.4 MAC) initially increases. With further increases in anesthetic concentration, a decrease in frequency and increased amplitude of the EEG waves occur. The wave amplitude increases to a peak (about 1 MAC), and then, with further dose increase, the amplitude progressively declines (burst suppression occurs at about 1.5 MAC; i.e., bursts of slow high-voltage activity separated by electrical silence) and eventually becomes flatline (predominance of electrical silence). With isoflurane, an isoelectric pattern occurs at about 2.0 MAC, whereas, on the other extreme, it is not seen with halothane until >3.5 MAC. Electrical silence does not occur with enflurane. The two newest volatile anesthetics—sevoflurane and desflurane—cause dose-related changes similar to those of isoflurane.^{76–78}

Several anesthetics in contemporary use have epileptogenic potential, especially in individuals predisposed to seizures. Enflurane is most prominent in this regard among the inhalation

anesthetics. Seizure activity is of concern because neuronal injury may result if demands for substrate (especially O₂) for maintaining neuronal function are greater than supply. A second concern is trauma to patients experiencing tonic-clonic muscle twitching, especially among horses. People assisting in the anesthetic and surgical management of these large patients may become injured. Finally, there is concern that seizures may persist into the postanesthetic period, especially unpredictably and when they occur in less well-controlled circumstances.

Systematic studies of EEG activity in people⁷⁹ and dogs⁸⁰ showed that enflurane was associated with spontaneous or noise-initiated intensified seizures. In addition, enflurane induces seizure activity that is associated with substantial increases in cerebral blood flow and cerebral metabolic use of O₂. In the studies by Joas et al.,⁸⁰ halothane, methoxyflurane, and isoflurane did not cause the frank epileptoid activity in dogs that was induced by enflurane. Indeed, both halothane and isoflurane have the capacity to produce an isoelectric EEG, with isoflurane doing so at a lower dose.¹ Present wide-spread opinion is that epileptogenesis is not a clinical concern with either agent.

The EEG responses to the two newest anesthetics—desflurane and sevoflurane—are reportedly similar to those of isoflurane,^{76–78} and all three can suppress drug-induced convulsive behavior.^{81–85} However, there are reports of seizure activity in animals^{86,87} and human patients^{88,89} during sevoflurane anesthesia. Because of the EEG-activating property of enflurane and perhaps sevoflurane it seems prudent to avoid their use in situations when events might predispose patients to seizures and when reasonable anesthetic alternatives exist.

Cerebral Metabolism

All volatile anesthetics decrease cerebral metabolic rate (CMR; cerebral O₂ consumption). The magnitude of decrease is least with halothane but similar with isoflurane, sevoflurane, and desflurane.^{76,81,86,90,91}

Cerebral Blood Flow

The volatile anesthetics cause no change or often an increase in cerebral blood flow (CBF).^{76,81,86,91,92} The effect on CBF is likely the sum of a tendency both to decrease as a result of anes-

themia reducing cerebral O₂ consumption and increase due to vasodilation caused by direct anesthetic action on vascular smooth muscle.⁹³ This can be summarized by saying the ratio of CBF relative to CMR is increased by the potent inhalation anesthetics. The effect is anesthetic dose related and influenced by agent. The rank order of CBF increase is generally regarded as halothane > enflurane, isoflurane, desflurane, and sevoflurane (all four being similar).⁶⁹ Effects on CBF have been shown to be time dependent in animals^{94–96} but not in humans.⁹⁷

Intracranial Pressure

The inhalation anesthetics increase intracranial pressure (ICP), and this change parallels the CBF increase that similarly accompanies these agents.^{76,98} In larger animals such as horses, body and head position further impacts the heart-to-brain hydrostatic gradient, which in turn can further impact ICP. Consequently, body position necessitates even greater consideration in anesthetized horses than is commonly considered in smaller species so as to minimize risks of inadequate CBF and cerebral ischemia.⁹⁹ It is generally regarded across species lines that ICP increases can be decreased by hyperventilation and decreasing PaCO₂.¹⁰⁰ Accordingly, use of hyperventilation is a common strategy in clinical situations in which even small elevations in ICP are of special concern. Mechanical ventilation and accompanying reduced PaCO₂ also reduce ICP in horses.¹⁰¹ However, because of the commonly associated, often large decrease in systemic blood pressure in this species, cerebral perfusion pressure may decrease out of proportion and further reduce CBF.

Analgesia

A clinically desirable general anesthetic includes both hypnotic and analgesic actions. However, studies to differentiate hypnotic potency from analgesic potency within the anesthetic-concentration range is, at the least, difficult to interpret. Studies of subanesthetic concentrations of inhalation anesthetics have been performed but with conflicting results. Some inhalation anesthetics have been reported to increase the response threshold to noxious stimulation compared with like, but unmedicated, conditions (e.g., diethyl ether), whereas others (e.g., isoflurane and sevoflurane) do not change the threshold,^{102,103} and still others, like halothane,¹⁰⁴ may decrease the threshold for response and contribute a heightened awareness to noxious stimulation (i.e., antianalgesia). More recent work even suggests that inhalation anesthetics (including diethyl ether and N₂O) can be antianalgesic.¹⁰⁵ An antianalgesic effect may enhance perception of noxious stimulation (pain) for varying periods during, for example, recovery from anesthesia when low-level alveolar concentrations are reached.

Respiratory System

Inhalation anesthetics depress respiratory system function. The volatile agents, in particular, decrease ventilation in a drug-specific and species-specific manner. Depending on conditions, including species of interest, some of the most commonly considered measures of breathing effectiveness—that is, breathing rate and depth (tidal volume)—may not be revealing or may even

Minimum alveolar concentration (MAC) is given in volume percent, and the AI is a ratio of the end-tidal anesthetic concentration at apnea and MAC. Similar data are not currently available for sevoflurane.

be misleading. In general, spontaneous ventilation progressively decreases as inhalation anesthetic dose is increased, because at low-dose tidal volume decreases more than frequency increases. As anesthetic dose is further increased, respiratory frequency also decreases. In otherwise unmedicated animals (as well as people) anesthetized with volatile agents, respiratory arrest occurs at 1.5 to 3.0 MAC (Table 13.9). The overall decrease in minute ventilation and the likely variable increase in dead-space ventilation (causing an increase in the dead space to tidal volume ratio, V_D/V_T , from a normal of about 0.3 to 0.5 or more) reduce alveolar ventilation. Decreases in alveolar ventilation are out of proportion to decreases in CO₂ production (O₂ use is decreased by general anesthesia), such that PaCO₂ increases (Fig. 13.18). In addition, the normal stimulation to ventilation caused by increased PaCO₂ (or decreased PaO₂) is depressed by the inhalation anesthetics, presumably via the action of these agents directly on the medullary and peripheral (aortic and carotid body) chemoreceptors.^{106–109} Changes in perianesthetic PaO₂ other than what might be related to the magnitude of alveolar ventilation are not notably different among the various inhalation anesthetics in a given species.

Bronchospasm is associated with some diseases and other patient conditions and contributes to increased airway resistance. A variety of early studies indicated that, among anesthetics available at the time, halothane was the most effective bronchodilator.^{110,111} The effect is believed to result at least partially by decreasing cholinergic neurotransmission.^{112,113} For years, therefore, it has been the anesthetic agent of choice for patients at risk of bronchospasm. The work of Hirshman and colleagues^{114,115} suggests that isoflurane and perhaps enflurane were as effective in decreasing experimentally produced airway resistance and therefore were good alternatives to halothane. More recent work with isoflurane, sevoflurane, and desflurane indicates that relaxation of constricted bronchial muscles by these agents is at least equal to or exceeds that caused by halothane.^{113,116,117}

Avoidance of airway irritation by inspiring inhalation anes-

Fig. 13.18. Respiratory response to an increase in the alveolar concentration (expressed in as a multiple of the minimum alveolar concentration [MAC]) of inhalation anesthetics in humans. PaCO₂, arterial carbon dioxide partial pressure. Data are taken from multiple sources.^{107,121–125}

thetics is important especially during induction of anesthesia because the irritation may cause breath holding, coughing, and laryngospasm (particularly in some species such as primates [human and nonhuman]) that, in turn, result in arterial oxyhemoglobin desaturation. At least in humans, none of the potent inhalation anesthetics seem to have irritant properties at subanesthetic concentrations. However, patient objection and airway irritation is evident with desflurane (and to a lesser degree with isoflurane¹¹⁸) at concentrations of 7% or greater,^{119,120} and as a result desflurane is not commonly used for anesthetic induction in human patients. Airway irritation has not been a generally recognized problem associated with induction of anesthesia in animals commonly anesthetized by veterinarians.

Arterial Carbon Dioxide Tension

The PaCO₂ is the most frequently used index of respiratory system response to general anesthetics. All contemporary inhalation anesthetics depress alveolar ventilation and, as a consequence, increase PaCO₂ in dose-related fashion. Figure 13.18 summarizes the effects of inhalation anesthetics in humans, the species for which data are most complete.^{107,121–125} Actual rank order of the magnitude of hypoventilation imposed by the four contemporary volatile anesthetics at a common alveolar dose differs slightly depending on the species.

Factors Influencing Respiratory Effects

Mode of Ventilation Ventilation is often assisted or controlled during inhalation anesthesia to compensate for the anesthetic-induced

respiratory depression. Controlled mechanical ventilation (i.e., the anesthetist controls both respiratory frequency and tidal volume) is used to predictably maintain a normal, or some other specific, PaCO₂ during anesthesia. Assisted ventilation (i.e., the anesthetist augments tidal volume, but the animal determines its own breathing frequency) is used to attempt to improve the efficiency of oxygenating arterial blood and reduce the work of breathing but is usually not effective in substantially lowering PaCO₂ compared with circumstances associated with spontaneous ventilation (i.e., the animal controls both the rate and depth of breathing).^{126,127}

Duration of Anesthesia Respiratory function, including PaCO₂, is little changed for as long as up to 10 h of constant, low-dose halothane (or methoxyflurane) in dogs.^{128,129} This is also supported by work in humans¹³⁰ anesthetized with constant low-dose halothane. However, in horses anesthetized for 5 h with a constant dose of 1.2 MAC isoflurane a substantial temporal increase in PaCO₂ was noted.¹³¹ A similar, but more modest, trend was noted in horses when halothane was used for anesthesia.^{132,133} At least in some species, if alveolar dose of halothane is increased above about 1.0 to 1.3 MAC and maintained constant at a heightened level, the magnitude of change in hypoventilation also worsens with time.¹²⁹ Conversely, there is evidence for recovery from the ventilatory depressant effects of volatile anesthetics in humans.¹²⁵

Surgery and Other Noxious Stimulation Noxious stimulation may cause sufficient central nervous stimulation to lessen the ventilatory depression of the inhalation anesthetic.^{134–137} This effect is of course diminished with increasing anesthetic depth.

Concurrent Drug Administration In humans the substitution of N₂O for an equivalent amount of a concurrently administered, more potent volatile agent such as isoflurane lowers PaCO₂ more (prevents hypoventilation) than does the volatile agent alone.¹⁹ In dogs and monkeys anesthetized with halothane, ventilation was at least as, and sometimes more, depressed when N₂O was substituted for a portion of the halothane requirement.^{138,139} The addition of opioid drugs like morphine may increase the respiratory depression produced by an inhalation anesthetic.^{136,140–142}

Cardiovascular System

All of the volatile inhalation anesthetics cause dose-dependent and drug-specific changes in cardiovascular performance. The magnitude and sometimes direction of change may be influenced by other variables that often accompany general anesthesia (Table 13.10). The mechanisms of cardiovascular effects are diverse but often include direct myocardial depression and a decrease in sympathoadrenal activity.

Cardiac Output

All of the volatile anesthetics decrease CO. The magnitude of change is dose related and depends on agent. In general, among the contemporary agents in use with animals, halothane depresses CO the most.^{1,143–145} Desflurane in many ways is similar in cardiovascular action to isoflurane, whereas sevoflurane has

characteristics resembling both halothane and isoflurane. All three of the newer volatile anesthetics tend to preserve CO at clinically useful concentrations.^{51,119,146–154} The decrease in CO is largely due to a decrease in stroke volume as a result of dose-related depression in myocardial contractility.^{1,119,150,155–157}

The effect of inhalation anesthetics on heart rate (HR) is variable and depends on agent and species. For example, in humans, HR is not substantially altered with halothane anesthesia but is usually increased by isoflurane, desflurane, and sevoflurane.^{153,158,159} Compared with conditions in awake, calm dogs, HR is increased with the use of any of the four anesthetics listed.^{149,154} There is evidence to suggest that differences between agents in the degree of increase in HR in dogs are explained by differences in the vagolytic activity of the agents.¹⁵² In dogs the HR usually remains constant over a range of clinically useful alveolar concentrations in the absence of other modifying factors (e.g., noxious stimulation).^{143,144,149,154,160,161} The distribution of blood flow to organs is altered during inhalation anesthesia. Readers with special interest in these changes are referred elsewhere for further information.^{162,163}

Arterial Blood Pressure

Volatile anesthetics cause a dose-dependent decrease in arterial blood pressure (Fig. 13.19).^{15,51,143,147,151,154,164–168} In general the dose-related decrease in arterial blood pressure is similar regardless of the species studied.^{60,143,145,148,164–166,168–170} In animals the dose-related decrease in blood pressure with all four of the contemporary agents is usually related mostly to a decrease in stroke volume. In some cases (agent and/or species) a decrease in peripheral vascular resistance may also play an important, but lesser, role. This common scenario in animals differs from results generally reported from studies with people anesthetized at least with isoflurane, sevoflurane, and desflurane, whereby pressure decreases primarily from a decrease in systemic vascular resistance.^{15,171} Indices of anesthetic influence on cardiovascular collapse are listed in Table 13.11.^{143,172,173}

Cardiac Rhythm and Catecholamines

Inhalation anesthetics may increase the automaticity of the myocardium and the likelihood of propagated impulses from ectopic sites, especially from within the ventricle.¹⁷⁴ Although spontaneously derived dysrhythmias were most notable with earlier inhalation anesthetics (e.g., halothane), none of the three most re-

Fig. 13.19. Inhalation anesthetics cause a dose (expressed as multiples of the minimum alveolar concentration [MAC])-dependent decrease in mean arterial blood pressure (MAP) in dogs whose ventilation is mechanically controlled to produce eucapnia. N₂O, nitrous oxide. Data are from many sources and referenced in the text.

cently introduced ether-derivative agents appear to predispose the heart to generated extrasystoles. However, any such effect can be exaggerated by adrenergic agonists.¹⁷⁵ The association of cardiac dysrhythmias with adrenergic drugs and anesthetic agents has received extensive study.

Inhalation anesthetics may sensitize the heart to arrhythmogenic effects of catecholamines. Halothane is most notable in this regard, as it markedly reduces the amount of epinephrine necessary to cause ventricular premature contractions.¹⁷⁶ There is some evidence that deeper levels of halothane decrease this incidence,^{177–179} but this is not a consistent finding.¹⁸⁰ Enflurane and methoxyflurane are less potent in regard to their ability to sensi-

tize the heart to arrhythmogenic effects of epinephrine, and isoflurane, desflurane, and sevoflurane are least arrhythmogenic.^{1,179,181–186} The potential for dysrhythmias follows administration of most catecholamine-type drugs, although the magnitude of such potential varies with the drug coadministered^{186–191} and other associated conditions.¹⁹² Such considerations are important in the design of anesthetic plans for patients in which it is desirable or necessary to administer catecholamines, for example, local application to minimize blood oozing from highly vascular surgical sites, to minimize blood pressure, or for CO support, or in patients in which high blood levels of endogenous catecholamines are anticipated.

Factors Influencing Circulatory Effects

A variety of circumstances occasionally associated with the anesthetic management of veterinary patients may add to or negate the primary effects of the anesthetic. In most cases the most profound modifications of drug action are on cardiovascular function. Some factors influencing cardiovascular performance include mechanical ventilation and alterations in PaCO₂, noxious (surgical) stimulation, duration of anesthesia, and coexisting drugs.

Mode of Ventilation and PaCO₂ There may be considerable difference in the cardiovascular effects of inhalation anesthetics in animals breathing spontaneously compared with when their breathing is mechanically controlled (e.g., intermittent positive-pressure ventilation [IPPV]) to produce and maintain a normal PaCO₂. In general, and considering a broad range of circumstances, cardiovascular function is usually depressed during IPPV relative to actions during spontaneous ventilation. Such action results from either the direct mechanical actions (e.g., intermittent elevation of intrathoracic pressure and resultant decrease in venous return to the heart) or lessening of the indirect pharmacological action of PaCO₂¹⁹³ or both. Carbon dioxide has pharmacological actions important for these considerations. For example, an increased PaCO₂ has direct depressant actions on the heart and smooth muscle of the peripheral blood vessels (i.e., vessel dilation) but indirect (via sympathetic nervous system) stimulation of circulatory function.

In generally healthy, sympathetically intact animals (light anesthesia) the stimulatory actions of hypercapnia usually predominate, so increased CO and arterial blood pressure usually accompany an increase in PaCO₂, becoming lower when PaCO₂ is normalized.^{51,126,145,151,164,168,169,194–197}

Noxious Stimulation Noxious stimulation during anesthesia modifies the circulatory effect of inhalation anesthetics via stimulation of the sympathetic nervous system. An increase in arterial blood pressure and HR (CO) commonly accompanies noxious stimulation.^{68,136,137,198,199} The response is anesthetic dose related. For example, Roizen et al.⁶⁸ and Yasuda et al.¹⁹⁸ showed that deeper levels of halothane and enflurane decreased or prevented surgically induced increases in serum norepinephrine levels in human patients.⁶⁸ Anesthetic doses that block the response are in the range of 1.5 to 2.0 MAC.

Duration of Anesthesia Some cardiovascular effects of inhalation anesthetics may change with duration of anesthesia. For example, in humans, halothane anesthesia lasting 5 to 6 h is associated with an increase in values of some measures of cardiovascular function, such as CO and HR.^{195,200} Similarly, varying degrees of time-related changes have been reported with the use of enflurane,¹²⁵ desflurane,^{159,201,202} and others.^{158,201–205}

Temporal changes in cardiovascular function have also been reported in a variety of animals with the use of halothane,^{129,132,206,207} isoflurane,^{131,206,208} and sevoflurane.²⁰⁸ Dose of anesthetic^{129,158,209} and body posture during anesthesia^{133,210} apparently also play a temporal role in some species.

The causes of these changes remain unclear. In vitro, depression of the cat papillary muscle exposed to a constant concentration of halothane does not vary over a 3-h period.²¹¹ This observation suggests that temporal effects associated with inhalation anesthetics are not the result of improved intrinsic cardiac function. Studies on human volunteers have shown that temporal responses to halothane can be prevented if the subjects are given propranolol before anesthesia, which suggests that the mechanism is related to increasing sympathetic nervous system activity.²¹²

Usually the temporal changes associated with inhalation anesthetics are of only minor or no concern to clinicians. However, such changes must be considered when interpreting results of laboratory studies in which these agents are used for anesthetic management.

Concurrent Drug Administration Drugs administered immediately before or in conjunction with inhalation anesthetics (pre-anesthetic medication, injectable anesthetic induction drugs, vasoactive and cardiotoxic drugs, etc.) may influence cardiovascular function by altering the anesthetic requirement (i.e., the MAC and thereby increase or decrease anesthetic level) or by their own direct action on cardiovascular performance.

For example, N₂O is used on occasion as a substitute for a portion of a more potent inhalation anesthetic. Because of its own anesthetic potency (albeit small; remember, the MAC for N₂O in animals is in the range of 2 atmospheres [Table 13.7]) its use may facilitate delivery of a reduced amount of the potent volatile agent and thereby contribute to some cardiovascular sparing. Nitrous oxide may depress the myocardium directly, but this effect is usually counterbalanced by its sympathomimetic effect, often resulting in a net improvement in cardiovascular function compared with conditions without N₂O. In animal patients the magnitude of N₂O effect is clinically limited and species dependent.^{138,139,166,213,214} More complete summaries of its cardiovascular actions have been published elsewhere.^{215,216}

Injectable drugs, such as acepromazine, α₂-agonists, thiobarbiturates, and dissociatives (e.g., ketamine), are frequently administered to animals as part of their anesthetic management. These drugs confound the primary effects of the inhalation anesthetics and may accentuate cardiovascular depression. On the other hand, sympathomimetic drugs, such as ephedrine,²¹⁷ dopamine, and dobutamine,^{218,219} are frequently given to counteract unwanted cardiovascular depression of the anesthetic.

Effects on the Kidneys

It is generally regarded that present-day volatile inhalation anesthetics produce similar mild, reversible, dose-related decreases in renal blood flow and glomerular filtration rate and that such changes largely reflect an anesthetic-induced decrease in CO.¹⁷¹ However, some studies show little or no change in these kidney-related parameters.^{44,163,220,221}

As a consequence of the anesthetic-induced decrease in glomerular filtration, healthy anesthetized animals commonly produce a smaller volume of concentrated urine compared with when awake. An increase in serum urea nitrogen, creatinine, and inorganic phosphate may accompany especially prolonged anesthesia.^{222–225} The reduction in renal function is highly influenced by an animal's state of hydration and hemodynamics during anesthesia.²²⁶ Accordingly, attendant intravenous fluid therapy and prevention of a marked reduction in renal blood flow will lessen or counteract the tendency for reduced renal function. In most cases, effects of inhalation anesthesia on renal function are rapidly reversed after anesthesia.

Among the inhalation anesthetics, methoxyflurane is the most nephrotoxic. Although it is no longer available for use in human or animal patients, its actions are of pathophysiological interest and therefore is briefly reviewed here. Particularly in humans and some strains of rats, the use of methoxyflurane caused renal failure that was characterized not by oliguria but by a large urine volume unresponsive to vasopressin.³² This was caused by the biotransformation of methoxyflurane and the large release of free fluoride ion that, in turn, directly damaged the renal tubules. Although renal injury in animals is rare, renal injury has been reported in dogs when methoxyflurane was used in combination with tetracycline antibiotics²²⁷ and flunixin.²²⁷

With the possible exception of enflurane and sevoflurane, the breakdown of other inhalation anesthetics does not pose a risk of fluoride-induced nephrotoxicity. Biotransformation of enflurane and sevoflurane by humans following a moderate duration of anesthesia causes serum inorganic fluoride concentrations to increase even beyond the 50- $\mu\text{mol/L}$ level, which is normally considered the nephrotoxic threshold in humans.^{32,171,228,229} However, clinical, histological, or biochemical evidence of injury related to increases in fluoride has only rarely been reported in human patients. The overriding consensus is that sevoflurane has little potential for nephrotoxicity caused by defluorination.^{32,171} Two factors may explain the general lack of injury despite the body's ability to degrade sevoflurane. In 1977, Mazze et al.²³⁰ proposed that the area under the serum fluoride concentration-versus-time curve may be a more important determinant of nephrotoxicity than is peak serum fluoride concentration. Because sevoflurane is poorly soluble and is rapidly eliminated via the lungs the duration of its availability for biotransformation is notably limited. More recently, Kharasch and coworkers²³¹ proposed another consideration: Sevoflurane is primarily metabolized by the liver, whereas hepatic and renal sites are important for methoxyflurane breakdown. The relative lack of intrarenal anesthetic defluorination may markedly reduce its nephrotoxic potential. Studies have confirmed the increase in serum fluoride in horses anesthetized with sevoflurane.^{49–51} In these reports the

magnitude and time course of fluoride increase were similar to that reported for humans. In addition, as with humans, no evidence has been reported of untoward renal effects associated with the increase in fluoride in horses.

Sevoflurane is degraded by CO₂ absorbents such as soda lime and Baralyme.^{45,53} A nephrotoxic breakdown product—compound A—is produced.^{45,232} Compound A can cause renal injury and death in rats,²³³ and the concentration threshold for nephrotoxicity in rats^{234–236} is within the range of concentrations that may be found associated with the anesthetic management of human patients.²³⁷ Not surprisingly, compound A is formed in the breathing circuits used for animals in veterinary medical practice.²³⁸ The ultimate importance of *in vitro* sevoflurane degradation to the well-being of veterinary patients like dogs, cats, and horses⁵⁰ remains to be established. Until such time that additional data appear, it seems prudent to avoid sevoflurane for prolonged anesthesia especially with concurrent low fresh gas inflow to the breathing circuit (which promotes the concentration of compound A) and in patients with known or marginal kidney disease.

Effects on the Liver

Depression of hepatic function and hepatocellular damage may be caused by the action of volatile anesthetics. Effects may be mild and transient or permanent, and injury may be by direct or indirect action. Studies by Reilly et al.²³⁹ suggested that at least halothane (but likely also other potent inhalation anesthetics) substantially inhibits the drug-metabolizing capacity of the liver. A reduction in intrinsic hepatic clearance of drugs along with anesthetic-induced alteration of other pharmacokinetically important variables (e.g., reduced hepatic blood flow) fosters a delayed drug removal or an increase in plasma drug concentration during anesthesia. Examples of such circumstances have been reported.^{239–243} Prolonged or increased (relative to conditions in the unanesthetized animal) plasma concentrations of some drugs have important toxic implications, especially in physiologically comprised patients.

All of the potent inhalation anesthetics can cause hepatocellular injury by reducing liver blood flow and oxygen delivery. However, available data suggest that, of the four contemporary volatile anesthetics, isoflurane is most likely to better maintain tissue O₂ supply and thereby is the agent least likely to produce liver injury even when administered for prolonged periods. The effects of the two newest agents sevoflurane and desflurane are nearly similar to isoflurane, whereas halothane produces the most striking adverse changes.^{32,147,163,167,244–250} Results of investigations indicate that ancillary influences, including the use of N₂O,²⁵¹ concurrent hypoxia,^{249,252–254} prior induction of hepatic drug-metabolizing enzymes,^{255,256} mode of ventilation,²⁵⁷ and positive end-expired pressure,²⁵⁸ may worsen conditions and increase the likelihood of hepatocellular damage.

It now appears that especially halothane produces two types of hepatotoxicity in susceptible individuals. One is a mild, self-limiting postanesthetic form of hepatocellular destruction and associated increase in serum concentrations of liver enzymes. Signs of hepatotoxicity occur shortly after anesthetic exposure. The other

is a rare, severe, often fatal hepatotoxicity with delayed onset and largely clinically limited to human patients (i.e., halothane hepatitis) and thought to be an immune-mediated toxicity.^{259,260} The mechanism of halothane hepatitis may also be family related.²⁶¹ The increased incidence of hepatic injury associated with halothane was the principal factor leading to the decrease in the use of halothane for human patients nearly three decades ago.

Effects on Skeletal Muscle: Malignant Hyperthermia

Malignant hyperthermia (MH) is a potentially life-threatening pharmacogenetic myopathy that is most commonly reported in susceptible human patients^{262,263} and swine²⁶⁴ (e.g., Landrace, Pietrain, or Poland China strains). However, reports of its occurrence in other species are available.^{265–271} Its clinicopathological, histopathological, and genetic basis has recently been further described for horses.^{272,273} All of the four contemporary volatile anesthetics can initiate MH, but halothane is the most potent triggering agent relative to other inhalation anesthetics.²⁶³ The syndrome is characterized by a rapid rise in body temperature that, if not treated quickly, causes death. Monitoring of temperature and CO₂ production is warranted in susceptible or suspected patients. Patients known to be susceptible to MH can be anesthetized safely. Avoiding the use of triggering agents and administering prophylactic dantrolene before anesthesia are effective in preventing the onset of MH.²⁶³

Further discussions on the clinical pharmacology and use of volatile inhalant anesthetics in various species and disease conditions, and for special procedures and patients, can be found in other sections of this book that emphasize individual anesthetic patient management.

The Gaseous Anesthetic: Nitrous Oxide

Nitrous oxide was introduced into clinical practice more than 150 years ago. Since then, its use has formed the basis for the use of more general anesthetic techniques in human patients than any other single inhalation agent.¹⁹ Its use became widespread because of its many desirable properties, including low blood solubility (Table 13.2), limited cardiovascular and respiratory system depression, and minimal toxicity.¹⁹ Its use in the anesthetic management of animals became a natural extension of its use in people.

Dose

Nitrous oxide is not the ideal anesthetic for people or animals. As discussed earlier in this chapter, N₂O is not a potent anesthetic (Table 13.7a and b) and will not anesthetize a fit, healthy individual. To derive the important benefits from the use of N₂O, it is usually administered in high inspired concentrations. However, as the concentration of N₂O is increased, there is a change in the proportion and partial pressure of the various other constituents of the inspired breath, notably O₂. Consequently, to avoid hypoxemia, 75% of the inspired breath is the highest concentration that can be administered safely under conditions at sea level. Use of N₂O at locations above sea level requires a lower N₂O concentration to ensure an adequate partial pressure of inspiratory O₂

(PiO₂). Nitrous oxide has less value in the anesthetic management of animals than in that of human patients because the anesthetic potency of N₂O in animals is only about half that found for humans (e.g., the MAC for dogs is about 200% vs. about 100% for people [Table 13.7a]).^{10,216} Thus, the value of N₂O in veterinary clinical practice is primarily as an anesthetic adjuvant, that is, accompanying other inhaled or injectable drugs. Since the effects of N₂O on vital organ function (including cardiovascular and respiratory) in the absence of hypoxemia are small in most veterinary patients, benefit is afforded by enabling a certain reduction in the amount of the primary, more potent, inhaled or injectable anesthetic agent.

Kinetics

Nitrous oxide's low blood solubility (Table 13.2) is responsible for a rapid onset of action. Although it does not have the potency to produce anesthesia, it may be used to speed induction of inhalation anesthesia as a result of its own (albeit limited) CNS effects and, as mentioned earlier, also by augmenting the uptake of a concurrently administered more potent volatile anesthetic such as halothane: the second gas effect.^{10,19,274,275} When a high concentration of N₂O is administered concurrently in a mixture with an inhalation agent (e.g., N₂O plus halothane), the alveolar concentration of the simultaneously administered anesthetic (halothane) increases more rapidly than when the "second" gas has been administered without N₂O. The second gas effect is the result of an increased inspiratory volume secondary to the large volume of N₂O taken up (remember, N₂O is used at high concentrations)²⁷⁴ and a concentrating effect on the second gas in a smaller volume (and thus increased gradient for transfer to blood) as a result of the uptake of the large volume of N₂O.^{10,275} Results of a more recent study with desflurane confirms previous findings for the second gas effect.²⁷⁶

Pharmacodynamics

As noted previously, N₂O's effects on cardiovascular and respiratory function (other than reducing the inspired O₂ concentration) are small compared with other inhalation anesthetics. It does depress myocardial function directly, but its sympathetic stimulation properties counteract some of the direct depression (its own as well as that from accompanying volatile anesthetics).²¹⁶ As a result of its sympathetic nervous system activation it may contribute to an increased incidence of cardiac arrhythmias.^{277,278} There is evidence to suggest that its use contributes to myocardial ischemia in some circumstances.^{279–282} Overall, a conservative outlook regarding N₂O use relative to respiration and circulation is that significant concern is warranted only in patients with initially compromised function.^{283,284} As with any agent, its advantages and disadvantages should be weighed on an individual patient basis.

Nitrous oxide has little or no effect on liver and kidney function.^{285–287} Although there is evidence of N₂O-induced interference with the production of red and white blood cells by bone marrow, the risk of adverse outcomes to a patient exposed under most clinical veterinary circumstances is little or none.^{286,288} However, prolonged exposure to N₂O causes megaloblastic hematopoiesis

and polyneuropathy. Seriously ill patients may have increased sensitivity to these toxicities. Problems result from N₂O-induced inactivation of the vitamin B₁₂-dependent enzyme methionine synthase, an enzyme that controls interrelations between vitamin B₁₂ and folic acid metabolism.²⁸⁹ Although an occasional patient may develop signs suggestive of vitamin B₁₂ and folic acid deficiency after an anesthetic technique that includes the use of N₂O, this is a rare event in human and animal patients.^{286,290} Prolonged occupational or abusive exposure to N₂O may be equally harmful, and this potential harm should be considered in management plans of veterinary practices.^{32,286,291,292} Nitrous oxide is rapidly and mainly eliminated in the exhaled breath. The extent of biotransformation (to molecular nitrogen [N₂]) is very small and mainly by intestinal flora.^{32,293,294} (Table 13.6).

Transfer of Nitrous Oxide to Closed Gas Spaces

Gas spaces exist or may exist in the body under a variety of conditions and to varying degrees. For example, gas is normally found in the stomach and intestines. The gut is a dynamic reservoir; the gas it contains is freely movable into and out of it according to the laws of diffusion. The gas in the gut originates from air swallowing, normal production of bacterial behavior, chemical reactions, and diffusion from the blood. There is marked variability in both composition and volume of stomach and bowel gas (e.g., herbivore vs. carnivore). There are other natural air cavities, such as the air sinuses and the middle ear, and then there are circumstances in which air may be electively or inadvertently introduced as part of diagnostic or therapeutic actions (e.g., pneumoencephalogram, pneumocystogram, endoscopy, and vascular air emboli).

Potential problems associated with gas spaces arise when an animal breathing air is given a gas mixture containing N₂O.^{10,19} Nitrogen is the major component of air (80%) and of most gas spaces (methane, CO₂, and hydrogen are also found in variable quantities in the gut). When N₂O is introduced into the inspired breath, a reequilibration of gases in the gas space begins with N₂O quickly entering and N₂ slowly leaving. That is, because of its greater blood solubility, the volume of N₂O that can be transported to a closed gas space is many times the volume of N₂ that can be carried away.¹⁰ For example, the blood-gas PC for N₂O is 0.47 (Table 13.2), whereas that for N₂ is about 0.015.²⁹⁵ Thus, N₂O is more than 30 times more soluble in blood than is N₂ (0.47/0.015). The result of the net transfer of gas to the gas space can be manifested as an increase in volume, as with the gut,^{296,297} pneumothorax,²⁹⁷ or blood embolus;^{298,299} an increase in pressure (e.g., middle ear^{300,301} or pneumoencephalogram³⁰²); or both (as the distending limits of the compliant space are reached). Usually air is used to inflate the cuff of an endotracheal tube. This cuff is another relatively compliant, enclosed air space. Nitrous oxide will similarly expand this gas space and may increase the pressure exerted on the tracheal wall.^{303–305}

Diffusion Hypoxia

A further issue requiring consideration for the differential movement of N₂O and N₂ is at the end of anesthesia when N₂O is dis-

continued. Because of the large volume of N₂O stored in the body during anesthesia and the unequal change of N₂O for N₂, a deficiency in blood oxygenation may occur at the end of anesthesia if air is abruptly substituted for N₂O. As discussed earlier in this chapter, this condition is referred to as *diffusion hypoxia*.^{35,36} The rapid outpouring of N₂O from the blood into the lung causes a transient but marked decrease in alveolar PO₂, with a resultant decrease in PaO₂.

Interaction with Respiratory Gas Monitoring

Routine monitoring of expired CO₂ is increasingly important and possible in the operating room of veterinary hospitals. Nitrous oxide interferes with the accurate recording of CO₂ with some monitoring devices. This interaction must be considered in decisions regarding the purchasing of equipment and overall anesthetic management plan. A more complete summary of the advantages and disadvantages of N₂O use is available elsewhere.¹⁹ Brief summaries of practical considerations of N₂O use in veterinary practice have also been published.^{306,307}

Occupational Exposure: Trace Concentrations of Inhalation Anesthetics

Operating-room personnel are often exposed to low concentrations of inhalation anesthetics. Ambient air is contaminated via vaporizer filling, known and unknown leaks in the patient breathing circuit, and careless spillage of liquid agent. Measurable amounts of anesthetic gases and vapors are present in operating-room air under a variety of conditions.^{308–315} Personnel inhale and, as shown by studies, retain these agents for some time.^{316,317} The slow rate of elimination of some vapors (especially the more blood-soluble agents like halothane) enables retained trace anesthetic quantities to accumulate from one day to the next.

Concern is raised because epidemiological studies of humans and laboratory studies of animals have suggested that chronic exposure to trace levels of anesthetics may constitute a health hazard. The possibility that chronic exposure to low levels of anesthetic agents constitutes a hazard to health science personnel has attracted and maintained worldwide interest since the early 1970s. Of particular concern are reports that inhaled anesthetics possess mutagenic, carcinogenic, or teratogenic potential. Depending on the point in life at which exposure occurs, there is concern that these underlying mechanisms in turn may be responsible for an increased incidence of fetal death, spontaneous abortion, birth defects, or cancer in exposed workers.^{318–320} However, to date, no genotoxic effect of long-term or short-term exposure to inhaled anesthetics has been demonstrated in humans, and “the conclusion from both animal and human studies is that there is no carcinogenic risk either from exposure to the currently used inhaled anesthetics.”³²

Although the data to date, especially regarding effects on human reproduction, remain equivocal, a firm cause-and-effect relationship between chronic exposure to trace levels of anesthetics and human health problems does not exist. Although the risk

Table 13.12. Methods to reduce occupational exposure to inhalation anesthetics in the operating room

1. Use waste gas scavenger to collect gas from the pressure-relief (pop-off) valve of the patient breathing circuit and ventilator
2. Conduct *regular inspection* and *maintenance* to detect and repair leaks in anesthetic machines and patient breathing circuits, piped gas supplies (nitrous oxide), etc.
3. *Alter work practices* (e.g., minimize leaks around the face mask and turn off the vaporizer and fresh gas flow when the patient breathing circuit is not attached to the patient)
4. Ventilate operating rooms adequately
5. Monitor room trace anesthetic gas levels
6. Educate personnel

of long-term exposure to trace concentrations of anesthetics for those in operating-room conditions appears minimal, current evidence is suggestive enough to cause concern and to encourage practices to reduce the contamination by anesthetics of operating-room personnel. Indeed, exposure levels have been recommended by the government: 2.0 parts per million (ppm) for volatile agents and 25 ppm for N₂O.³¹⁸ In this regard, inexpensive methods to reduce and control anesthetic exposure by operating-room personnel are available and should be used (Table 13.12).

Frequent monitoring of actual levels of anesthetic gas or vapor is of obvious value and is encouraged in specialized circumstances and/or environments where there is high use. Likely the greatest impact results from educating personnel about the potential problem of waste anesthetic gases and methods for controlling exposure levels.^{318–321} For further information on this subject, readers are directed to a more complete report of current knowledge and conclusions from available data that have been developed by the American Society of Anesthesiologists (ASA) Task Force on Trace Anesthetic Gases of the ASA Committee on Occupational Health of Operating Room Personnel.³²²

Introduction

Local anesthetics are a group of chemically related compounds that reversibly bind sodium channels and block impulse conduction in nerve fibers.¹ The interruption of neural transmission in sensory afferent nerves or tracts by a local anesthetic drug after local tissue infiltration, regional nerve blocks, or epidural or intrathecal (subarachnoid) injection uniquely and most effectively prevents or reduces pain or nociceptive input during and after surgery. Analgesia in the desensitized area is not only complete by such techniques, but it also removes the immediate secondary (central) sensitization to pain and reduces the central facilitation of the nociceptive pathway. The use of a local anesthetic is essential if surgery is to be performed in a conscious patient and the pain associated with trauma and inflammation is to be relieved. The use of a local anesthetic technique before surgery may also benefit patients by avoiding general anesthesia or reducing the amount of required general anesthetics. Sustained analgesia into the recovery period is a great benefit to patients when a local anesthetic with a longer anesthetic effect is used. Knowledge of the clinical pharmacology of individual local anesthetics enables the achievement of effective and safe neural blockade. Each of the local anesthetic techniques discussed herein has its own particular rate of onset, duration, and risk of complication.

History

The 100-year history of local anesthetic use in humans has typically involved self-experimentation, followed by widespread application with little testing for electrophysiology and neurotoxicity in animals and humans. Desensitization of a body region dates from 1884, when Koller reported the first topical use of cocaine for rendering the eye temporarily insensible to pain at the Congress of the German Society for Ophthalmology.² However, cocaine was found to be extremely toxic and addictive. Einhorn synthesized procaine, the first nontoxic prototype of amino-ester local anesthetics, in 1904. Subsequently, other amino-ester local anesthetics, including tetracaine in 1932 and 2-chloroprocaine in 1955, were synthesized. The next milestone in local anesthetic synthesis was in 1943, when Lofgren developed lidocaine, the prototype for all subsequent amide-type local anesthetics. Within 60 years thereafter, additional amide local anesthetics were produced, including mepivacaine (1956), bupivacaine (1957), prilocaine (1959), etidocaine (1971), articaine (1974), and ropivacaine (1980s).^{3,4} Levobupivacaine is the newest member of the

amino-amide class of long-lasting local anesthetics approved by the Food and Drug Administration (FDA) in 1999.

Electrophysiological Effects

The conduction of impulses in excitable membranes requires a flow of sodium ions through selective sodium channels into the nerve in response to depolarization of the nerve membrane.⁵ Mammalian voltage-gated sodium channels consist of one large alpha subunit that contains four homologous domains (D1 to D4), each with six putative α -helical transmembrane segments (S1 to S6) and one or two smaller auxiliary beta subunits.⁶ Under resting conditions, sodium ions are at a higher concentration outside than inside the nerve, and a voltage difference across the axonal membrane, known as *resting potential*, of -70 mV exists. When the nerve is stimulated, the permeability of the membrane to sodium ions increases transiently, and sodium passes through the membrane by way of sodium-selective ionic channels that exist in various conformations (i.e., resting, open, or inactivated), depending on the transmembrane potential, depolarizing the plasma membrane. During the depolarization, the action potential moves in obligatory fashion along the axon, allowing for impulse propagation along the nerve membrane (Fig. 14.1). After a few milliseconds, the membrane repolarizes as a result of inactivation or “closing” of the sodium channels. During repolarization, the membrane is no longer permeable to sodium ions, but potassium channels open, and potassium ions flow down their electrochemical gradient out of the cell.¹

Mechanisms of Action

The precise mode of action of local anesthetic drugs is unknown. A number of theories have been offered: (a) the surface-charge theory (benzene’s lipophilic end binds to the membrane hydrophilic end in solution and increases the transmembrane potential), (b) the membrane-expansion theory (benzocaine expands the axonal membrane, compressing the ionic channels), (c) the specific-receptor theory (the biotoxins tetrodotoxin and saxitoxin bind to receptors at the external surface at or near the sodium channels, producing a potent conduction block, and (d) the combination membrane-expansion and specific-receptor theory. In this theory, the quaternary ammonium compounds (amides) and ester local anesthetics first pass through the cell membrane as the uncharged base (B) to reach the intracellular site where the uncharged base is protonated and the charged cation (conjugated acid, BH⁺) binds to the receptor and “plugs” the channel (Fig. 14.2).¹ Charged or hydrophilic drugs reach the receptor primarily through the open sodium channels and bind more strongly to the closed than open channel. Highly lipid-soluble molecules approach the receptor through the membrane. Perhaps best accepted is the idea that local anesthesia results when local anesthetics bind to sodium-selective ionic channels in nerves, inhibiting the sodium permeability that underlies action potential and depolarization of the cell membrane.⁷ Electrical transmission through a myelinated axon stops when enough concentration of the anesthetic is applied to bathe at least three consecutive nodes of Ranvier.^{8,9} More recently, local anesthetic binding has been mapped to homologue domains D4 to S6 and inactivation to D3

Fig. 14.2. Site of action of amino-ester and amino-amide local anesthetics. The uncharged base form diffuses most readily across the lipid barriers and interacts at the intermembrane portion of the sodium channel. The charged form (BH^+) gains access to a specific receptor via the axoplasmic surface of the sodium channel pore. Modified from Carpenter and Mackey,⁷⁶ p. 414, with permission.

to S6 of α -helical transmembrane segments of membrane proteins in sodium channels.⁶

Frequency-Dependent Block

Local anesthetics may differ in their ability to bind to sodium channels, depending on the channel status.¹⁰ Open ion-conducting and inactivated sodium channels have a greater local anesthetic affinity than resting, nonconducting sodium channels. If a frog sciatic nerve preparation is stimulated at low frequency (3 Hz) and exposed to a low concentration of a local anesthetic (1.5 mM lidocaine, 0.125 mM etidocaine, or 0.06 mM tetracaine), a minor decrease in impulse transmission develops. An increase in the stimulus frequency (100 Hz) increases the degree of block.¹¹ Repetitive stimulation of nerve fibers increases the binding affinity of the receptor site for local anesthetics and facilitates the development of neural blockade, a phenomenon called *use-dependent* or *frequency-dependent block*, or *phasic block*.

Other Mechanisms of Action

Local anesthetics will bind to many different sites that may contain a variety of different sodium channels. The sodium channels in the heart, brain, and axons are not identical.¹² However, if local anesthetics achieve a sufficient tissue concentration, they will affect all excitable membranes, including such as exist in the heart, brain, and neuromuscular junction. The molecular mechanisms by which local anesthetics produce epidural or spinal (subarachnoid) analgesia may include local anesthetic binding to sodium and potassium channels within the dorsal and ventral horns¹³ and binding to neural calcium channels, which causes hyperpolarization of cell membranes.¹⁴ Alterations in membrane calcium ion (Ca^{2+}) may be responsible for deformation or expansion of the cell membrane and thus the transmission or conduc-

tion of nerve impulses.¹⁵ Local anesthetics may inhibit substance P binding and evoked increases in intracellular calcium (Ca^{2+}),¹⁶ and potentiate γ -aminobutyric acid (GABA)-mediated chloride currents by inhibiting GABA uptake.¹⁷ Spinal anesthesia may also be mediated via complex interactions at neural synapses and disruption of electrical information coding.¹⁸

Other chemicals, such as toxins, α_2 -adrenergic agonists, ketamine, meperidine, calcium-channel blockers, antihistamines, anticholinergics, alcohol, anticonvulsants, barbiturates, and volatile general anesthetics also bind and inhibit sodium channels and often exhibit weak local anesthetic activity.^{19–21} Xylazine,²² ketamine,²³ and meperidine²⁴ have reportedly produced perineal anesthesia when applied to the caudal epidural space of horses.

Antimicrobial Activity

Additional and sometimes controversial benefits of local anesthetics, which are routinely administered before minor skin surgery and for postoperative pain relief, include both a potent antimicrobial effect^{25–27} and improved wound healing.^{28,29}

Administration of 1%, 2%, and 4% lidocaine demonstrates a dose-dependent inhibition of growth for all strains of bacteria tested (e.g., *Staphylococcus aureus*, *Escherichia coli*, *Pseudomonas aeruginosa*, and *Enterococcus faecalis*) and no change in the susceptibility of the bacteria to lidocaine by the addition of epinephrine.²⁶ Likewise, administration of 2% and 5% lidocaine and 1% prilocaine demonstrates a powerful antimicrobial effect on various bacteria, including *Escherichia coli*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Candida albicans*.²⁷ In contrast, 0.25% and 0.5% bupivacaine shows poor antimicrobial effectiveness, and ropivacaine has no antimicrobial effect on such microorganisms.

Investigation of the in vivo effects of lidocaine on leukocyte

function in surgical wounds of rats demonstrates lower leukocyte cell counts in the wounds of lidocaine-treated versus placebo-treated rats 48 and 72 h after surgical implantation of hollow titanium implants.²⁸ At least one histopathological study indicates that local infiltration of 0.5% and 2.0% lidocaine and 0.5% bupivacaine does not substantially alter the healing of midline abdominal incisions in rabbits.³⁰

Clinical Pharmacology

Chemical Structure

All local anesthetics contain an aromatic ring at one end of the molecule and an amine at the other, separated by a hydrocarbon chain (Table 14.1).^{1,31,32} The aromatic end is derived from benzoic acid or aniline and is lipophilic. The amine end is derived from ethyl alcohol or acetic acid and is hydrophilic. Substitution of alkyl groups on the aromatic ring or amine end increases lipid solubility and potency.

Chirality

In general, local anesthetics are supplied commercially as racemic mixtures of both *R*-(+) and *S*-(-) optical stereoisomers. Differences in structure result in various pharmacodynamic and pharmacokinetic actions.

Ropivacaine is provided as the hydrochloride of the pure *S*-(-) enantiomer.^{33,34} It is associated with a reduced incidence of both cardiovascular and central nervous system (CNS) toxicity, a concern with use of racemic bupivacaine.³⁵ In addition, epidural ropivacaine is similar to bupivacaine in onset, depth, duration, and extent of sensory blockade, although motor block is less intense and briefer.³⁶

More recently, levobupivacaine, the pure *S*-(-) enantiomer of bupivacaine, has been produced. In common with ropivacaine, levobupivacaine is less toxic than bupivacaine, which is attributable to a lesser affinity for brain and myocardial tissue than either that of the *R*-(+) enantiomer or racemic bupivacaine.³⁷

Grouping of Local Anesthetics

The clinically useful local anesthetic drugs essentially segregate into amino esters and amino amides, based on the chemical link between the aromatic moiety and the hydrocarbon chain (Table 14.1). Amino esters have an ester link, and the amino amides have an amide link, respectively. The nature of linkage (ester versus amide) has a notable effect on the chemical stability and the route of metabolism. Ester-linked local anesthetics are cocaine, benzocaine, procaine, chlorprocaine, and tetracaine. Most esters are readily hydrolyzed by plasma cholinesterase and have short half-lives when stored in solution without preservatives. Amide-linked local anesthetics are lidocaine, prilocaine, dibucaine, etidocaine, mepivacaine, bupivacaine, levobupivacaine, ropivacaine, and articaine. The amide agents are very stable, cannot be hydrolyzed by cholinesterase, and rely on enzymatic degradation in the liver. The amide structure of articaine is similar to that of other local anesthetics but contains an additional ester group, which is quickly hydrolyzed by esterases, shortening its duration of action. Ropivacaine and levobupivacaine are synthesized as

single *S*-(-) optical isomers. Other local anesthetics exist as racemates or have no asymmetrical carbons.

The clinical action of local anesthetics may be described by their inherent anesthetic potency, speed of onset of action, duration of action, and tendency for differential block (Table 14.2). These properties do not sort independently.

Local Anesthetic Potency

There tends to be an association between the lipid solubility (octane-water partition coefficient) of a local anesthetic and the local anesthetic potency *in vitro*.³⁸ The smaller the molecule and larger the lipophilic property of the local anesthetic, the more readily the anesthetic permeates the axonal nerve membranes, which are highly lipid in composition, and binds sodium channels with greater affinity. The addition of side chains to the lipophilic end of the basic chemical structure increases the lipid solubility and potency of the local anesthetics. The addition of a butyl group to the lipophilic end of procaine forms tetracaine, which is 80 times more lipid soluble and 8 times more potent than procaine. Similarly, replacement of the methyl group with a butyl group on the lipophilic end of mepivacaine yields bupivacaine, which is approximately 30 times more lipid soluble and 8 times more potent than procaine, making it also 15 times more lipid soluble and 4 times more potent than mepivacaine (Table 14.2).

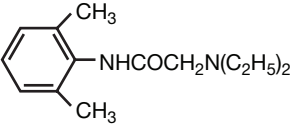

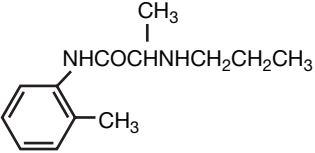

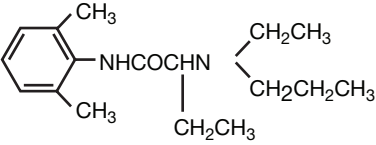

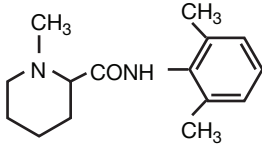

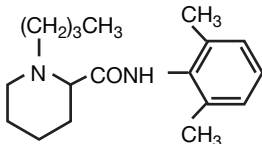

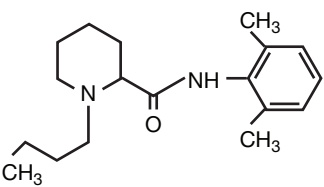

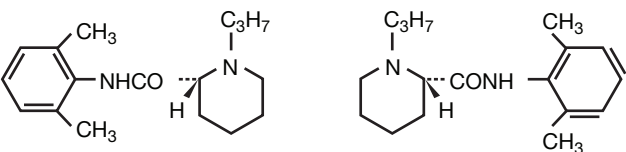

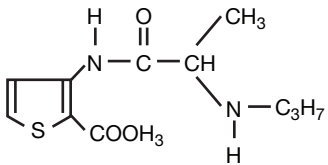

Speed of Onset

The onset of local anesthetic effects in isolated nerves is most likely associated inversely with the lipid solubility and acid dissociation constant (pK_a) of the anesthetic. Most local anesthetics have pK_a values that range from 7.7 to 9.1 (Table 14.2). The percentage of local anesthetic molecules present in the uncharged, nonionized base form, which is primarily responsible for membrane permeability, decreases with increased pK_a at any given tissue pH.³⁹ When comparing mepivacaine (pK_a , 7.7) with bupivacaine (pK_a , 8.1), mepivacaine with its pK_a nearer to tissue pH 7.4 has a noticeable faster onset of action than bupivacaine (5 to 10 vs. 20 to 30 min). Etidocaine is highly lipid soluble (partition coefficient, 140) and has a low pK_a (7.74), so it penetrates diffusion barriers around A- α nerves relatively easily, producing good motor block within 5 to 10 min. Articaine has good lipid solubility (partition coefficient, 52) and low pK_a (7.8). Articaine (4% solution) produces successful (complete) local anesthesia for periodontal surgery or tooth extraction in 1 to 3 min that lasts for 50 to 60 min.⁴⁰ Although chlorprocaine has a higher pK_a than procaine (9.1 vs. 8.9), chlorprocaine is more potent and has a faster onset of action. The pK_a of ropivacaine is 8.07, approximately the same as bupivacaine (8.1) or mepivacaine (7.7). However, ropivacaine has an intermediate degree of lipid solubility (partition coefficient of 14 at pH 7.4) compared with bupivacaine (partition coefficient, 30) and mepivacaine (partition coefficient, 2).

Duration of Anesthetic Effect

The duration of clinical local anesthetic action correlates with the high lipid solubility, which also relates to increased potency, as previously described, and to increased protein binding within the axonal membrane and the vasoactivity of the local anesthetic

Table 14.1. Trade names, chemical structure, and main clinical uses of ester-linked and amide-linked local anesthetic agents

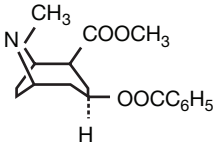

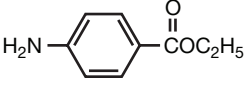

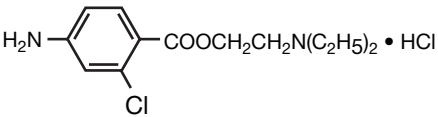

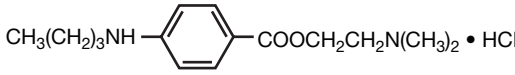

Trade Name	Chemical Structure	Main Clinical Use
Amides		
Lidocaine Xylocaine Lignocaine		Infiltration, nerve blocks, intra-articular, epidural
Prilocaine Citanest		Infiltration, nerve blocks, epidural
Etidocaine Duranest		Infiltration, nerve blocks, epidural
Mepivacaine Carbocaine		Infiltration, nerve blocks, intra-articular, epidural
Bupivacaine Marcaine		Infiltration, nerve blocks, epidural, subarachnoid
Levobupivacaine Chirocaine		Infiltration, nerve blocks, epidural, subarachnoid
Ropivacaine Naropin		Infiltration, nerve blocks, epidural, subarachnoid
Articaine Ultracain Carticain		Infiltration, nerve blocks, intravenous, regional anesthesia, epidural

(continued)

drug. Increasing the side chain of the local anesthetic molecule increases the protein binding and prolongs the duration of action. More lipid-soluble local anesthetics are relatively water insoluble and, therefore, highly protein bound (Table 14.2).

The duration of effect of local anesthetics at the site of action is inversely related to the rate of systemic absorption. The rate of vascular absorption varies directly with the vascularity of the injection site and the physicochemical and pharmacological prop-

Table 14.1. Trade names, chemical structure, and main clinical uses of ester-linked and amide-linked local anesthetic agents (*continued*)

Trade Name	Chemical Structure	Main Clinical Use
Esters		
Cocaine		Topical
Benzocaine	Americaine 	Topical
Procaine	Novocain 	Infiltration, nerve blocks, epidural
Chlorprocaine	Nesacaine 	Infiltration, nerve blocks, epidural
Tetracaine	Pontocaine Amethocaine 	Topical, subarachnoid

erty and dose of the local anesthetic. Lidocaine is a better vasodilator than prilocaine, so lidocaine is removed from the site of injection faster. This makes lidocaine a shorter-acting anesthetic than prilocaine (60 to 120 vs. 120 to 180 min), even though lidocaine is more protein bound (65% vs. 55%).

Articaine is better able to diffuse away through soft tissues and bone than are other local anesthetics, and it contains an ester group, which is quickly hydrolyzed by esterases, shortening its duration to approximately 30 to 45 min.⁴¹ By using articaine in peribulbar anesthesia for cataract surgery, corneal sensation returns quickly, thereby reducing the likelihood of inadvertent damage to an anesthetized eye after discharge.⁴²

Tonicaine is a lidocaine derivative compound that produces sciatic nerve blockade with a relatively fast onset (<10 min) and long duration (12 to 16 h). Tonicaine requires additional local and systemic toxicity studies before it can be safely used in animals and people.⁴³

Bupivacaine, tetracaine, etidocaine, and ropivacaine are highly lipid-soluble local anesthetics that are only slowly “washed out” from isolated nerves *in vitro*, and they are not readily removed by the bloodstream from nerve membranes, making their duration of action long (180 to 480 min) (Table 14.2).

Mixtures of Local Anesthetics

Neural blockade produced by mixing of local anesthetics is unpredictable and controversial and may depend on a number of factors, which include not only the types of drugs but also the pH of the mixture. If lidocaine (with fast onset and intermediate duration) and bupivacaine (with long onset and duration of action)

are mixed, neural blockade may begin faster and last longer.⁴⁴ One study suggests that there is no clinical advantage, with respect to onset and duration of sensory blockade in humans, to using a 50:50 mixture of plain lidocaine (1%) and plain bupivacaine (0.25%) in place of their independent use.⁴⁵ Prior administration of chlorprocaine (with fast onset and brief duration) to bupivacaine (with longer onset and duration) shortens the duration of bupivacaine-induced nerve blockade, because the metabolites of chlorprocaine may inhibit the binding of bupivacaine to sodium-channel receptor sites.^{46,47} Administration of bupivacaine (2.4 µg/mL) and etidocaine (2.3 µg/mL) causes 38% and 21% inhibition, respectively, of the rate of chlorprocaine hydrolysis by human serum.⁴⁸ A mixture of equal parts of 2% chlorprocaine and 0.5% bupivacaine produces a rat sciatic nerve blockade with the characteristics of a chlorprocaine block. Changing the pH of this mixture from 3.6 to 5.6 changes the characteristics to a blockade resembling that produced by bupivacaine.⁴⁹ For mixtures of lidocaine-bupivacaine and lidocaine-tetracaine, there is no evidence of a synergistic or antagonistic interaction in rats.⁵⁰

Novel Local Anesthetic Delivery Systems

Vehicles for Sustained Release of Local Anesthetics

Various approaches have been tried to prolong neural blockade and postoperative analgesia for several hours or days after a single administration of a local anesthetic drug. Polyactic, polycar-

Table 14.2. Physical, chemical, and biological properties of currently available local anesthetic agents.

Drug	Lipid Solubility	Relative Anesthetic Potency ^a	pK _a	Plasma Protein Binding (%)	Onset of Action	Duration of Action (min)
Ester linked						
Low potency, short duration						
Procaine	1	1	8.9	6	Slow	45–60
Chlorprocaine	1	1	9.1	7	Fast	30–60
High potency, long duration						
Tetracaine	80	8	8.6	80	Slow	60–360
Amide linked						
Intermediate potency, short duration						
Articaine	52	4	7.8	65	Fast	30–45
Intermediate potency and duration						
Lidocaine	3.6	2	7.86	65	Fast	60–120
Mepivacaine	2	2	7.7	75	Fast	90–180
Prilocaine	1	2	7.7	55	Fast	120–180
Intermediate potency, long duration						
Ropivacaine	14	6	8.07	95	Intermediate	180–480
High potency, long duration						
Bupivacaine	30	8	8.1	95	Intermediate	180–480
Levobupivacaine	31.1	ND	8.09	>97	Intermediate	180–480

bonate, and polymer microspheres containing local anesthetics,^{51–53} lecithin-coated methoxyflurane microdroplets,⁵⁴ local anesthetics from biodegradable polymer matrices,⁵⁵ lecithin-coated tetracaine microcrystals,⁵⁶ and liposome-encapsulated lidocaine⁵⁷ or bupivacaine⁵⁸ have been developed to serve as vehicles for sustained release of local anesthetic agents.

The large unilamellar vehicles (diameter, 300 nm) that exhibit a pH gradient (pH 7.4, outside; and pH 4.0, inside) and encapsulate 0.75% bupivacaine can subsequently provide a sustained-release system that increases the duration of neural blockade from 2 to 6.5 h.⁵⁸ In the guinea pig cutaneous wheal model, more than 85% of the liposomal carrier remains at the site of administration for 2 days.⁵⁸ The duration of intercostal nerve blockade in sheep increases from 4 to 13 days after using the controlled release of 8 to 80 mg of bupivacaine/kg of body weight and 0.05% dexamethasone from polymer microspheres (470 mg of microspheres containing 352 mg of bupivacaine per nerve).⁵³

Continuous Peripheral Nerve Blockade

This can be accomplished by the use of a continuous-catheter insertion system and a disposable infusion pump.⁵⁹ Local anesthetic delivery has been applied at the end of surgery on 17 dogs submitted for forelimb amputation, total ear-canal ablation with lateral bulla osteotomy, or median and lateral thoracotomies. The continuous infusion of 2% lidocaine (2 mL/h) into the surgical sites was well tolerated by the patients, producing good postoperative analgesia for up to 50 h, with no acute local anesthetic toxicity, hemodynamic instability, or breakthrough pain.⁶⁰

Differential Nerve Blockade

Controversy still surrounds the differential susceptibility of nerve fibers to local anesthetics and its relation to selective functional deficit. It is apparent that differential block of impulses in nerve fibers exists, varying among different anatomical features (different peripheral nerves, fiber diameter, presence or absence of myelination, and surrounding tissue), different local anesthetics, critical duration of drug exposure (absorption, distribution, and elimination of drug from the site of injection), and different animal species (e.g., frogs, rats, cats, and people).

Sensory and motor fibers have a characteristic neurophysiological profile, motor and sensory function, and conduction-block susceptibility (Table 14.3).

In Vitro Studies

One of the oldest observations about local anesthetic block with cocaine is that dogs and frogs lose sensation before motor function.⁶¹ In vitro studies with desheathed rabbit vagus and sciatic nerve indicate that various local anesthetics (i.e., cocaine, procaine, chlorprocaine, tetracaine, lidocaine, bupivacaine, etidocaine, tetrodotoxin, and saxitoxin) block C fibers before A- α fibers.⁶² These findings have led to the belief that the susceptibility to local anesthetic depends inversely on fiber diameter. The “size principle” that smaller (slower) axons are always blocked first, however, is not always true. When equilibrium is achieved between the nerve and the local anesthetic solutions, the large A- α fibers are blocked at the lowest drug concentration, the inter-

Table 14.3. Classification of nerve fibers and order of blockade

	Fiber Type					
	A- α	A- β	A- γ	A- δ	B	C
Function	Somatic motor	Touch, pressure	Proprioception	Fast pain, temperature	Vasoconstriction, preganglionic sympathetic	Slow pain, postganglionic sympathetic polymodal nociceptors
Myelin	Heavy	Moderate	Moderate	Light	Light	None
Diameter (μM)	12–20	5–15	3–6	2–5	1–3	0.4–1.5
Priority of blockade	← 5	← 4	← 3	← 2	← 1	→ 2
Signs of blockade	Loss of motor function	Loss of sensation to touch and pressure	Loss of proprioception	Pain relief, loss of temperature sensation	Increased skin temperature	Pain relief, loss of temperature sensation

mediate B fibers are blocked at a higher concentration, and the smallest, slowest-conducting C fibers require the highest drug concentration for conduction blockade.^{63,64}

Similarly, earlier reports indicate that the larger A- β fibers in rabbit vagus nerve are more susceptible to the local anesthetic blockade than are the small, preganglionic, myelinated B fibers.^{64–66} The larger A- δ fibers in the dorsal roots of saphenous nerve of cats are also reported to be more susceptible to procaine blockade than are the C fibers.⁶³

In Situ Studies

Local anesthetics have been found to block pain fibers (small unmyelinated C fibers and myelinated A- δ fibers) more readily and before other sensory and motor fibers (large myelinated A- γ , A- β , and A- α fibers) (Table 14.3). Local anesthetics also will block small-diameter myelinated or unmyelinated fibers at a lower concentration than is required to block large fibers of the same type. This is probably attributable to the longer action potentials and the discharge at higher frequencies of smaller fibers.

A recent in vivo electrophysiological study with rats confirmed such results.⁶⁷ If the minimal effective threshold concentration of lidocaine in rat sciatic nerve was measured that produced 50% of tonic fiber blockade in large, myelinated A- α and A- β fibers, small myelinated A- δ fibers, and unmyelinated C fibers of sensory axons, and in large myelinated A- α fibers and small A- γ of motor axons, then the order was motor = proprioception (A- γ > A- δ = A- α > A- β fibers) > nociception (C fibers). At 1% lidocaine, all fibers were tonically blocked.

On the other hand, if compound action potentials of the saphenous nerve were recorded before and during blockade with low concentrations with either a low lipid-soluble local anesthetic (e.g., procaine or 2-chloroprocaine) or intermediate lipid-soluble anesthetic (e.g., lidocaine or bupivacaine), then priority of fiber blockade appeared to be C > A- δ > A- α fibers.⁶⁸ However, with very lipid-soluble etidocaine, A- δ fibers are blocked before C fibers. Of the local anesthetics tested, 2-chloroprocaine produced the greatest differential rate of block of peripheral nerve fibers, and etidocaine produced the least. Mepivacaine appears to block

sensory and motor fibers at the same rate, and bupivacaine and ropivacaine can produce selective sensory analgesia, with little or no motor blockade.^{69–71}

Brachial Plexus Infiltration

Deposition of local anesthetics to the brachial plexus of humans has produced either equally fast anesthesia and paralysis by 1% lidocaine or a more rapid motor blockade than sensory blockade by 1% mepivacaine,⁷² 0.5% bupivacaine, or 0.5% ropivacaine.^{73,74} Similarly, brachial plexus block in dogs produced more rapid onset of motor block when compared with sensory block after the administration of bupivacaine (0.375% with 5 Mg/mL epinephrine, 4 mg/kg) (9.7 vs. 26.2 min, mean values).⁷⁵ This phenomenon has been explained by some authors by the somatotopical arrangement of nerve fibers such that the motor fibers would be located at the periphery of the nerve trunk (mantle bundles) and the sensory fibers in the center (or core) (Fig. 14.3).^{72,76} Consequently, if sufficient analgesic drug is applied to produce motor blockade, the diffusion of the analgesic or its transport into the nerve by the local blood supply will first affect the motor fibers. However, anatomical studies of the radial, median, and ulnar nerves in humans do not support this concept, making the mechanism for the differential rate of brachial plexus blockade controversial.⁷⁷ Analgesia during brachial plexus block in dogs lasted 11 ± 0.5 h in one study, but the relative rates of recovery of motor activity and sensation in dogs after brachial plexus blockade have not been investigated.⁷⁵

Differential Epidural and Spinal Blockade

In general, progression of epidural and spinal anesthesia is related to the diameter, myelination, and conduction velocity of affected nerve fibers. Exposure of mixed-nerve trunks within the spinal vertebral column to a sufficient concentration of an analgesic drug might cause a loss of sensation in this order: pain, heat and cold, touch, proprioception, and skeletal muscle tone. Recovery of sensation is expected to be in the reverse order.⁷⁸

Autonomic small unmyelinated C fibers and myelinated B fibers seem to be readily desensitized after epidural or spinal ad-

Fig. 14.3. Somatosensory arrangement of nerve fibers in the trunk of the brachial plexus of the dog. Nerve fibers in the mantle or peripheral bundles innervate primarily motor fibers of the proximal limb, whereas nerve fibers in the core or center bundles innervate for the most part the sensory fibers of the distal foot. The concentration gradient that develops during initial diffusion of local anesthetic into the nerve trunk causes onset of anesthesia to proceed from proximal to distal. Recovery from anesthesia also proceeds from proximal to distal because of absorption of local anesthetic into the circulation surrounding the nerve trunk.

ministration of local anesthetics. Spinal anesthesia is generally characterized by preganglionic sympathetic nerve blockade (B fibers) that extends further than sensory block (A- δ fibers), and sensory block extends further than somatic motor block (A- α fibers).⁷⁹

The relative importance of blockade of each class of fiber (A- β , A- δ , and C) for surgical anesthesia has been assessed by measuring cutaneous perception thresholds in people. In this study, A- β , A- δ , and C fibers of the skin were stimulated at 2000, 250, and

5 Hz, and demonstrated differential block by the sequential return of sensation to touch (A- β function), then pinprick (A- δ function), and lastly cold (C-fiber function), respectively.⁸⁰

Sensory anesthesia sufficient for surgery usually cannot be obtained without motor impairment. Adequate sensory analgesia with little or no motor blockade can be achieved with the epidural administration of low concentrations of bupivacaine or ropivacaine combined with opioids and/or α_2 -agonists. Epidural blockade may be able to differentiate between sympathetic, somatic, and central pain in patients with chronic pain.

Factors Influencing Anesthetic Activity

A variety of factors can influence the quality of regional anesthesia, including the local anesthetic dose, site of administration, additives such as epinephrine or hyaluronidase, pH adjustment and carbonation, baricity, temperature, mixtures of local anesthetics, and pregnancy.

Dose of Local Anesthetic Agent

A greater dose (volume and/or concentration) will facilitate overall efficacy, thereby decreasing the delay of onset of action and increasing both the likelihood of successful anesthesia and its duration. The potential of systemic toxicity by inadvertent intravenous injection of an anesthetic,⁸¹ or neurotoxicity after inadvertent subarachnoid injection,⁸² precludes the routine administration of larger doses of local anesthetic.

All local anesthetics can be neurotoxic, particularly in concentrations and doses larger than those used clinically. Large-scale surveys, using histopathological, electrophysiological, behavioral, and neuronal cell models, indicate that lidocaine and tetracaine seem to have a greater potential for neurotoxicity than does bupivacaine at clinically relevant concentrations administered intrathecally (spinal).⁸³

Volume of Local Anesthetic

Generally, a larger volume of local anesthetic will produce a faster and denser block. An exception to this rule is articaine, which readily penetrates tissues and produces anesthesia in approximately 2 min, irrespective of the volume injected. The necessity of a larger injected volume of anesthetic solution for a high rate of complete sensory block can be minimized during axillary plexus blocks in people⁸⁴ and dogs⁷⁵ if an adequate concentration of a local anesthetic agent (e.g., 1% mepivacaine or 0.375% bupivacaine) is precisely administered at multiple injection sites covering all major nerves of the brachial plexus.

Administration of large volumes (0.22 to 0.33 mL/kg) of bupivacaine (0.75%), lidocaine (2%), or 2-chloroprocaine (3%) into the subarachnoid space of sheep and monkeys has produced neurological deficits and histological abnormalities of the spinal cord, but no one local anesthetic was considered more neurotoxic than another.⁸²

Concentration of Local Anesthetic

A higher concentration of local anesthetic will also produce a faster and denser block. Increasing the concentration of lidocaine

and bupivacaine during phasic (“use dependent”) inhibition of sodium currents increases the rate of binding but has no effect on unbinding sodium channels.⁸⁵ In general, the chance for successful desensitization and anesthesia decreases when the concentration is lowered. One study suggests that lumbar epidural anesthesia with 10 mL of 2% lidocaine in humans produces more intense blockade of large-diameter and small-diameter sensory nerve fibers than that with 20 mL of 1% lidocaine.⁸⁶ Similarly, administration of 0.75% ropivacaine into the lumbar epidural space of dogs produces a higher rate of complete anesthesia than does 0.5% ropivacaine of similar volume (0.22 mL/kg).⁸⁷

Injection Site

In general, the fastest onset (within 3 to 5 min) and shortest duration (1 h) of anesthesia is usually produced after subcutaneous and intrathecal injections of 2% lidocaine or mepivacaine hydrochloride solution, followed in order of increasing onset time for minor nerve blocks (5 to 10 min), major nerve blocks, and epidural anesthesia (10 to 20 min).

Additives

Vasoconstrictors

As a general rule, the addition of a vasoconstrictor to a local anesthetic agent, such as epinephrine, allows for decreased local perfusion, delayed rate of vascular absorption of local anesthetic, and therefore increased intensity and prolonged anesthetic activity. Lumbar epidural anesthesia, using 10 mL of 1% lidocaine with epinephrine 1:200,000 produces a more intense block of both large-diameter and small-diameter sensory nerve fibers than that achieved with lidocaine alone.⁸⁸

The usual concentration of epinephrine is 5 µg/mL or 1:200,000 (1 mg/200 mL of saline), which may be obtained by adding 0.1 mL of 1:1000 (0.1 mg) epinephrine to 20 mL of local anesthetic solution. Alternatively, 1:1000 epinephrine may be diluted with preservative-free normal saline. The maximum safe concentration of epinephrine is 1:50,000; concentrations less than 1:200,000 are less effective.

Market preparations of local anesthetics that contain epinephrine 1:200,000 have a lower pH (to retard oxidation) than do plain solutions; for example, 2% lidocaine without and with epinephrine 1:200,000 has a pH of 6.78 and 4.55; and 0.5% bupivacaine without and with epinephrine (1:200,000) has a pH of 6.04 and 3.73, respectively. The pH of solutions freshly prepared with epinephrine is higher than the pH of commercial preparations containing epinephrine; for example, the pH of 2% lidocaine and 0.5% bupivacaine with freshly added epinephrine 1:200,000 is 6.33 and 5.99, respectively. The low pH of the epinephrine preparations will potentially decrease the amount of free protonated anesthetic base available for diffusion through the axonal membrane, thereby slowing the onset of action.

Epinephrine effects depend on the injection site and the local anesthetic, but, in general, it reduces the potential toxicity of local anesthetics by causing vasoconstriction and thus preventing higher blood concentrations.⁸⁹ Epinephrine (1:200,000) reduces the average anesthetic blood concentration in dogs given an epidural injection of either 3 mL of 1% ropivacaine or 0.75%

bupivacaine at various time intervals, but not the time to achieve maximal blood levels, and it does not alter onset or duration of sensory or motor blockades produced by epidural ropivacaine 1% or bupivacaine 0.75% in dogs.⁹⁰

Acidic epinephrine-containing local anesthetic solutions can decrease the pH at the site of injection, depending on the buffer demand of the injectate and the buffer capacity of the tissue. Epinephrine should not be added to local anesthetics intended for nerve blocks that have an erratic blood supply and for intravenous regional anesthesia with use of a tourniquet because it can cause nerve ischemia and prolonged blockade. Epinephrine often causes tissue necrosis along wound edges. Lidocaine, bupivacaine, and etidocaine equally protect against epinephrine (5 µg/kg/min)-induced arrhythmias in dogs anesthetized with a 1.4 minimum alveolar concentration of halothane.⁹¹ Norepinephrine and phenylephrine appear to have no clinical advantage over epinephrine.

Hyaluronidase

This depolymerizes hyaluronic acid, the tissue cement or ground substance of the mesenchyme, aiding in the local anesthetic spread of an anesthetic agent.⁹² The addition of hyaluronidase 3.75 IU/mL to 2% lidocaine, 0.75% bupivacaine, or a 1:1 mixture of 0.75% bupivacaine and 2% lidocaine is reported to improve the diffusion of local anesthetics, resulting in more effective retrobulbar-peribulbar anesthesia and extraocular muscle akinesia after retrobulbar injections.^{93,94} Increasing the concentration of hyaluronidase to 7.5 IU/mL does not provide any further advantage over 3.75 IU/mL. The increased permeability of tissues may enhance systemic absorption (and toxicity) but shortens the duration of anesthetic effects because more drug is available in base form. The addition of 5 IU of hyaluronidase/mL of 1% lidocaine with 1:200,000 epinephrine solution in a standard dose and technique for ophthalmic surgery (2 mL as retrobulbar injection for intraocular anesthesia, 2 mL for upper-eyelid anesthesia, and 4 mL for extraorbital facial nerve blockade) reportedly does not increase the systemic absorption and cerebrospinal fluid (CSF) concentration of lidocaine in dogs.⁹⁵ However, administration of hyaluronidase does not seem to enhance the efficacy of newer local anesthetics with improved spreading power (e.g., articaine and ropivacaine). Administration of 2% articaine or 1% ropivacaine produces a faster onset of anesthesia and less pain on injection than does administration of 1% bupivacaine.^{42,96} Hyaluronidase is a protein that cannot be heat sterilized.⁹⁷

pH Adjustment and Carbonation

The pH of the local anesthetic solution affects the local distribution of the anesthetic. Extracellular increase of bicarbonate increases the cross-membrane pH gradient, the intracellular concentration of the ionized local anesthetic, and local anesthetic effects.

The addition of sodium bicarbonate to procaine, chlorprocaine, mepivacaine, or lidocaine will shorten the onset of nerve block, enhance the density of block, and prolong the duration of block in isolated nerve preparations.⁹⁸ This is likely because the amount of nonionized base increases, which enhances diffusion

of the local anesthetic through axonal membranes and ion trapping due to the increased cross-membrane pH gradient.

The efficacy of alkalization depends on the local anesthetic and regional block techniques. The addition of sodium bicarbonate for median nerve block in humans decreases the pain on injection and increases the rate of onset of motor block, but has no effect on duration of sensory anesthesia.⁹⁹ Similarly, adjusting the pH of 1% lidocaine or 0.25% bupivacaine with sodium bicarbonate to 7.4 has little effect on duration of anesthesia after injection into the infraorbital area or abdominal musculature.¹⁰⁰

In humans, alkalization produces the best results with 2% lidocaine and 0.5% bupivacaine for epidural block, with 2% lidocaine for axillary brachial plexus block, and with 2% mepivacaine for sciatic and femoral nerve blocks.¹⁰¹ Bicarbonate has minimal effects when added to ropivacaine.

Increasing the pH of lidocaine or mepivacaine from 4.5 to 7.2 by adding 1 mEq of sodium bicarbonate/10 mL of local anesthetic before injection has been shown to accelerate the onset of epidural anesthesia in humans.^{102,103} A pH increase of 2% 2-chloroprocaine from 7.1 to 7.7 with sodium bicarbonate accelerates epidural anesthesia in humans, but a pH increase from 7.1 to 7.7 with tromethamine does not, indicating that factors other than just pH are responsible for the more rapid onset of anesthesia.¹⁰⁴

Local anesthetic solutions may deteriorate with time upon addition of bicarbonate. Solutions of lidocaine and 2-chloroprocaine readily alkalize to near physiological pH without precipitation. Mepivacaine 1.5% precipitates above neutral pH within 20 min. Bupivacaine and etidocaine precipitate after the addition of small amounts of sodium bicarbonate and cannot be alkalized to physiological pH.¹⁰⁵ The mixtures should be used within 20 min of their preparation.

The addition of carbon dioxide to lidocaine produces a more rapid onset and better quality of epidural anesthesia in humans.¹⁰⁶ Marketed solutions of carbonated lidocaine have an adjusted pH ranging from 6.35 to 6.9, and the PCO₂ is 700 mm Hg.¹⁰² Opening the vial lets the carbon dioxide escape, thereby increasing the pH to above 7.0.

The use of carbonated lidocaine for epidural anesthesia in horses did not demonstrate the theoretical expectations of increased diffusion and faster onset of perineal anesthesia.¹⁰⁷

Baricity

This is defined as the calculated ratio of the density of a solution to the density of CSF. One of the most important physical properties affecting the spread of local anesthetic solutions and level of analgesia achieved after intrathecal administration of a local anesthetic is its density relative to the density of CSF at 37°C.¹⁰⁸

Density is the weight of a unit volume of solution (grams per milliliter) at a specific temperature, whereas the *specific gravity* (SG) is the calculated ratio of the density of a solution (x) to the known density of water (y), ($SG = x/y$). The density of a drug in solution cannot be determined from a simple formula because it depends on the physical state of that substance in solution.¹⁰⁹ The density of intrathecal agents is usually compared with the density of the CSF. At room temperature, most glucose-free drugs are isobaric with respect to CSF, but as drugs warm to body

temperature they become relatively hypobaric. The densities of 2% lidocaine and 0.5% and 0.75% bupivacaine, for example, are slightly less than that of normal range of CSF in humans and therefore can be considered slightly hypobaric.¹¹⁰ The density of 0.2% tetracaine is the same as water (0.993 g/mL). Continued dilution of 0.75% bupivacaine with water produces increasingly hypobaric solutions. The 0.075% bupivacaine (1:9 dilution) has a density comparable to that of water (0.993 g/mL).¹¹¹

Hypobaric solutions have a baricity less than that of CSF and will migrate to nondependent areas during and immediately after the injection. Glucose-free 0.5% bupivacaine acts as a hypobaric solution, which produces a higher level of analgesia in the nondependent side compared with the dependent side in patients positioned laterally.¹¹² The unpredictability of extent of spinal block provided by spinal bupivacaine (0.5%) and tetracaine (0.5%) in humans may be related to individual variations in CSF densities.¹¹³ Humans with higher CSF densities demonstrate a higher spinal block after administration of plain bupivacaine (0.5%, 3 mL).¹¹⁴

Dextrose and hypertonic saline-containing local anesthetic solutions (e.g., tetracaine in 10% glucose, and dibucaine in 5% hyperbaric saline) have a specific gravity greater than that of CSF. They will migrate from the site of injection to dependent areas.¹¹⁵ Hyperbaric solutions are created by combining local anesthetics (e.g., 0.5% bupivacaine or 0.5% ropivacaine) with an equal volume of 10% dextrose, producing final drug and dextrose concentrations of 0.25% and 5%, respectively.¹¹⁶ Lidocaine (1.5%) in 7.5% dextrose in water is clinically indistinguishable from 5% lidocaine in 7.5% dextrose in water as a spinal anesthetic for lower abdominal surgery in humans.¹¹⁷

Local anesthetic agents and solvent solutions often contain additives, which affect pH, osmolality, preservation, and vasoconstriction, that may in turn alter the density and specific gravity of the local anesthetic and, therefore, spread of spinal anesthesia.¹¹⁸ CSF pH and the addition of vasopressors (0.2 mg of epinephrine or 2 mg of phenylephrine) minimally affect the onset of spinal anesthesia with 10 mg of tetracaine and 1 mL of 10% dextrose. However, the addition of epinephrine or phenylephrine at these doses prolonged spinal anesthesia by 53% and 72%, respectively.¹¹⁹

Temperature

The cooling of mammalian nerves *in vitro* slows the conduction velocity and increases the susceptibility to local anesthetic inhibition of transmission.¹²⁰ The potency of local anesthetics increases *in vitro* and *in vivo* with cooling in some instances but not in others. Inhibition of C fibers (as assessed by galvanic skin potentials) is marginally faster when ice-cold lidocaine (1%) is used compared with room-temperature lidocaine (1%) for median nerve blocks in volunteers.¹²¹ Cooling of lidocaine increases its pK_a and the relative amount of the protonated (active) form within lipid, thereby potentiating the anesthetic effect.¹²² On the other hand, a decrease in temperature from 37° to 20°C decreases the uptake of lidocaine in mammalian sciatic nerve by 45%. It is unlikely that cooling of local anesthetics (5°C) before injection of small volumes (5 mL) will be of any effect under clinical condi-

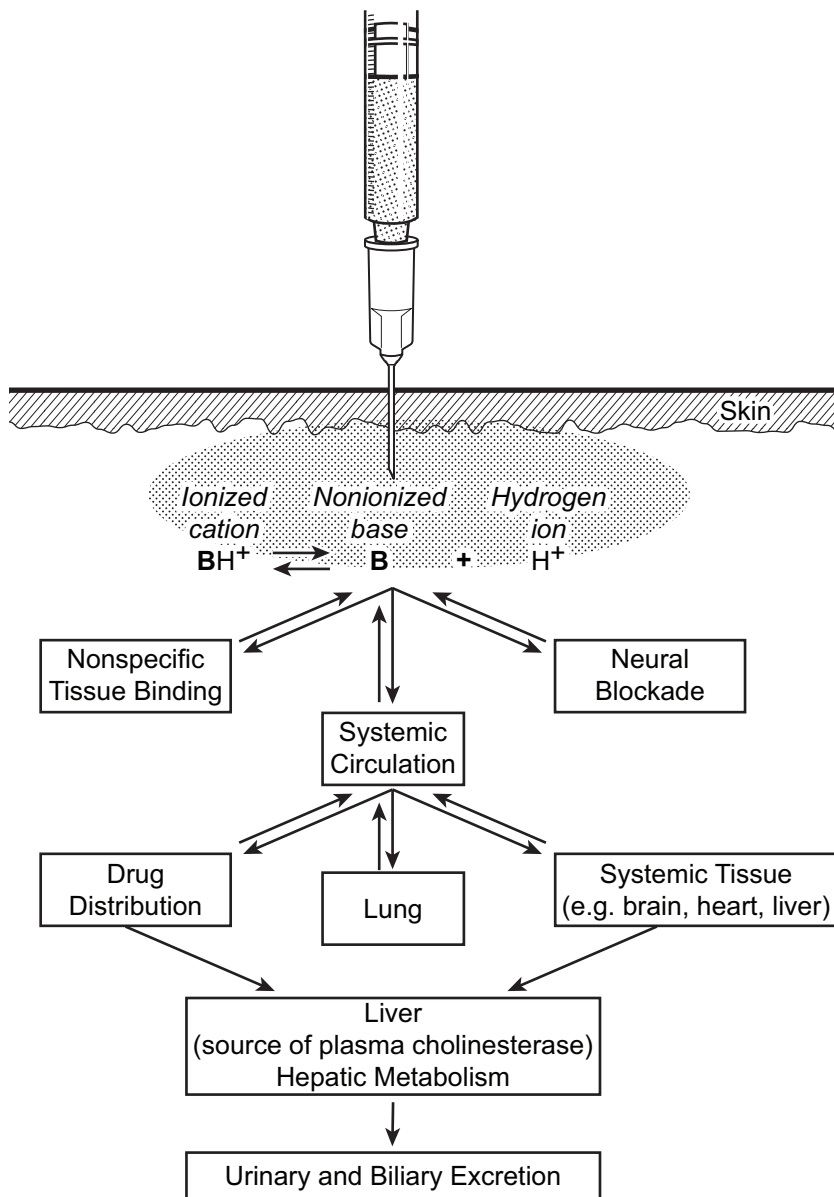

Fig. 14.4. Factors that determine the diffusion of local anesthetic near the site of injection and within the body. The nonionized base of the anesthetic (B) diffuses into the axon and nonspecific tissues. Nonspecific tissue binding and absorption into the bloodstream reduce the mass of drug available to diffuse into neural tissue. Further explanation is under the Drug Disposition section.

tions because of rapid warming of the local anesthetic by the surrounding tissue, preventing the nerve itself from growing cold.¹²³

Pregnancy

This appears to increase the susceptibility of nerves to local anesthetics. Pregnant women with lidocaine (1%)-induced median nerve block at the wrist have a greater decrease in sensory nerve action potential than do nonpregnant women, indicating that pregnancy increases median nerve susceptibility to lidocaine desensitization.¹²¹ Similarly, isolated vagus nerves removed from pregnant rabbits are more susceptible to bupivacaine-induced conduction block than are nerve fibers from nonpregnant animals.^{124,125} Progesterone administration to nonpregnant rabbits replicates the increased local anesthetic susceptibility of pregnancy. Distention of the lumbar epidural venous plexus during pregnancy may displace the local anesthetic solution to more cranial

regions of the spinal canal. Therefore, to prevent excessive cranial spread of anesthesia, a reduced dose of epidural and spinal anesthetics during pregnancy is recommended.

Drug Disposition

Local anesthetics, as the name implies, are deposited at or near the desired site of action. In general, local anesthetics are injected near a nerve bundle. Intraneural injection is painful and may cause nerve damage. The factors that determine the distribution of local anesthetic near the injection site are illustrated in Fig. 14.4. Most clinically used local anesthetics are weak bases and are supplied as mildly acidic hydrochloride salts to improve solubility and stability. In solution, local anesthetics exist as nonionized base (B) and ionized cation (BH^+). The nonionized anesthetic (B) diffuses across the tissue barriers and into the ax-

onal nerve membrane, where membrane stability and neural blockade occur.¹ Nonspecific binding of anesthetic in connective tissue, fat, and muscles and absorption of anesthetic into the vascular and lymph systems reduce the mass (volume × concentration) of the anesthetic available at the neural tissue. Once absorbed into the bloodstream, the local anesthetic is distributed to the lungs, where a significant part (20% to 30%) is absorbed, depending mainly on the physicochemical properties of the local anesthetic.^{126,127} After back diffusion of the anesthetic from the lung into the blood, the anesthetic is distributed to systemic tissues (e.g., brain, heart, and liver) and is metabolized in the liver to compounds that are primarily excreted by the kidney and bile.

Absorption

Systemic absorption of local anesthetics is determined primarily by the drug dose (volume or concentration), duration of effect at the site of action, vascularity of the injection site, and use of a vasoconstrictor. Local anesthetic solutions generally are ineffective when applied to the intact skin.

Topical Application Products

Topical application of local anesthetics includes transdermal patches, creams, and iontophoretic delivery systems. Proparacaine is the topical local anesthetic most commonly used in veterinary medicine.

After application of a lidocaine patch (Lidoderm; Endo Laboratories, Chadds Ford, PA), a sufficient amount of 5% lidocaine penetrates the human intact skin to produce analgesia in patients with neuropathic pain associated with postherpetic neuralgia and in patients with postthoracotomy and postmastectomy pain, but less than the amount necessary to produce a complete sensory block.¹²⁸ A single patch (10 × 14-cm adhesive bandage) contains 700 mg of lidocaine, which is used in a 12-h-on and 12-h-off period to minimize systemic absorption.

The eutectic mixture of 2.5% lidocaine and 2.5% prilocaine (EMLA Cream; Astra Pharmaceuticals, Wilmington, DE) contains 25 mg of lidocaine and 25 mg of prilocaine per each gram or milliliter, which has a sufficiently high concentration of readily available anesthetic base and high water content to penetrate the intact skin and produce reliable cutaneous anesthesia for a wide range of applications in people (e.g., venipuncture in children, radial artery cannulation in adults, and laser treatment)^{129,130} and for venipuncture in dogs, cats, rabbits, and rats.¹³¹ In humans, the EMLA preparation is applied as a thick layer under an occlusive dressing, and maximum depth of analgesia of approximately 5 mm is achieved for 30 min after a 90-min application and for a 60-min period after a 120-min application of the cream.¹²⁹ In general, the depth of cutaneous analgesia in people ranges from 1 to 6 mm and is believed to be time dependent (1 to 4 h).¹³²

Amethocaine cream 1 g (5% wt/wt) applied for 30 or 60 min on the dorsum of the hand produces good analgesia for venous cannulation similar to analgesia produced by 5% EMLA Cream (2.5 g) applied for 30 or 60 min.¹³³ In comparison to the gel preparation, a 30-min application of the amethocaine-patch system provides profound topical anesthesia of human skin that lasts longer than a 60-min application of EMLA (3 to 6 h vs. 20 min).¹³⁴

ELA-Max Cream (Ferndale Laboratories, Ferndale, MI) is designed to produce analgesia of the skin to reduce venipuncture pain in 20 to 30 min in children without the use of an occlusive dressing. The preparation contains 4% lidocaine, which is liposome encapsulated to enable fast penetration into the stratum corneum. It remains in the epidermis after absorption and minimizes the rapid metabolism of lidocaine.¹³⁵ ELA-Max Cream lacks the active ingredient of prilocaine (EMLA Cream), which has been associated with methemoglobinemia in infants.^{128,135} ELA-Max Cream may be more suitable for use in cats, which are susceptible to methemoglobin formation.¹³⁶

Numby Stuff patches (Iomed; Salt Lake City, UT), which consist of 2% lidocaine and 1:100,000 epinephrine, are percutaneously administered through iontophoretic drug administration by using a battery generator to deliver small electrical current (4 mA) through two small electrodes.^{137,138} Each application device delivers 1 mL of the anesthetic to a depth up to 10 mm in 10 min, giving a transient blanching and tingling of the skin.¹³⁸

Transdermal local anesthesia by iontophoresis, but not EMLA, reduces the pain of intravenous injection of hyperosmolar saline, whereas venipuncture is painless with both methods.¹³⁹ The technique involves the use 0.5 mL of lidocaine (2% to 4%) with or without epinephrine 1:50,000 and a current intensity of 0.1 to 0.2 mA/cm² at the anode and placement of the cathode on the dorsal surface of the forearm for 10 min.

Although veterinary applications of Lidoderm patches, ELA-Max Cream, Numby Stuff patches, and transdermal local anesthesia by iontophoresis have been minimal, potential uses include local analgesia for small-wound repair, venipuncture, or catheter placement (intravenous and epidural).

Distribution

Local distribution of local anesthetic at the injection site depends on the volume of local anesthetic injected, inclusion of a vasoconstrictor or hyaluronidase in the local anesthetic solution, and the specific drug employed. The specific gravity (baricity) of the solution relative to the specific gravity of the CSF influences distribution within the CNS.

The distribution of amino-ester local anesthetics (e.g., procaine, chlorprocaine, and tetracaine) in body tissues is limited because of their rapid enzymatic hydrolysis by nonspecific plasma pseudocholinesterases. Amide-type local anesthetics (e.g., lidocaine, mepivacaine, prilocaine, bupivacaine, levobupivacaine, etidocaine, and ropivacaine) are widely distributed in the body after intravenous bolus injection or a fast rate of vascular absorption. Their pharmacokinetic properties are usually described by a two- or three-compartment model.^{140,141}

Plasma Protein Binding

The *plasma protein binding* of local anesthetic drugs refers to the mode by which drugs are transported in the blood. It has a significant effect on numerous aspects of clinical pharmacokinetics and pharmacodynamics.¹⁴² In blood, all amide-linked local anesthetics are partially protein bound, primarily to α_1 -acid glycoprotein (AAG) and, to a lesser extent, to albumin.^{32,141,143} In general, the protein binding of local anesthetics is positively correlated

with the degree of ionization in the physiological pH range and the drug's potency. Plasma protein binding of local anesthetics ranges from 6% for the least potent and short-acting procaine to 95% for the more potent and longer-persisting bupivacaine, etidocaine, and ropivacaine (Table 14.2). Plasma protein binding for articaine and its metabolite articainic acid is between 57% and 90% (average 65%), and the resultant half-lives of the substances are between 1 and 3.9 h.⁴¹

The free drug concentration in plasma, but not the protein-bound concentration of drug, governs tissue concentrations. The effect of serum protein binding on lidocaine distribution into the brain and CNS in dogs after intravenous lidocaine administration indicates that the free or unbound fraction of lidocaine is an important determinant of lidocaine entry into the brain and CSF.¹⁴⁴ Protein binding of lidocaine in dogs that receive a loading dose (2 mg/kg) and a maintenance infusion (50 µg/kg/h) of lidocaine is associated with increased protein binding and only slight increases of free plasma concentrations of lidocaine.¹⁴⁵

In dogs, the concentration of lidocaine bound to AAG varies considerably, and it is higher in dogs with inflammatory disease than in healthy dogs.¹⁴⁶ Studies in normal subjects and patients with myocardial infarction, renal disease, hepatic failure, and in patients that are receiving antiepileptic drug therapy, demonstrate a good relationship between the AAG concentration and the binding ratio for lidocaine.¹⁴⁷

Local anesthetic protein binding approaches saturation only at very high drug concentrations, primarily after prolonged infusion of a long-acting local anesthetic (e.g., ropivacaine or levobupivacaine) and local anesthetic-opioid combination to provide prolonged postoperative analgesia. The slow rise in total plasma concentration with increasing duration of infusion of ropivacaine and levobupivacaine appears to be the predominant reason for rare complications related to systemic toxicity produced by these drugs.³⁷

Biotransformation and Excretion

The liver and lungs are major sites for plasma clearance of local anesthetics. Metabolism converts relatively lipid-soluble local anesthetics into smaller, more water-soluble agents.

For esters, the primary step is ester hydrolysis, catalyzed by nonspecific plasma cholinesterases. The rate of plasma hydrolysis is rapid, yielding half-lives measured in seconds, and is inversely related to toxicity (chlorprocaine [most rapid] > procaine > tetracaine [least rapid]).^{32,143}

Procaine and benzocaine are metabolized to paraaminobenzoic acid (PABA),^{148,149} a breakdown product responsible for allergic reactions and anaphylaxis in some human patients. The majority of the PABA is excreted unchanged or as conjugated product in the urine.³² Chlorprocaine and tetracaine are metabolized similarly, but not to PABA.

Cocaine is an atypical ester in that it undergoes either ester hydrolysis or *N*-demethylation to norcocaine and then ester hydrolysis and significant hepatic metabolism and urinary excretion. Cocaine is rarely used in veterinary medicine, although it can be abused for stimulation of horses before a race. An intravenous dose of above 0.04 mg/kg increases spontaneous locomotor ac-

tivity of horses,¹⁵⁰ whereas 200 mg of intravenous cocaine to adult horses undergoing an increased treadmill exercise increased the time to exhaustion by 92 s (15%).¹⁵¹

Ester metabolism can, theoretically, be slowed by reduced cholinesterase activity during pregnancy and long-term cholinesterase inhibition via poisons, thereby prolonging the clearance of ester anesthetics and increasing the potential for toxicity.

The amino-amide local anesthetics undergo nearly exclusive metabolism by the liver and hepatic degradation, which requires conjugation with glucuronic acid.²⁵ Cats glucuronidate drugs to a lesser extent than dogs, making cats more prone to develop toxic side effects when given amide local anesthetics.²⁵ Little (<5%) of these agents is excreted unchanged in urine.

The order of clearance of amides is prilocaine (most rapid) > etidocaine > lidocaine > mepivacaine or ropivacaine > bupivacaine (least rapid). Lidocaine undergoes oxidative *N*-dealkylation by cytochrome P450III A4.^{32,143} Mepivacaine, etidocaine, bupivacaine, and ropivacaine also undergo *N*-dealkylation and hydroxylation. They are further conjugated with glucuronide before they are excreted from the body via the urine or bile. Prilocaine undergoes hydrolysis to *o*-toluidine, a compound that can oxidize hemoglobin to methemoglobin.^{32,143}

Since all amide local anesthetics are metabolized by the liver, drug clearance is highly dependent on hepatic blood flow, hepatic extraction, and enzyme function. Clearance of amide local anesthetics can be reduced or prolonged by factors that decrease hepatic blood flow, such as β-adrenergic or H₂-receptor blockers, by hypotension during regional and general anesthesia, or by heart or liver failure.^{32,143}

Local Anesthetic Toxicity

When careful technique and appropriate dose are used, local anesthetics are relatively free of harmful side effects. However, as with any pharmacological agents, local anesthetics may cause severe toxic reactions after unintentional intravenous administration,³⁵ vascular absorption of an excessive dose (large volume or high concentration) of the local anesthetic agent,¹⁵² or ingestion of topical local anesthetic preparations.¹⁵³

Doses of local anesthetics, especially those for cats and small dogs, should always be carefully calculated and reduced in sick animals. For example, in healthy dogs and cats, the dose of lidocaine should not exceed 12 and 6 mg/kg, respectively, to prevent toxicity. Repeated applications, the application of higher than the recommended doses, or impaired elimination may all contribute to increasing blood concentration of local anesthetics. Potential damage may also occur from chemical contamination of the local anesthetic solution, allergic reactions, or methemoglobinemia, or from neural ischemia produced by local pressure or hypotension. The systemic toxicity of local anesthetics involves primarily alterations in the CNS and the cardiovascular system.

Central Nervous System Toxicity

In general, toxic and lethal doses of local anesthetic drugs produce signs of CNS excitation leading ultimately to convulsive activity followed by CNS depression (unconsciousness and coma)

Fig. 14.5. Toxic effects produced by increasing lidocaine plasma concentrations. EEG, electroencephalogram.

with eventual respiratory arrest and cardiovascular collapse.¹⁰ Acute CNS toxicity occurs at lower doses than those required to produce acute cardiovascular system toxicity.

As the plasma concentration of the drug increases, humans experience a predictable sequence of signs and symptoms, such as numbness of tongue, light-headedness, visual disturbance, muscle twitching, unconsciousness, and convulsions, which may progress to coma, respiratory arrest, cardiovascular depression, and death (Fig. 14.5). The seizure frequency and accompanying cardiovascular changes in patients undergoing various regional block techniques (e.g., brachial plexus block or epidural and caudal regional anesthesia) have been reviewed, indicating a rate of seizure development with caudal > brachial > epidural anesthetics and no adverse cardiovascular, pulmonary, or nervous system events occurring with seizures.¹⁵⁴

In small animals, low concentrations of local anesthetics produce sedation, whereas higher concentrations produce seizures, probably because of selective depression of inhibitory fibers in the subcortical area (amygdala), with subsequent spread, leading to grand mal seizures. Muscle twitching and convulsions are usually the first signs of local anesthetic toxicity observed in dogs and cats. More potent local anesthetics consistently produce seizures at lower blood concentrations and lower doses than do the less potent local anesthetics.

In awake dogs, the mean cumulative dose of serially and rapidly administered intravenous local anesthetics to produce convulsions is 4.0 mg/kg tetracaine, 5.0 mg/kg bupivacaine, 8.0 mg/kg etidocaine, and 22 mg/kg lidocaine, indicating a relative CNS toxicity of tetracaine, bupivacaine, etidocaine, and lidocaine of about 1:1.2:2:4.⁸¹

In cats, procaine (the least potent CNS depressant, less lipid soluble and less protein bound) produces seizures at 35 mg/kg intravenously (IV), whereas bupivacaine (one of the most potent

CNS depressants, highly lipid soluble and highly protein bound) induces convulsions at approximately 5 mg/kg IV.^{155,156} Intravenously administered lidocaine at a dose of 11.7 ± 4.6 mg/kg causes seizures in cats.¹⁵⁷ Increased arterial PCO₂ (68 to 81 mm Hg) and decreased pH reportedly decrease the convulsive dose of procaine, lidocaine, and bupivacaine by approximately 50% in cats.¹⁵⁵

Horses are reported to be more sensitive to the CNS toxicity of lidocaine than other species, although the mechanism of this increased sensitivity is not known. Seizures in horses may occur at plasma levels of 600 ng of procaine/mL¹⁵⁸ and 6.0 µg of lidocaine/mL,¹⁵⁹ respectively, and usually are brief because of rapid redistribution. Such concentrations are not readily achieved with careful local and regional anesthetic techniques; for example, the procaine plasma concentration can reach 400 ng/mL within 1 h after subcutaneous injection of 3.3 mg of procaine/kg of horse body weight, whereas the lidocaine plasma concentration approaches 3.5 µg/mL approximately 15 min after a flank “line block” using 10 mg of lidocaine/kg of body weight.

The toxic effects of local anesthetics within the CNS are enhanced by increased cerebral blood flow, by increased concentration of ionized drug in the brain, or by the direct excitatory effect on subcortical structures.

Cardiovascular Toxicity

Since an alarming editorial in 1979 about cardiac arrest in humans following regional anesthesia with etidocaine and bupivacaine,¹⁶⁰ ropivacaine and, recently, levobupivacaine were developed as alternative long-acting amide local anesthetics with less potential for cardiovascular toxicity.^{161–166}

Local anesthetic cardiovascular toxicity may result from direct electrophysiological and mechanical effects on the heart or the peripheral circulation and from local anesthetic actions on the autonomic nervous system. The use of lower concentrations can result in CNS excitation, with increased heart rate, arterial blood pressure, pulmonary artery pressure, and cardiac output. With larger toxic blood concentrations, the systemic effects are characterized by decreased heart rate, arterial blood pressure, pulmonary artery pressure, and cardiac output.^{167,168}

Results from animal studies demonstrate increased systemic toxicity associated with bupivacaine and etidocaine as compared with lidocaine, the most extreme of which include severe CNS and cardiovascular reactions, eventually leading to hemodynamic instability, cardiovascular collapse, and death. In intact, ventilated dogs anesthetized with pentobarbital, minimal changes in various cardiovascular functions are seen with lidocaine, mepivacaine, prilocaine, bupivacaine, and etidocaine at doses of 0.3 to 3 mg/kg. At 10 mg/kg, lidocaine, mepivacaine, and prilocaine produce moderate hypotension and increased pulmonary vascular resistance, and bupivacaine and etidocaine produce significant decreases in cardiac output and stroke volume.⁸¹ Irreversible cardiovascular depression is not produced with lidocaine, bupivacaine, etidocaine, or tetracaine in ventilated dogs anesthetized with pentobarbital, until the blood concentration is at least 3.5 to 6.7 times the dose producing seizures.⁸¹ However, in humans and animals, both bupivacaine and etidocaine administration have

produced simultaneous CNS and cardiovascular toxicity manifested as severe cardiac dysrhythmia, fibrillation, and cardiac arrest.^{32,160,168,169}

In another study of pentobarbital-anesthetized dogs, the intravenous administration of bupivacaine (4 mg/kg) or etidocaine (8 mg/kg) depressed electrophysiological and hemodynamic function; lidocaine (16 mg/kg) induced bradycardia and arterial hypotension, whereas mepivacaine (12 mg/kg) induced minimal cardiovascular changes.¹⁷⁰ The cumulative lethal dose varies from approximately 80 mg/kg for lidocaine and mepivacaine to 40 mg/kg for etidocaine and 20 mg/kg for bupivacaine in ventilated dogs anesthetized with pentobarbital.¹⁷¹ Direct injection of equipotent doses of 2% lidocaine (8 mg) or 0.5% bupivacaine (2 mg) in a 4:1 ratio into a branch of the left coronary artery in morphine (2.5 mg/kg subcutaneously) + α -chloralose (10 mg/kg/h IV)-anesthetized and ventilated dogs produced a 50% reduction of systolic contraction that lasted 25% longer after bupivacaine than after lidocaine injection.¹⁷²

When a comparable prolongation of the QRS interval (as a measure of electrophysiological toxicity) was recorded in pentobarbital-anesthetized pigs after injection of 2 mg of bupivacaine, 4.5 mg of ropivacaine, or 30 mg of lidocaine into the left anterior descending coronary artery, the electrophysiological toxicity ratio for bupivacaine-ropivacaine-lidocaine was 15:6.7:1.¹⁷³ Thus, ropivacaine appears to provide a much greater margin of safety than does bupivacaine.

In sheep, the mean fatal dose of intravenous lidocaine is 30.8 ± 5.8 mg/kg, that of bupivacaine is 3.7 ± 1.1 mg/kg, and that of ropivacaine is 7.3 ± 1.0 mg/kg; thus the ratio of fatal doses of lidocaine, bupivacaine, and ropivacaine is approximately 9:1:2.¹⁷⁴ Respiratory depression with bradycardia and hypotension without arrhythmias were the causes of death in lidocaine-treated sheep, whereas most bupivacaine-treated or ropivacaine-treated sheep died after sudden onset of ventricular tachycardia and fibrillation. Not surprisingly, the cardiotoxicity of lidocaine and bupivacaine in awake, unanesthetized sheep is enhanced by hypercarbia, acidosis, and hypoxia.¹⁷⁵

Local anesthetics bind and inhibit cardiac sodium channels.^{168,176} Bupivacaine binds more readily and for a longer duration to cardiac sodium channels than does lidocaine.¹⁷⁷ The bupivacaine *S*-(-) isomer binds cardiac sodium channels less readily than does the *R*-(+) isomer, forming the basis for the development of levobupivacaine and ropivacaine.³⁷ In vitro studies of guinea pig hearts (Langendorff model) indicate that *R*-(+) bupivacaine, based on intracardiac distribution, prolongs atrioventricular (AV) conduction more and produces more second-degree AV conduction blocks than does *S*-(-) or racemic bupivacaine.¹⁷⁸ Similarly, *S*-(-) bupivacaine produces less QRS widening and fewer AV conduction blocks, less ventricular fibrillation, and less asystole in paced rabbit hearts than does *R*-(+) or racemic bupivacaine.¹⁷⁹ Comparative effects of equal concentrations of bupivacaine, levobupivacaine, and ropivacaine in electrically paced rabbit hearts (210 beats/min) indicate that the free concentration of the three drugs necessary to double the basal QRS duration is 2.4, 7.2, and 14.4 μ g/mL

for race-mic bupivacaine, levobupivacaine, and ropivacaine, respectively.¹⁸⁰

Toxicosis After Ingestion or Application of Topical Preparations

Topical local anesthetic preparations containing lidocaine, benzocaine, tetracaine, and dibucaine, which are in many prescription and nonprescription products, such as ointments, teething gels, suppositories, and aerosols, can be hazardous to animals if ingested. Ingestion of topical benzocaine preparations or spray before endotracheal intubation has produced varying degrees of vomiting, cyanosis, dyspnea, respiratory depression, prolonged sedation, hypotension, cardiac arrhythmias, tremors, seizures, and death in dogs and cats. Likewise, digestion of ointments and creams containing 0.5% and 1.0% dibucaine hydrochloride, which may not be considered dangerous by pet owners, has produced salivation, vomiting, hypothermia, bradycardia, hypotension, weakness, seizures, dysrhythmia, and death in dogs and cats. Between 1995 and 1999 the National Animal Poison Control Center (NAPCC) recorded over 70 cases of toxicosis induced by either ingestion or the inappropriate use of lidocaine, benzocaine, or dibucaine in a variety of animals, including dogs, cats, and ferrets. The clinical signs in a variety of animal species, including dogs, cats, and ferrets, with lidocaine and dibucaine toxicosis included salivation, vomiting, hypothermia, depression, tremors, weakness, bradycardia, hypotension, and seizures.¹⁵³

Local Toxicity

Neurotoxicity

When properly used, local anesthetics rarely produce neurotoxic effects or localized tissue damage. Neurotoxicity of local anesthetics can be demonstrated in vitro by the collapse of growth cones and neuritis in cultured neurons.¹⁸¹ Comparison of seven local anesthetics in a study on growing neurons of the freshwater snail demonstrates neurotoxicity in this order: procaine = mepivacaine (least neurotoxic) < ropivacaine = bupivacaine < lidocaine < tetracaine < dibucaine (most neurotoxic). Similarly, mepivacaine also induced less growth cone collapse and neurite degeneration in the growing dorsal root ganglion neurons from chick embryos than did lidocaine, bupivacaine, or ropivacaine, indicating that mepivacaine is the safest among clinically used local anesthetics.¹⁸²

During the 1980s, 2-chloroprocaine (Nesacaine) occasionally produced cauda equina syndrome in people when large doses (formulated with the antioxidant sodium metabisulfite at an acidic pH) were accidentally injected into the subarachnoid space.^{32,183-185} Experiments with sheep and monkeys document that a large volume (10 mL) of subarachnoid administration of 2-chloroprocaine (3%), bupivacaine (0.75%), or the carrier solution of 2-chloroprocaine (Nesacaine) is neurotoxic and that no local anesthetic appears to be more toxic than another when injected in large volumes into the subarachnoid space of sheep and monkeys.¹⁸⁶ The large doses and volumes of local anesthetics simulate the clinical reality of accidental spinal anesthesia when epidural anesthesia is intended.

Several studies have been completed since then to evaluate the potential neurotoxicity of repeated injections or continuous infusions of local anesthetics in laboratory animals *in situ* and *in vitro*. Experiments using surgically exposed vagus nerves in rabbits bathed *in situ* for up to 1 h in 1.5% 2-chloroprocaine, 2% lidocaine, or 0.75% bupivacaine indicate that 2-chloroprocaine is more neurotoxic than either lidocaine or bupivacaine.¹⁸⁷ Histological sections of nerves excised 10 to 12 days after drug exposure revealed epineurial cellular infiltration and fibrosis, perineurial fibrosis, and axonal degeneration following the administration of 2-chloroprocaine or a mixture of 2-chloroprocaine and bupivacaine, and only minor pathology following exposure to lidocaine or bupivacaine.

Controversy exists about whether lidocaine produces persisting sacral deficits and whether it may be associated with an excessive incidence of transient radicular irritation after spinal anesthesia in humans.¹⁸⁸ Solutions of 5% lidocaine and 0.5% tetracaine, unlike other spinal local anesthetic solutions (1.5% lidocaine with or without 7.5% dextrose, or 0.75% bupivacaine without dextrose), have been associated with clinical cases of cauda equina syndrome after continuous spinal anesthesia. These solutions cause irreversible conduction block in desheathed amphibian nerves 15 min after exposure to 5% lidocaine or 0.5% tetracaine.¹⁸⁹ Neurotoxic effects, including paralysis, have been produced after subarachnoid infusion of 100 $\mu\text{L}/\text{h}$ of 1.5% lidocaine, 0.5% bupivacaine, or 2% 2-chloroprocaine in rats. The incidence of paralysis depended on the duration of exposure to the local anesthetic and was more intense in rats receiving lidocaine or 2-chloroprocaine than those infused with bupivacaine.¹⁹⁰

Myotoxicity

All clinically used local anesthetics are myotoxic, with a drug-specific and dose-dependent rate of toxicity that worsens with serial or continuous administration.¹⁹¹ Some reports indicate that single and repeated injections of clinical doses of mepivacaine (Carbocaine)¹⁹² or bupivacaine (Marcaine)¹⁹³ produce skeletal muscle damage in rats. With 200 μL of local anesthetic (1% procaine, 0.2% tetracaine, 0.5% lidocaine, 0.75% bupivacaine, 2% chloroprocaine, 0.25% dibucaine, and 0.5% lidocaine with 1:200,000 epinephrine, and 2% piperocaine) injected into the tibialis anterior muscle of rats, the muscle fibers recovered from the initial damage in 30 days, with relatively few long-term residual effects.¹⁹⁴

The administration of 20 mL of bupivacaine (5 mg/mL) or ropivacaine (7.5 mg/mL) via catheter to the femoral nerve of minipigs, and subsequent continuous infusion of bupivacaine (2.5 mg/mL) or ropivacaine (3.75 mg/mL) over 6 h, induced necrosis and apoptosis in muscle fibers with bupivacaine and less severe fiber injury with ropivacaine, without affecting vasculature, neural structures, and connective tissues.¹⁹⁵ The administration of bupivacaine and ropivacaine induces Ca^{2+} release of the sarcoplasmic reticulum and simultaneously inhibits Ca^{2+} reuptake into the sarcoplasmic reticulum, suggesting that these synergistic effects may be an important mechanism in bupivacaine and ropivacaine's observed myotoxicity.¹⁹⁵

Although skeletal muscle damage from local anesthetics is not a major clinical problem, case reports have been published of local anesthetic-induced myotoxicity in humans after local and regional anesthesia, peripheral nerve blocks, retrobulbar injections, and trigger-point infiltration for treatment of myofascial pain.¹⁹¹

Methemoglobinemia

Methemoglobinemia (MHG) or increased concentration of methemoglobin (MHb) in the blood is defined as an altered state of hemoglobin whereby the ferrous form of iron (Fe^{2+}) is oxidized to the ferric state (Fe^{3+}), which increases oxygen affinity for hemoglobin (as seen with MHG) and reduces oxygen release at tissues.¹⁹⁶ In addition, oxidative denaturation of hemoglobin can cause Heinz-body formation, which can lead to erythrocyte lysis. MHG can cause hypoxia, cyanosis, or even death.

A number of local anesthetic agents, most notably benzocaine and prilocaine, and less often procaine and lidocaine, are implicated as causative agents. Benzocaine induces MHG in several species, whereas lidocaine may increase MHG in cats and people.¹⁹⁷ It appears that these agents do not directly produce MHG, but rather that one of their metabolites, *o*-toluidine, is responsible.

An intense chocolate brown-colored blood and central cyanosis unresponsive to the administration of 100% oxygen suggest the diagnosis of MHG. MHb concentrations of 15% or more cause a brown discoloration to the blood, which is visible on a white paper towel. Laboratory confirmation is by blood cooximetry, indicating an MHb concentration of greater than 15% (1% to 2% is normal). Spectrophotometry for quantitating the percentage of MHb may be available in a local human hospital laboratory. Blood smears can be useful in determining the presence and degree of Heinz-body formation.

The clinical consequences of MHG are related to the blood concentration of MHb. In humans, dyspnea, nausea, and tachycardia occur at an MHb concentration of > 30%, whereas lethargy, stupor, and deteriorating consciousness occur as the MHb concentration approaches 55%.¹⁹⁸ Acquired toxic MHG has been induced with benzocaine topical anesthetics (spray, cream, and ointment), which were used for bronchoscopic procedures,¹⁹⁹ transesophageal echocardiography,²⁰⁰ fiberoptic orotracheal intubation, and skin application.²⁰¹ Peak MHb concentrations were directly related to the total dose of benzocaine or prilocaine administered and did not occur until 4 to 8 h after epidural administration of prilocaine.²⁰²

MHG has been induced by the nasal, oropharyngeal, and dermal applications of benzocaine in sheep,²⁰³ dogs, and cats.^{204–206} A 2-s spray of benzocaine (estimated dose, 56 mg) to the mucous membranes of the nasopharynx of dogs, cats, monkeys, rabbits, and miniature pigs produces MHb concentrations, ranging from 3.5% to 38%, 15 to 60 min after drug administration.¹⁹¹ A 2-s benzocaine dose and a 10-s dose produce MHb up to 26.4 and 50.5%, respectively, in sheep.¹⁹⁷

Benzocaine is combined with butamben and tetracaine in a topical anesthetic spray (Cetacaine) that has been commonly

used to desensitize the larynx before intubation.²⁰¹ Cats are well recognized to be at an increased risk for developing MHG and Heinz-body anemia with benzocaine-containing products, including Cetacaine. Because of the susceptibility of cats, ferrets, or other exotic animals to MHG, the topical use of Cetacaine should be avoided in these species.

Allergic Reactions

Although allergic reactions to local anesthetics may occur, they are uncommon and often misdiagnosed after accidental intravenous injection of local anesthetics. True anaphylaxis or life-threatening allergic immune reaction is mediated by immunospecific antibodies (immunoglobulins E or G) that interact with mast cells, basophils, or the complement system to liberate vasoactive mediators and recruit other inflammatory cells. Such reactions have been documented with amino-ester local anesthetics (e.g., procaine), particularly those that are metabolized directly to PABA, which is a common allergen. Anaphylaxis to amide local anesthetics (e.g., lidocaine) is much less common.²⁰⁷ Some reaction may result from hypersensitivity to a preservative (e.g., methylparaben, whose chemical structure is similar to that of PABA). Allergic reactions of dogs and cats treated with amide-linked local anesthetics are very rare, which is probably because of their different metabolism and breakdown products when compared with humans.

Adverse drug reactions may mimic anaphylaxis, characterized by bronchospasm, upper-airway edema, vasodilatation, increased capillary permeability, and cutaneous wheal and flare. Rapid cardiopulmonary intervention with airway maintenance, epinephrine administration, and volume expansion is essential to avoid a fatal outcome. Patients with local anesthetic allergy can have their skin tested to determine nonreactive agents.

Treatment of Adverse Reactions

Treatment of adverse reactions after administration of local anesthetics depends on an animal's presenting signs, and involves stabilizing, decontaminating, and supporting the patient.

When local anesthetic-induced convulsions occur, hypoxia, hypercarbia, and acidosis develop rapidly.²⁰⁸ Because these metabolic changes greatly increase the toxicity of local anesthetics,^{175,209,210} prompt therapy with oxygen administration by mask to a dyspneic patient and supporting ventilation (e.g., endotracheal intubation, oxygen supplementation, and positive-pressure ventilation) is indicated.²¹¹

The administration of oxygen by mask and intravenous fluids are often all that is necessary to treat mild signs of local anesthetic toxicity, including mild seizures.²¹² Anticonvulsant drug therapy is indicated if seizure activity interferes with ventilation or is prolonged. Diazepam or midazolam can be given intravenously in dogs and cats at 0.5 to 1 mg/kg in increments of 5 to 10 mg to effect, with minimal side effects. Thiopental or propofol (1 to 2 mg/kg IV) acts more rapidly but may produce greater cardiorespiratory depression than that produced with benzodiazepine therapy.^{213,214}

Acute hypotension may be treated with intravenous fluids (10

mL/kg/h) and vasopressors (phenylephrine, 0.5 to 5.0 µg/kg/min, or norepinephrine, 0.02 to 0.2 µg/kg/min). Hemoglobin-based oxygen carriers (HBOCs), such as HBOC 301 (Oxyglobin) or HBOC 201 (Hemopure and Biopure) (Biopure, Cambridge, MA), are polymerized bovine hemoglobin glutamers that provide a most effective colloid, similar to plasma, and oxygen-carrying effect.^{215,216} Oxyglobin can be a good substitute for stored blood, which may not always be available. Severely hypotensive dogs and cats with obvious severe blood loss (>30 mL/kg in dogs, 15 mL/kg in cats) and those that continue to be dyspneic despite oxygen therapy may rapidly improve from an initial Oxyglobin bolus (4 to 6 mL/kg in dogs, and 2 to 3 mL/kg in cats) as a stop-gap measure to prevent cardiovascular collapse. A one-time intravenous dose of 30 mL/kg Oxyglobin at a rate of 10 mL/kg/h may be given to hypotensive dogs to increase arterial pressure and flow. Every 10 mL of Oxyglobin infused contains 1.3 g of HBOC. Caution must be exercised to avoid intravascular volume overload, which can produce pulmonary edema, pleural effusion, mucous membrane discoloration, pigmenturia, vomiting, and neurological abnormalities, particularly in small dogs and cats.²¹⁵

An intravenous bolus of epinephrine (1 to 15 µg/kg) may be required in presence of myocardial failure. Guidelines for cardiopulmonary resuscitation should be followed when toxicity progresses to cardiac arrest. Animal studies suggest that lidocaine intoxication causes myocardial depression that can be successfully treated with continued advanced cardiac life support.²¹⁷ In contrast, cardiotoxic effects in anesthetized dogs associated with incremental overdosage of bupivacaine, levobupivacaine, or ropivacaine are not as easily treated by resuscitation efforts. The administration of epinephrine may lead to severe arrhythmias, including ventricular fibrillation, with a subsequent mortality rate from bupivacaine, levobupivacaine, ropivacaine, and lidocaine of approximately 50%, 30%, 10%, and 0%, respectively.²¹⁷

Even though the risk of cardiovascular toxicity of ropivacaine has not been completely eliminated, ropivacaine may offer clear advantages over bupivacaine, in that ropivacaine accumulates less sodium-channel blockade at physiological heart rates, dissociates from sodium channels more rapidly, is less cardiotoxic, and is more susceptible to treatment than is bupivacaine.^{218,219}

Ventricular dysrhythmias, including life-threatening ventricular tachycardia associated with local anesthetic toxicity in dogs, have been treated with bretylium tosylate (2 to 6 mg/kg IV).^{220,221} Procainamide and quinidine may be effective treatments for ventricular antiarrhythmias in dogs and cats. Lidocaine is generally contraindicated in patients with amide local anesthetic toxicity.

MHG is easily treated and rapidly reduced to hemoglobin by slow (over several minutes) intravenous administration of a 1% solution of methylene blue (methylthioninium chloride, 4 mg/kg in dogs and 1 to 2 mg/kg in cats).¹⁹⁸ The dose can be repeated in dogs, but repeated administration of methylene blue in cats is controversial because of the risk of Heinz-body anemia and the aggravation of subsequent hemolysis without further lowering MHb content.²²²

Tachyphylaxis

Tachyphylaxis, or the acute tolerance to local anesthetic agents, is defined as decreases in intensity, segmental spread, or duration after repeated administration of equal doses of an anesthetic. Various ester-amide-type local anesthetics (e.g., cocaine, procaine, and tetracaine) and amide-type local anesthetics (e.g., lidocaine, lidocaine-carbon dioxide, mepivacaine, bupivacaine, etidocaine, and dibucaine) have been used at increasing doses to maintain a similar level of effect during surface anesthesia, nerve blocks, brachial plexus block, and epidural and subarachnoid anesthesia. The underlying mechanisms of tachyphylaxis are not well understood. Local alterations in disposition and absorption of local anesthetics—but not in structure (ester vs. amide) or the pharmacological properties of local anesthetics themselves (e.g., brief vs. long acting), technique, mode of administration (intermittent vs. continuous), and pharmacodynamic processes (interactions at receptor sites)—may all play a role in the development of tachyphylaxis.²²³

Choices of Local Anesthetics

The use of specific local anesthetics for local and regional anesthetic and analgesic techniques in animals is described in Chapters 20 (dogs), 21 (cats), 22 (horses), and 23 (cattle, sheep, goats, and pigs).

Local Anesthetics Approved for Veterinary Use by Codified Federal Register (CFR)

Lidocaine injection with epinephrine: cats, cattle, dogs, and horses (21 CFR 522.1244, p. 280, April 1, 1993, editions).

Mepivacaine hydrochloride injection: horses (21 CFR 522.1372, p. 281, April 1, 1993, editions).

Proparacaine hydrochloride ophthalmic solution: animal species not specified (21 CFR 524.1883, p. 338, April 1, 1993, editions).

The CFR also lists a number of combination products containing local anesthetics plus corticosteroid or antimicrobial agents for treatment of surface bacterial infections and/or allergy.

Introduction

Muscle relaxants are anesthetic adjuncts administered to improve relaxation of skeletal muscles during surgical or diagnostic procedures. The term *neuromuscular blocking agents* (NMBAs) is a cumbersome, but descriptive, name that refers to this class of drugs producing their effect by actions at the neuromuscular junction. The more general term *muscle relaxant* refers to any drug that has relaxant properties and would include centrally acting agents such as benzodiazepines, α_2 -adrenoceptor agonists, and guaifenesin. Beneficial effects of NMBA administration during general anesthesia include facilitation of tracheal intubation, reduction of skeletal muscle tone at light planes of inhalant or injectable anesthesia, and prevention of patient movement during delicate ocular, neurological, or cardiac surgery. Although used frequently in human anesthesia and in some veterinary specialties such as ophthalmology, the use of NMBAs in general veterinary practice is limited. Inhalant anesthetics such as isoflurane are complete anesthetics in that they fulfill the *triad* of anesthesia: unconsciousness, analgesia, and muscle relaxation. All three of these properties are required in order to perform most invasive surgical procedures. Of the three properties of the triad, inhalant anesthetics are very good at producing loss of consciousness at comparatively light planes of anesthesia, whereas substantially deeper planes are required to obtund nociceptive processing and skeletal muscle contraction. Indeed, these last two properties are provided by potent inhalant anesthetics only by virtue of more profound depression of the central nervous system (CNS). Unfortunately, deeper planes of inhalant anesthetics are associated with a decrease in cardiovascular function; thus, the properties of muscle relaxation and analgesia are accompanied by reduced cardiovascular performance. In young, healthy animals having good cardiovascular reserve, this may be well tolerated; in patients having poor cardiovascular function, however, significant morbidity and mortality may result. Rather than using inhalant anesthetics to provide all three components of the triad, a safer approach may be one that uses lower concentrations of an inhalant to provide unconsciousness, an analgesic to inhibit nociceptive processing, and an NMBA to relax skeletal muscle. This approach has historically been termed *balanced anesthesia*. Balanced anesthetic techniques are frequently chosen because they provide optimal conditions for both the surgeon and the patient.

History of Muscle Relaxants

The introduction of NMBAs into anesthesiology in 1942 is a relatively recent event in medical practice. Indigenous South Americans had been using a paralyzing poison for centuries on the heads of their hunting arrows. This lethal compound was derived from the tropical plant *Chondodendron tomentosum* and caused paralysis and death to quarry that had been impaled by a coated arrow. Such a poison was an advantage because animals suffering a normally nonlethal wound would succumb and could be harvested by the hunter. The existence of this poison, known as curare, was recognized outside of South America, but its medical uses were not realized. The link was made when an explorer, Richard Gill, returned from the jungles of South America and was diagnosed with multiple sclerosis. The suggestion that the spastic paralysis might be relieved by administration of the arrow poison led Gill to overcome his disability and return to the South American jungle. He returned to the United States in the late 1930s having obtained a quantity of curare, which he sold to a pharmaceutical company that then purified the raw curare and marketed it under the trade name of Intocostrin. Initially, Intocostrin was used only in psychiatric medicine to control seizures that were associated with treatments of psychotic states. A physician in the company realized the potential the drug might have in the field of anesthesiology and convinced an anesthesiologist to undertake studies in humans. This was to be a monumental undertaking because the anesthesia community of the day was understandably not receptive to administration of a paralytic arrow poison to surgical patients. Indeed, the mere suggestion that one would administer a drug that would intentionally cause respiratory arrest was unthinkable to a generation of physicians who had grown up with the motto "Where there is breath, there is hope." Studies which suggested that d-tubocurarine, a quaternary alkaloid isolated from raw curare, was safe and useful for relaxing abdominal muscles during general anesthesia began to emerge, and use of the drug spread to Great Britain by 1945.¹ Another drug with paralytic properties similar to d-tubocurarine, but having the advantage of rapid onset and offset (succinylcholine), was introduced into human practice in the early 1950s.² Reports of the use of NMBA in dogs also began to appear in the early 1950s, and administration of succinylcholine to horses was described in the 1960s.^{3,4} Both d-tubocurarine and succinylcholine have a number of undesirable cardiovascular effects. These agents can affect autonomic ganglia and cardiac muscarinic receptors, as well as induce histamine release. Although succinylcholine has the advantage of rapid onset and offset compared with d-tubocurarine, the additional disadvantages of hyperkalemia, arrhythmias, postanesthetic myalgia, and the changing nature of its block dictated that other NMBAs be developed.

Synthetic relaxants developed during the ensuing years included gallamine, decamethonium, alcuronium and, finally, steroid-based pancuronium. Most are now only of historical interest, although alcuronium is still frequently used in many parts of the world, and pancuronium serves as a parent molecule of several contemporary NMBAs. Atracurium and vecuronium, introduced in the 1980s, have the advantage of minimal to no car-

diovascular effects, minimal histamine release, and a controllable and predictable duration of action. Both are widely used in human anesthesia practice. Mivcurium, an analogue of atracurium with a rapid onset and brief action, was developed to take advantage of rapid onset of action in facilitating tracheal intubation after induction of anesthesia. It is essentially devoid of the problems of hyperkalemia, arrhythmia, and myalgia. Recently developed NMBAs include doxacurium, pipecuronium, and rocuronium, which represent an effort to produce an NMBA that has a precise, predictable duration of action and minimal toward cardiovascular side effects.

Physiology of the Neuromuscular Junction

All muscle relaxants exert their effects at the *neuromuscular junction*, which forms the interface between the large myelinated motor nerve and the muscle that is supplied by that nerve. The neuromuscular junction itself may be divided into the presynaptic motor nerve ending, the synaptic cleft, and the postsynaptic membrane of the skeletal muscle fiber. Present on the presynaptic and postsynaptic areas of the neuromuscular junction are nicotinic receptors, which bind and respond to acetylcholine (ACh) or another suitable ligand. The presynaptic receptor is thought to be important in the synthesis and mobilization of ACh stores, but not for its release.⁵ There appear to be two types of postsynaptic receptors: junctional and extrajunctional.⁶ The *junctional receptors* are found on the motor end plates of normal adult animals and are responsible for interacting with the released ACh, initiating muscle contraction. Antagonism of ACh at the junctional receptors is responsible for the relaxant effect seen when an NMBA is administered. The *extrajunctional receptors* are not present in high numbers on the skeletal muscle membranes of adult mammals, but are important because they are synthesized by muscles that are receiving a less than normal degree of motor nerve stimulation.⁷ Thus, their number may be increased following spinal cord injury or after a period of muscle disuse, such as when a limb is cast. They are also present in neonates. The location of extrajunctional receptors is not restricted to the motor end plate and they may be located over the entire muscle cell surface.^{8,9} Extrajunctional receptors appear to be more responsive to depolarizing NMBAs such as succinylcholine and less responsive to nondepolarizing NMBAs such as atracurium.¹⁰ If the degree of neuromuscular deficit is severe, extrajunctional receptors may be more numerous and widely distributed over the muscle membrane. Such patients may have a more intense response to the actions of a depolarizing NMBA and a more profound release of intracellular potassium ions (K⁺) with its concomitant adverse cardiac effects.¹¹

The presynaptic nerve endings synthesize and store a quantity of ACh in synaptic vesicles. During normal neuromuscular transmission, an action potential arrives at the presynaptic motor nerve ending, causing depolarization of the nerve terminal. The depolarization of the nerve membrane activates adenylate cyclase, which converts adenosine triphosphate to cyclic adenosine monophosphate. The resultant conversion results in calcium-

Neuromuscular Contraction

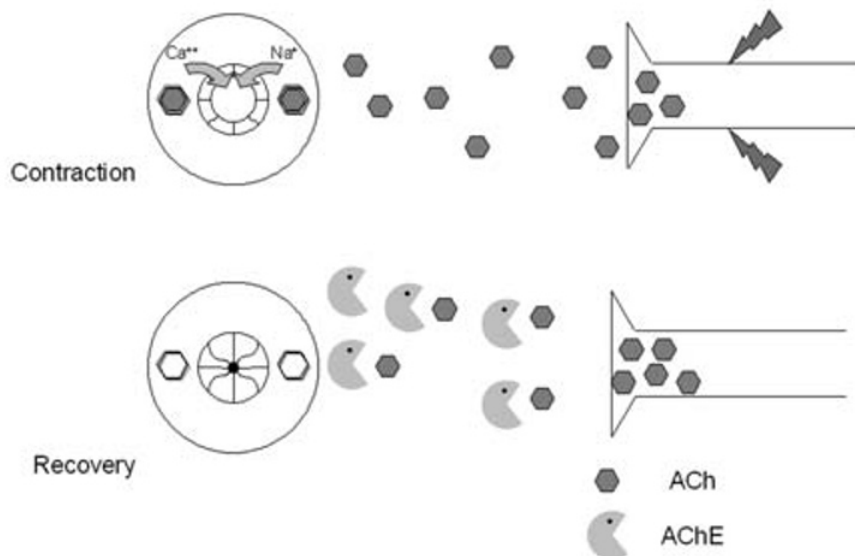

Fig. 15.1. Top: Normal neuromuscular transmission. An action potential arriving at the motor end plate causes the release of acetylcholine (ACh) into the synaptic cleft. ACh binds to both postsynaptic receptors, which opens the ion channel and subsequent muscular contraction. **Bottom:** Recovery and repolarization occur when ACh is degraded by acetylcholinesterase (AChE), the receptor sites are cleared, and the ion channel closes. Ca²⁺, calcium ions; and Na⁺, sodium ions.

ion (Ca²⁺) entry into the nerve terminal and resultant release of ACh into the synaptic cleft. ACh can then diffuse to the postsynaptic membrane and interact with postjunctional nicotinic receptors, resulting in the development of an end-plate potential (a muscle cell action potential) and ultimately muscular contraction (Fig. 15.1). ACh is rapidly hydrolyzed into choline and acetate by acetylcholinesterase. Thus, the muscle cell is depolarized by the end-plate potential created by the binding of ACh to the receptor and then is repolarized as the ACh is removed from the receptor and hydrolyzed.

The postjunctional receptors are concentrated on the end plate immediately opposite the sites of ACh release.¹² Electron microscopy of these receptors shows them to have a central pit surrounded by a raised circular area; thus, they look similar to a spool of thread that is viewed end on.^{13,14} The raised circular area is the mouth of a cylinder of protein that protrudes through the cell membrane, and it contains the binding sites for ACh and other ligands. The pit is the extracellular opening of an ion channel that runs throughout the cylinder's length. The receptor is composed of five subunits of four distinct subunit types designated alpha, beta, gamma, and delta. The two alpha subunits of each receptor and the others are arranged into a cylinder having a potential space, the ion channel, contained within.¹⁵ The functional opening of the channel is controlled by the ACh-binding sites present in the two alpha subunits. When two molecules of ACh are bound to the two binding sites on each of the two alpha subunits, the protein rotates into a new conformation and, in so doing, opens the ion channel and permits ion flow.¹⁶ The open channel enables flow of small cations (sodium ions [Na⁺] and Ca²⁺ flow in and K⁺ flows out) but not large cations or anions. Ion-current flow depolarizes the postjunctional membrane.¹⁷ As the ACh molecules dissociate from the nicotinic receptors and are hydrolyzed by acetylcholinesterase, the ion channel closes, current flow stops, and the membrane is repolarized.

Binding of ligands to the nicotinic receptor at the neuromuscular junction is competitive and reversible. Since two molecules of ACh bound to each of the receptor alpha subunits are required for normal function, antagonists have a distinct advantage in that they need only bind to one of the subunits to prevent normal neuromuscular transmission and thus paralysis.¹⁸ The interaction of ACh and NMBA at the postjunctional receptors is a dynamic process of binding and dissociation and, coupled with the sheer number of receptors present (10,000 to 20,000/μm²), the success or failure of neuromuscular transmission in the presence of an NMBA is determined by the concentration of the NMBA versus the concentration of ACh. A high percentage of receptors binding ACh favors muscular contraction, whereas a high percentage of receptors binding NMBA favors paralysis. This suggests a method for reversing paralysis induced by an NMBA. Increasing the concentration of ACh compared with the concentration of NMBA will increase the probability that the receptor will bind ACh and normal neuromuscular transmission will again result. Clinically, ACh concentration is increased by administration of inhibitors of acetylcholinesterase, such as neostigmine. When acetylcholinesterase is inhibited, ACh is not degraded immediately after release from the receptor, its half-life within the synapse is longer, and more of it is available to interact with receptors. Increased ACh activity is also seen as the concentration of an NMBA declines due to degradation of the drug. As the concentration declines, the competitive balance favors ACh and more normal neuromuscular transmission returns.

Pharmacology

Ligand-Receptor Interactions

The classic mechanism of action of an NMBA such as d-tubocurarine or atracurium is the competitive binding of the drug to the receptor thus blocking transmission of the nerve action po-

tential. There are at least two other less well understood mechanisms: desensitization and channel blockade.

Earlier it was stated that the cholinergic receptor is inactive with its potential ion channel collapsed when two molecules of ACh are not attached to the alpha subunits of the receptor. Binding of ACh to each of the two alpha subunits of the receptor causes the conformational change to the active state and enables the ion channel to open. However, the channel does not have to exist only in the open or collapsed state. A third possible conformation is the desensitized state, in which receptors bind ACh to the alpha subunits, but a conformational change and channel opening do not occur. A number of drugs, including agonists, antagonists, and inhalant anesthetics, appear to be able to switch the cholinergic receptor to the desensitized state. The desensitized-state hypothesis explains the synergistic action that inhalant anesthetics have with NMBAs because it is known clinically that much lower doses of NMBAs achieve an acceptable degree of relaxation when a patient is anesthetized with a volatile anesthetic. A large number of drugs may cause or promote desensitization, such as succinylcholine, thiopental, Ca²⁺-channel blockers, local anesthetics, phenothiazines, cyclohexamines, inhalant anesthetics, and some antibiotics.^{19–22}

Channel blockade occurs when a molecule becomes stuck within the channel, obstructing normal ion flux. This is possible because the mouth of the ion channel is much wider than the transmembrane portion, which enables molecules to enter the channel but not necessarily pass completely through it. Therefore, channel blockade blocks normal neuromuscular transmission not by competing for binding sites on the nicotinic receptor, but by interfering with the depolarization process in response to binding of an agonist.^{23,24} This is an important distinction because the paralysis induced by channel blockade may not be antagonized by administration of an anticholinesterase. In fact, inhibition of cholinesterase enzyme may intensify the block because the opening of more ion channels in response to a greater concentration of ACh may provide a greater opportunity for the offending molecules to become trapped within the channel. It is known that many drugs can cause channel blockade, but the fact that NMBAs themselves can block the neuromuscular receptor channels may partially explain why administration of an anticholinesterase drug in an effort to antagonize neuromuscular blockade may sometimes intensify rather than lessen the paralysis.^{25,26}

Depolarizing and Nondepolarizing Drugs

Depolarizing and nondepolarizing neuromuscular junction-blocking drugs both have an affinity for, and bind to, nicotinic ACh receptors at the neuromuscular junction; however, their intrinsic activity at the receptor is very different. Nondepolarizing drugs bind to the receptor but do not activate it (Fig. 15.2). Their onset of action is characterized by a progressive weakening of muscle contraction and, ultimately, flaccid paralysis. Depolarizing drugs also bind to the receptor and, similar to ACh, the receptor is stimulated, causing depolarization of the postjunctional membrane. Unlike ACh, succinylcholine and other depolarizing NMBAs are not susceptible to breakdown by acetylcholinesterase and thus the ion channel remains open and repo-

larization does not occur. The persistent state of depolarization associated with administration of depolarizing NMBAs causes inexcitability of the motor end plate and, as with nondepolarizing NMBA, a flaccid paralysis results. In addition to the differing mechanism of action of depolarizing drugs, several other differences are clinically apparent when comparing depolarizing and nondepolarizing NMBAs. Succinylcholine administration can cause muscle fasciculations immediately prior to the development of flaccid paralysis. Large doses, repeated administration, or administration of succinylcholine as an infusion causes the character of the block to change from the aforementioned classic depolarizing action (i.e., phase I block) to a phase II block which resembles that of nondepolarizing drugs such as d-tubocurarine. Despite years of investigation into the genesis of phase II block, its mechanism is still not clearly understood. Prolonged exposure of the cholinergic receptors to the agonist succinylcholine likely causes receptor desensitization, channel blockade, or a combination of both. Both receptor desensitization and channel blockade have properties that would mimic those of the nondepolarizing NMBAs and thus would change the mechanism and nature of the succinylcholine-induced block.

Individual Neuromuscular Blocking Drugs

The NMBAs are quaternary ammonium compounds that mimic the quaternary nitrogen atom of ACh. They are attracted to the nicotinic receptors at the motor end plate, as well as to nicotinic receptors located in autonomic ganglia. Most NMBAs are positively charged, water-soluble compounds that have a limited volume of distribution and, in many cases, limited hepatic biotransformation.²⁷ The water-soluble nature of these compounds suggests their pharmacokinetics differ markedly from those of most anesthetic drugs, such as thiopental and propofol. A hallmark of lipid-soluble anesthetic agents is their rapid onset of action and their rapid termination of effect after intravenous administration.

In contrast, the low lipid solubility exhibited by the NMBAs limits drug transfer across membrane structures, including the placenta and blood-brain barrier. Hepatic metabolism and redistribution to sites other than the skeletal muscles are not major mechanisms in the termination of NMBA effects. An exception is vecuronium, where biliary excretion is important in its elimination from the body.²⁸ Because of their water solubility, most NMBAs are excreted by glomerular filtration and are generally not reabsorbed by the renal tubules. The water-soluble nature of these drugs may also contribute to the observation that neonates may require relatively higher doses of NMBAs because neonates have a higher percentage of body water than do adults and typically higher apparent volumes of distribution for water-soluble drugs. Recommended doses of muscle relaxants used in common domesticated species are listed in Table 15.1.

Succinylcholine

This is currently the only depolarizing NMBA used in veterinary medicine. Structurally, the succinylcholine molecule is two ACh molecules joined end to end. This drug is rapidly hydrolyzed in

Neuromuscular Blockade

Fig. 15.2. **Top:** Normal neuromuscular transmission proceeds as described in Fig. 15.1. **Bottom:** Atracurium competes with acetylcholine (ACh) at the postsynaptic receptor. The occupation of at least one of the two receptor sites by atracurium prevents receptor activation, and the ion channel remains closed. Ca²⁺, calcium ions; and Na⁺, sodium ions.

Table 15.1. Doses of commonly used neuromuscular blocking agents in some domestic species.

Drug (mg/kg)	Dog	Cat	Horse
Succinylcholine	0.3–0.4	0.2	0.12–0.15
Pancuronium	0.07	0.06	0.12
Atracurium	0.15–0.2	0.15–0.25	0.07–0.15
Vecuronium	0.1–0.2	0.025–0.05	0.1
Pipecuronium	0.05	0.003	

plasma by pseudocholinesterase (plasma cholinesterase), so only a small fraction of the injected dose survives degradation in plasma to reach the site of action at the neuromuscular junction. Very little pseudocholinesterase is present in the synaptic cleft, so succinylcholine-induced paralysis is terminated by diffusion of the drug away from the neuromuscular junction and into the extracellular fluid. Paradoxically, the rapid degradation of succinylcholine in the plasma is in some way responsible for the rapid onset of effect achieved by the drug. Because of the rapid degradation by plasma pseudocholinesterase, comparatively large doses of succinylcholine may be administered without worry of an increased duration of effect. The higher the succinylcholine dose, the more rapid the onset of paralysis will be. This strategy does not apply when using nondepolarizing NMBAs, where a significant increase in the duration of action will follow increased dosages. Because of its rapid onset of effect and brief action, succinylcholine is often the relaxant of choice to facilitate rapid human endotracheal intubation. Use of NMBAs to facilitate endotracheal tube placement is not common in veterinary practice because, with the arguable exception of cats and pigs, laryngeal contraction is rarely an impediment to tracheal intuba-

tion. Pseudocholinesterase is synthesized in the liver, and production is decreased by liver disease, chronic anemia, malnutrition, burns, pregnancy, cytotoxic drugs, metoclopramide, and cholinesterase-inhibitor drugs.^{29–32} Additionally, species differences in pseudocholinesterase activity may exist. A reduction in plasma cholinesterase activity can be expected to prolong the action of succinylcholine. Administration of organophosphate insecticides, such as dichlorvos and trichlorfon, to horses has been shown to reduce pseudocholinesterase activity and prolong the duration of succinylcholine-induced neuromuscular blockade.³³ Conversely, cats wearing a dichlorvos flea collar had no increased duration of succinylcholine effect.³⁴

Pancuronium

This was the first in a series of nondepolarizing NMBAs having a steroid nucleus. The drug has a dose-dependent onset of approximately 5 min and action ranging from 40 to 60 min in dogs. A large fraction of the drug is excreted by the kidney, and the remainder is metabolized by the liver. As may be expected, the action lasts longer in patients with renal insufficiency. In addition to having affinity for the nicotinic receptors at the neuromuscular junction, pancuronium can also inhibit cardiac muscarinic receptors, thus mildly to moderately increasing heart rate in some patients. This effect appears to vary among species. The muscarinic receptor-blocking effect and associated increase in heart rate appear to be caused by a second positive charge attached to the steroid ring. Removal of a single methyl group and, thus, of the positive charge, creates vecuronium, which is devoid of these cardiovascular effects.

Atracurium

This is a short-acting nondepolarizing NMBA having a benzylisoquinoline structure similar to that of d-tubocurarine. The

drug has a dose-dependent onset of action of approximately 5 min, and its action lasts approximately 30 min in dogs. Repeated doses do not tend to be cumulative, so neuromuscular blockade is sometimes maintained via continuous intravenous infusion. Atracurium is unique in that almost half of it is degraded by Hofmann elimination and nonspecific ester hydrolysis. The remaining fraction is degraded by as yet undefined routes, although evidence exists that its action is not prolonged in people in hepatic or renal failure.^{35,36} Hepatic metabolism and renal excretion are not necessary for termination of effect. Consequently, atracurium may be administered to patients with hepatic or renal insufficiency without significantly increasing its duration of action.

Hofmann elimination is a process of spontaneous molecular decomposition and appears to be pH and temperature dependent. It does not require enzymatic activity. Because Hofmann elimination may occur *ex vivo*, atracurium should be kept refrigerated and is supplied at a pH of 3.25 to 3.65. When injected intravenously, it spontaneously decomposes into laudanosine and a quaternary monoacrylate at physiological pH and temperature. The laudanosine metabolite is a known CNS stimulant and can induce seizures. Unlike atracurium, laudanosine is almost totally dependent on hepatic biotransformation for elimination; thus, laudanosine plasma concentrations may be elevated in patients who have hepatic insufficiency and are given atracurium for longer surgical procedures. Laudanosine-induced CNS stimulation and seizures are unlikely unless atracurium is administered for prolonged periods, as might occur in intensive care settings. Since Hofmann elimination is pH and temperature dependent, hypothermia may increase the duration of atracurium neuromuscular blockade and require a decrease in the infusion rate necessary to maintain neuromuscular blockade.³⁷ Ester hydrolysis of atracurium is accomplished by several plasma esterases unrelated to plasma cholinesterase. In contrast to succinylcholine metabolism, the duration of action of atracurium is not prolonged in the presence of cholinesterase inhibitors.

Many NMBAs having the benzyloisoquinoline structure are associated with histamine release and a varying degree of hypotension. d-Tubocurarine, the prototypical benzyloisoquinoline NMBA, is among the most potent at releasing histamine, but newer drugs having the benzyloisoquinoline structure, such as atracurium and mivacurium, require several times the effective dose for neuromuscular blockade before appreciable amounts of histamine are released.^{38,39} Although signs of histamine release, such as hypotension and tachycardia, are not usually observed when atracurium is administered, slow intravenous administration is always preferred.

Cisatracurium

Atracurium is a racemic mixture of ten optical isomers. The 1*R*-*cis*, 1*R*¹-*cis* isomer, or cisatracurium, comprises approximately 15% of racemic atracurium, is approximately four times more potent, and has much less potential for histamine release. For example, in cats, plasma histamine concentrations were unchanged when up to 60 times the effective dose of cisatracurium was administered.⁴⁰ Cisatracurium has a similar onset time and duration

of action to atracurium. Hofmann elimination metabolizes more than half the administered dose of cisatracurium, but, unlike with the racemic compound, ester hydrolysis does not occur. As with atracurium, Hofmann elimination causes laudanosine production. Since cisatracurium is approximately fourfold as potent as atracurium, the administered dose is correspondingly less, as is production of laudanosine.⁴¹

Vecuronium

Introduced in the 1980s, this was one of the first NMBAs free of cardiovascular effects. The discovery that the vagolytic properties and associated tachycardia seen with pancuronium administration were caused by two positive charges within the steroid molecule led investigators to remove a single methyl group from the parent pancuronium molecule. Vecuronium, the resultant drug, has remarkable cardiovascular stability and does not induce tachycardia nor release histamine.⁴² This drug has a dose-dependent onset of action of approximately 5 min and an intermediate duration of action similar to that of atracurium: 30 min. As with atracurium, a cumulative effect with subsequent doses is not a prominent feature of this drug. Vecuronium is unstable when prepared in solution and is supplied as a lyophilized powder that is reconstituted with sterile water prior to injection. The powder does not need refrigeration, and, once reconstituted, the solution is stable for 24 h. Slightly more than half of the drug is metabolized by hepatic microsomal enzymes and excreted in the bile while a significant fraction undergoes renal elimination.⁴³ In humans, the action of vecuronium is either slightly prolonged or unchanged in patients who exhibit renal insufficiency but not in patients who suffer hepatic failure unless increased doses are administered.⁴⁴

Rocuronium

This is a derivative of vecuronium, having approximately one-eighth the potency of the parent compound. Since vecuronium and rocuronium have similar molecular weights and rocuronium has lower potency, a higher injected dose of rocuronium places a greater number of molecules near the neuromuscular junction translating into a more rapid onset of neuromuscular blockade. The rapid onset of effect of rocuronium makes the drug an attractive nondepolarizing alternative to succinylcholine for tracheal intubation. Its duration of action in dogs is similar to that of vecuronium and atracurium.⁴⁵ Similar to vecuronium, rocuronium seems to be without cardiovascular effects and does not release histamine.⁴⁶ The primary route of elimination is via the hepatic system while a small fraction is eliminated via the kidney.⁴²

Doxacurium

This is a very potent benzyloisoquinoline NMBA with a long duration of action.⁴⁷ Similar to other benzyloisoquinoline NMBAs, such as atracurium, doxacurium does not have vagolytic properties or cause ganglion blockade. Similar to cisatracurium, administration of clinical doses does not cause appreciable histamine release. Doxacurium appears to be minimally metabolized and is excreted unchanged into the bile and urine.

Mivacurium

This drug is a rapid-acting, short-duration NMBA marketed for use in humans for facilitating tracheal intubation at anesthetic induction. Similar to atracurium, mivacurium can induce histamine release if high doses are administered. Mivacurium is rapidly biotransformed by plasma pseudocholinesterase, and metabolites do not have appreciable neuromuscular blocking activity. Its dose-dependent duration of action differs between species. The action of typical doses used in humans lasts approximately 25 min, about one-half to one-third less than that of atracurium. Mivacurium also shows marked differences in potency among species, being much more potent in dogs than in people. In dogs, one-third of the human dose is associated with blockade that is five times longer.⁴⁸ The differences in duration of action between species may in part reflect the reduced activity of pseudocholinesterase in dogs, because normal plasma cholinesterase concentrations for dogs are reportedly from 19% to 76% of human values.⁴⁹ Also, canine pseudocholinesterase enzyme might have differing affinity for the three primary isomers of mivacurium.⁴⁹ Clinical observations indicate that mivacurium has a much briefer action in cats than in dogs.

Nonneuromuscular Effects

The NMBA's primary action is at the nicotinic receptors at the motor nerve plate, but most drugs affect other cholinergic receptors, including the cardiac muscarinic receptors and nicotinic ganglionic receptors within the autonomic nervous system. Many undesirable effects can be caused by either the blocking of receptors or the mimicking actions of ACh.

Cardiovascular Effects

ACh is the primary neurotransmitter of preganglionic and postganglionic neurons within the parasympathetic nervous system, whereas the sympathetic nervous system employs ACh only as a preganglionic neurotransmitter in most tissues. The ubiquitous presence of ACh and the structural similarities between ACh and the NMBA's provides an opportunity to induce physiological effects other than paralytic actions. Agonist or antagonist action at cardiac muscarinic receptors or nicotinic receptors at sympathetic ganglia may decrease or increase heart rate and cause cardiac dysrhythmias. Succinylcholine can mimic the effect of ACh at cardiac muscarinic receptors, leading to sinus bradycardia, junctional rhythms, and even sinus arrest.^{50,51} Alternatively, by virtue of its ACh-like effects at sympathetic ganglia, administration of succinylcholine may increase heart rate and blood pressure.⁵² The net clinical effect observed in an individual animal is probably a function of the species, dose, and timing of administration.

Nondepolarizing drugs, particularly the older agents, may also influence a patient's cardiovascular status. The rapid intravenous injection of a paralyzing dose of d-tubocurarine can decrease blood pressure significantly. This may occur by blocking the action of ACh at sympathetic ganglia, which then decreases sympathetic efferent activity, leading to hypotension. Alternatively, histamine release associated with the rapid intravenous adminis-

tration of d-tubocurarine could cause hypotension. This mechanism probably causes the majority of hypotension, because either slow intravenous administration, or prior administration of an antihistamine, usually attenuates the response.⁵³

Rapid intravenous administration of clinically used doses of pancuronium may produce an increase in heart rate and corresponding increases in arterial pressure and cardiac output.^{54,55} This response is caused by blockade of cardiac muscarinic receptors and resultant decreased parasympathetic nervous system effects on the heart.⁵⁶ In addition, there is evidence that pancuronium may stimulate the release of norepinephrine from sympathetic adrenergic nerves.⁵⁷ A modest increase in heart rate is not always disadvantageous, particularly when drugs having vagomimetic effects (e.g., opioids and α_2 -adrenergic agonists) are concurrently administered to a patient. The ability of pancuronium to increase heart rate is inconsistent among species, however. In dogs, heart rate, blood pressure, and cardiac output typically increase.^{55,56} Heart rate does not change in horses anesthetized with halothane and administered pancuronium, whereas both heart rate and blood pressure may increase in ponies.^{58,59} Pancuronium administration does not change heart rate or blood pressure in anesthetized calves, but increases heart rate and blood pressure in pigs.^{60,61} The newer, intermediate-duration agents, such as atracurium and vecuronium, are virtually devoid of these cardiovascular effects. Atracurium and mivacurium may release histamine, but blood pressure is rarely decreased when modest doses of these NMBA's are used.

The newest NMBA's—pipecuronium, doxacurium, and rocuronium—were designed with cardiovascular stability in mind and their administration is unlikely to be associated with profound changes in cardiovascular function. Rapacuronium induces histamine release, but this is minimized if rapid intravenous administration is avoided.⁶²

Histamine Release

The quaternary ammonium structure inherent in the NMBA's is responsible for the propensity of many of these compounds to stimulate histamine release following intravenous injection. Release of histamine in animals causes vasodilation, a decrease in blood pressure, and possibly a compensatory increase in heart rate. Histamine release is usually associated with administration of the benzylisoquinoline class of NMBA's but has been reported with low-potency steroid relaxants.⁶³ Because d-tubocurarine is a potent inducer of histamine release at doses required to produce clinically useful neuromuscular block, vasodilation and increased heart rate are commonly encountered.⁵⁴ For newer NMBA's, the dose necessary to evoke clinically significant histamine release is much higher than the dose necessary to produce relaxation. For example, in people, approximately 2.5 times the effective dose of atracurium is required to stimulate histamine release.⁶⁴ Pretreatment of patients with H₁-receptor and H₂-receptor antagonists is effective in preventing the cardiovascular effects associated with NMBA-induced histamine release.⁶⁵ Worries about histamine release with newer NMBA's may be avoided simply by administering relaxants more slowly and refraining from administering higher doses.

Placental Transfer

All clinically used NMBAs are large, hydrophilic, polar molecules. As a consequence, their transfer across cell membranes, including the placenta, is limited. At clinical doses, placental transfer of relaxants is minimal and effects on the neonate are unlikely. There is widespread use of NMBAs during human cesarean operations, and atracurium and succinylcholine have been used clinically in small and large domestic animals without consequence to neonates. Administration of NMBAs—such as pancuronium, succinylcholine, gallamine, and d-tubocurarine—to pregnant ferrets and cats does not impair muscle-twitch strength in neonates.⁶⁶

Central Nervous System Effects
