Maintenance and Monitoring

Maintenance of anesthesia with isoflurane in oxygen and delivered from a precision vaporizer is recommended. The breathing circuit should be appropriate for the size of the ratite. Emus and ostriches under 130 kg can be maintained on a small animal breathing circuit. Larger ostriches can be maintained on a large animal breathing circuit. Ventilation of the larger ratites is recommended for two reasons. First, ventilation, as judged by respiratory rate and analysis of arterial blood for carbon dioxide, appears to be markedly depressed by anesthetic induction drugs. Second, ventilation appears to facilitate the uptake of inhaled anesthetics. Despite high vaporizer settings (3% to 5%), it may take 30 to 60 min to stabilize the plane of anesthesia. The reasons for this are not completely clear. A large respiratory volume (approximately 15 L in a 70- to 100-kg bird) certainly contributes, but ostriches may have a functional shunting system, which affects uptake of anesthetic gas.¹⁸¹ Unlike flighted birds, in which increased ventilation tends to be linked to the increased muscular activity of flight, ostriches pant to cool themselves. Apparently this mechanism enables ostriches to cool themselves without effectively hyperventilating.¹⁸¹

Because of their larger size, ratites are generally easier to monitor than other avian species. An ECG should be used, with the leads positioned by attaching one electrode to the neck, one to a wing fold, and the third electrode near the keel or on the opposite wing. Standardizing the placement of leads can be difficult because of the large size, tight skin, and surgical incision sites.

Blood pressure can be measured directly or indirectly. Indirect measurement with an oscillometric technique or a Doppler flow probe can be accomplished in emus and ostriches. The cuff is placed on the leg above the tarsus over the tibial artery. In ostriches, direct arterial blood pressure can be monitored with a catheter placed in the brachialis or ulnar artery of the wing or in the metatarsal artery of a pelvic limb (Fig. 34.10). In emus, since the wing is vestigial, the brachial artery is very small and difficult to catheterize, so the pedal artery must be used. The transducer is zeroed at the level of the keel. Normal blood pressure values for awake or anesthetized ratites have not been reported. Ostriches have been observed to have high blood pressures (Tables 34.5 and 34.6) that increase over time during anesthesia and are not the result of hypoxia, hypercarbia, or a light plane of anesthesia. In fact, if the pressures are not higher than those expected in anesthetized normal small animals, hypovolemia or anesthetic depression of cardiovascular function should be suspected. In emus, blood pressures appear to be somewhat lower than in ostriches. Tourniquet-induced hypertension has been reported in an ostrich undergoing surgery for removal of a sequestrum on the tarsometatarsal bone. Immediately after tourniquet release, blood pressure decreased from approximately 240 to 175 mm Hg.¹⁸²

Oxygen saturation of hemoglobin can be monitored with a pulse-oximeter probe placed on the upper or lower beak. Oxygen-hemoglobin dissociation differs among species. The oxygen-hemoglobin dissociation curve for birds is qualitatively similar to that for mammals, but there are quantitative differences.¹² For this reason, the accuracy of pulse oximetry in birds

Fig. 34.10. Catheter in the digital artery of an ostrich for measuring arterial blood pressure and collecting arterial blood samples for analysis of pH, arterial carbon dioxide partial pressure (PaCO₂), and arterial oxygen partial pressure (PaO₂).

Table 34.7. Arterial blood-gas values from nine ostriches anesthetized with isoflurane and mechanically ventilated^a.

pH	CO ₂	O ₂	HCO ₃	BE	TV	Beats/min
7.53 (0.06)	24.1 (3.9)	471 (97)	20 (2.4)	0.6 (2.4)	13 mL/kg (1)	11 (3)

^aValues were corrected for body temperature by using a Ciba Corning blood-gas analysis machine. Arterial blood samples were taken approximately 30 min after the induction of anesthesia. Values shown are mean, with standard deviation in parentheses. BE, base excess; TV, tidal volume.

Table 34.8. Arterial blood-gas values from ten emus anesthetized with isoflurane and breathing spontaneously^a.

pH	CO ₂	O ₂	HCO ₃	BE
7.20 (0.08)	56.7 (2.9)	355 (24)	20.1 (0)	-7.0 (4)

^aValues were corrected for body temperature by using a Ciba Corning blood-gas analysis machine. Arterial blood samples were taken approximately 30 min after the induction of anesthesia. Values shown are mean, with standard deviation in parentheses. BE, base excess.

is unknown. Clinical experience indicates that saturation of peripheral oxygen (SpO₂) and PaO₂ are generally high.

Rate and depth of ventilation can be monitored as a measure of anesthetic depth, in the same manner as for other avian species. During controlled ventilation, tidal volumes of 10 to 13 mL/kg, respiratory rates of 8 to 16 breaths/min, and inspiratory pressures of 10 to 15 cm of water have been used for controlled positive-pressure ventilation. These settings effectively ventilate or slightly hyperventilate ostriches, as judged by analysis of PaO₂ and carbon PaCO₂ (Tables 34.7 and 34.8). Similar settings

are used for emus, but because of the greater difficulty in collecting arterial blood-gas samples, correlation with mechanical ventilation has not been reported.

Muscle relaxants appear to be effective in ratites. Both atracurium (0.3 mg/kg IV) and vecuronium (0.08 mg/kg IV) have been used during general anesthesia. Duration of effect appears to be similar to that in mammalian species. A peripheral nerve stimulator, with its electrodes placed on the proximal and distal ends of the wing, can be used to assess the block.

Recovery

Recoveries from inhalant anesthesia are generally prolonged, even when every attempt has been made to maintain a light anesthetic plane or decrease the anesthetic plane in the later stages of surgery. Weaning from the ventilator is also slow, and ventilation is often maintained with an Ambu-bag (bag valve mask), or similar device, after disconnection and while moving to the recovery area. Ratites usually undergo recovery in a darkened, padded area, or a well-bedded stall. In the ideal setting a ratite recovery box would be small and narrow, yet tall enough to allow the bird to stand, and would be padded to protect its head. Manual restraint as a means of controlling recovery of adult ratites is dangerous and is not recommended.

Complications

Many of the complications, such as bradycardia associated with visceral manipulation, do not require treatment or are manageable. It is not clear whether the high incidence of complications is typical of ratites or is due to health-related factors, since many of the birds are debilitated. Cardiac problems are particularly common and include bradycardia (heart rate under 30 beats/min), atrial and ventricular premature beats, cardiac fibrillation, and cardiac arrest.¹⁸³ Bradycardia usually responds to glycopyrrolate (0.01 mg/kg) or reversal with yohimbine when xylazine has been used. This high incidence of complications points out the need for good preoperative assessment, stabilization of the patient prior to anesthesia, and adequate intra-anesthetic monitoring.

Summary

Anesthetic management of birds is an art and a science. There is a pressing need for pharmacokinetic and dose-response studies of drugs commonly used in avian anesthesia. Without this scientific information, anesthesia will continue to be limited by anecdotal information and clinical judgment.

Introduction

Successful herptile (reptile and amphibian) anesthesia requires an understanding of anatomy and physiology in health and disease.^{1,2,3} Most herptiles are physiologically resilient, capable of surviving severe hypoxemia and hypothermia that would rapidly kill other vertebrates.^{1,3} Survival into the immediate postopera-

tive period is an inadequate measure of the safety of an anesthetic regimen. Physiological disruptions incurred by poor drug selection and anesthetic technique may not be immediately obvious.

As in all animals, physical restraint alone is inhumane for performing painful procedures even if the animal does not physically respond. During strenuous exercise, the muscles of reptiles and amphibians rapidly produce large amounts of lactic acid due to anaerobic metabolism.⁴ Lactic acidemia occurs in apparently immobile, bound reptiles due to isometric muscle contractions and has been incriminated in mortality of translocated crocodiles.⁴ The use of hypothermia for immobilization is controversial. It is questionable whether it induces altered mentation sufficient for painful diagnostic and surgical procedures; furthermore, hypothermia impairs drug metabolism, digestion, and immune function.⁵

Biology, Anatomy, and Physiology

Herptile biology (herpetology) is comprehensively described by Pough et al. and Zug et al.^{1,3} The approximately 4600 living amphibian species are divided into the Gymnophiona (caecilians, 165 species), Anura (frogs and toads, 4100 plus), and Urodela (salamanders and newts, 415).¹ There are approximately 7150 reptile species.¹ Most are squamates (lizards, snakes, and amphisbaenians, 6850 species), followed by chelonians (turtles and tortoises, 260), crocodylians (crocodiles, alligators, caiman, and gharial, 22), and tuatara (2 species).¹

Herptiles maintain their body either at a specific set-point temperature or within the range between an upper and a lower set point (preferred optimum temperature).¹ As ectotherms, they are reliant on external or environmental heat sources for thermoregulation. Amphibians generally prefer lower environmental temperatures. Water loss increases in amphibians as temperature increases. Set-point temperatures change seasonally and differ between the sexes. Body temperatures are higher during food digestion, pregnancy, and bacterial infections.¹

Although frogs, toads, and salamanders have one ventricle, it is functionally divided, and blood tends to remain unmixed.² Pulmonary arterial branches supply the skin to support its respiratory function. In submerged amphibians, pulmonary gas exchange is absent, and systemic blood flow to the skin is increased for gas exchange. Squamate and chelonian hearts are also anatomically three-chambered, but are functionally five-chambered.¹ The heart has two inflow routes (the right and left

atria) and three outflows (the pulmonary artery and the left and right aortic arches). Both heart chambers are completely divided in crocodylians and, although the left aortic arch originates from the right ventricle, a foramen connects both arches.² This foramen enables both aortic arches to carry unmixed oxygenated blood from the lungs. During the dive response, pulmonary blood flow decreases, and most of the right ventricular output is ejected into the left aortic arch and bypasses the lungs.²

Amphibian hearts are found in the cranial third of the coelomic cavity. Lizard cardiac location ranges from between the forelimbs (e.g., iguanas, chameleons, skink, and water dragons) to almost the middle of the body (e.g., monitor lizards and tegu).⁶ Snake hearts are usually located 20% to 25% of body length from the head. This position is influenced by the animal's predominant lifestyle, the distance being ranked arboreal < terrestrial < aquatic.⁷ To determine cardiac location, the snake is placed in dorsal recumbency, and the ventral scale movement over the heart is visualized. Allowing light to reflect off the ventral scales facilitates this. The shell surrounds the chelonian heart. Crocodile hearts are found on the midline in the cranial third of the coelomic cavity.

Heart rate is influenced by temperature, body size, metabolism, respiratory state, and the presence or absence of painful stimuli.⁸ It varies inversely with temperature except at the extremes of temperatures studied. In lizards, an increase in body temperature of 10°C, over the range 20° to 40°C, increases heart rate by a factor of approximately 2.0 to 2.5.⁸ Heart rates are often higher during heating than cooling, inversely related to body size, and decreased during apnea.⁸

The lungs are only one of several respiratory structures in amphibians.^{1,3} In most adults and larvae, the highly vascularized, moist skin is the major respiratory surface. The buccopharyngeal cavity is also often heavily vascularized and is a minor gaseous exchange surface. Amphibians use buccal pumping to force air into the lungs. Gills are the major respiratory structures in larvae and a few adult salamanders.

The left lung is vestigial in snakes except boas and pythons, and two regions are present: the vascular lung and an air sac.¹ The vascular lung in the anterior part of the body is folded into chambers, providing a large surface area for gas exchange. The air sac posterior to the vascular lung regulates airflow and may extend through most of the coelomic cavity. Although reptile lung volume is greater than that of a comparably sized mammal, gaseous exchange surface area is less.¹

Reptiles do not have a true diaphragm, but do use a negative-pressure pumping system to ventilate.^{1,9} Both inspiration and expiration are active.⁹ Inhalation occurs by thoracic cavity expansion that lowers lung pressure, causing passive airflow into the lungs. The ventilatory cycle airflow is biphasic, commencing with exhalation followed by inhalation.⁹ There are two main respiratory patterns: (a) single breaths interspersed by periods of breath holding and (b) episodes of consecutive lung ventilations followed by long apneic periods lasting from a few minutes to more than an hour. In general, aquatic animals exhibit an episodic breathing pattern, whereas terrestrial herptiles breathe in single breaths. Also, aquatic herptiles usually have longer apneic periods.⁹ There is normally a pause after the relaxation phase of

ventilation, sometimes for several minutes before initiation of exhalation. Ventilatory responses to both hypoxemia and hypercapnia are temperature dependent.⁹ The hypoxic threshold increases as body temperature rises.

In chelonians, the dorsal surface of the lung is attached to the carapace, and the ventral surface is joined to a connective-tissue sheet attached to the viscera.¹ Exhalation occurs when the viscera is forced upward against the lungs. Extension and retraction of the legs increase the coelomic cavity volume. This enables the viscera to fall ventrally, pulling the lungs down, increasing lung volume and drawing air inward. Extension and retraction of the legs can also be used to ventilate an apneic chelonian. The crocodylian liver, posterior to the lungs, acts as a plunger for compression and expansion.¹ Abdominal muscles pull the liver forward during expiration to compress the lungs. Conversely, during inhalation, the diaphragmatic muscles attached to the pelvis pull the liver caudally. Connective tissues attach the liver to the lungs.

Physical Restraint

Amphibians

All amphibians secrete a variably potent toxin from dorsal skin glands. Most require direct contact with mucous membranes for absorption. To prevent intoxication, as well as injury to patient skin, amphibians should be handled with talc-free latex gloves that have been washed in clean water. The gloves decrease abrasion and prevent contact with the oils and other substances present on human skin. Some amphibians will bite. When not being handled, amphibians are confined to clean plastic containers that contain water from the animal's enclosure (Fig. 35.1). Plastic bags are useful to facilitate examination and procedures such as radiography of agile animals, which may also be restrained with small, moist, foam pads. Large anurans may be grasped with one hand placed immediately anterior to the back legs, while the other hand grips around the front legs (Fig. 35.2). Salamanders are grasped immediately behind the forelegs and then in front of the hind legs. Their tails are fragile and may break away. Caecilians, sirens, and amphiumas are difficult to restrain without using some form of chemical restraint. A snake tube may be used for examination and induction.

Nonvenomous Snakes

Aggressive snakes should be approached from behind using a piece of newspaper, a leather glove, or a towel to prevent the animal from biting. Many snakes detect infrared heat and, therefore, a warm hand. Handling of food items such as birds and small mammals prior to handling snakes should be avoided. The snake's head is grasped at its base while supporting the rest of the body. Tame snakes may be gently lifted from below, but it will be necessary to restrain the head for manipulation for anesthesia. Large snakes require multiple handlers and are preferably restrained in large cloth bags.

Venomous Snakes

Venomous snakes are restrained by experienced handlers, and at least two people are always present. Induction is performed in a

Fig. 35.1. A red-eyed tree frog confined in a clear plastic container containing a solution of tricaine methane sulfonate (MS-222) for induction of anesthesia. The container prevents escape while still allowing the animal to be monitored.

room that allows easy personnel movement and no hiding places in the event of an escape. Snake tongs and hooks are used to transfer animals from transport containers to either a Plexiglas tube, squeeze cage, or induction chamber. Fast, agile snakes are either transferred from container to induction chamber through a snake tube or anesthetized in their transport containers. Head restraint will not necessarily prevent handler envenomation.

Snake tubes made of clear, shatterproof plastic are used for restraint during either physical examination or anesthetic induction. The snake is placed on the floor with no obstructions. The tube is held with tongs and placed in front of the snake, which is either gently coerced with a snake hook or allowed to move freely into the tube. Once it advances sufficiently far into the tube, the handler grasps its body and the tube and prevents any retrograde movement. The tube diameter is carefully selected to allow the snake easy movement, but prevent it from turning around. The tube may be connected to the anesthetic breathing system for induction with an inhalant anesthetic. Squeeze cages are constructed of clear plastic and usually possess a foam pad into which the snake is compressed. Multiple holes are drilled through the squeeze wall to enable intramuscular (IM) injection. Induction chambers are made of clear plastic, have a solid lid that can be locked, and an inlet and outlet for the inhalant anesthetic and carrier gas.

Turtles and Tortoises

Although most chelonians are gentle and easy to handle, they may bite either in response to pain or when they feel threatened. Large tortoises will damage fingers and hands that interfere with the rapid leg retraction during a startle response. Aquatic chelonians will bite and scratch and are restrained at either the lateral

Fig. 35.2. A physical restraint technique for a large anuran such as this American bullfrog.

or caudal shell margins. Soft-shelled and common snapping turtles will reach their heads back almost two-thirds the length of their carapace. All sea turtles have the potential to deliver a major bite to the handler and, when removed from the water, will vigorously flap their flippers.

Lizards

All lizards will bite. Large lizards will also scratch and whip with their tails. Small lizards are restrained in a plastic bag or with a towel. Inappropriate tail restraint may elicit tail autotomy (shedding). Gecko skin is fragile and easily torn during restraint. The Gila monster and beaded lizard are venomous. Iguanas are immobilized for short periods by gently pressing down on their eyes and will “revive” spontaneously in response to loud noises and position changes.

Crocodiles, Alligators, Caiman, and Gharial

All crocodylians bite, whip their tail, and roll to escape physical restraint. They can sweep their head 180° from side to side and are preferably approached from behind. Small crocodylians are grasped around the neck and at the base of the tail. A towel may be used temporarily to blind the animal and hold it to the handler's body. In small animals, the neck grip includes a foreleg to reduce rolling. Medium to large crocodylians are very dangerous. In captivity, these animals can be induced with food or training to enter a physical restraint device. If an animal is semiconfined, a zip tie may be placed over the upper and lower jaws and the mouth tied closed. The jaw opening force is much less than the closing force, so it is relatively easy to keep the mouth closed. Once this is accomplished, a rope is placed around the neck to include a forelimb, and the animal is hauled onto land. A physical restraint board will facilitate handling and transportation (Fig. 35.3). The mouth is taped closed using electricians tape because it is less injurious to the skin and appears more resilient in a wet environment than are other tapes. Care is taken to prevent occlusion of the nares at the tip of the maxilla. In many crocodylians, teeth protruding outside the jaw can still lacerate an unwary handler if the animal swings its head. Prolonged restraint with the mouth closed will result in dehydration, even if the animal is allowed to immerse. Very large crocodylians are preferably chemically immobilized with a remote delivery device before handling. This is not only for personnel safety, but also to reduce lactic acidemia, as discussed previously. Particular care must be taken in narrow-snouted crocodylians (e.g., gharial) to not fracture the jaws.

Preanesthetic Preparation

Values for respiration rate, heart rate, and temperature are determined for reference. Accurate admission weight and subsequent daily weighing are essential patient care. The shell is included in the body weight of chelonians when calculating drug dosages. Minimal diagnostic testing includes blood collection for packed cell volume, total protein, and glucose. Blood glucose levels are generally lower (30 to 100 mg/dL) than those observed in mammals. Anesthesia is preferably performed in the morning to allow monitoring and ventilation during regular work hours if recovery is prolonged. A herptile anesthetic patient is maintained within its preferred optimum temperature during the perianesthetic period (25° to 30°C for amphibians and temperate and aquatic reptiles, and ≥30°C for tropical species). Although regurgitation and aspiration are unlikely to cause problems, perioperative fasting is recommended because of impaired digestion.

Premedication

Prolonged parenteral drug clearance generally precludes the use of sedatives and tranquilizers that cannot be reversed with an antagonist. Parasympatholytics are not indicated to reduce secretions. α_2 -Adrenergic agonists alone produce minimal to no sedation and questionable restraint. Benzodiazepines, particularly midazolam, appear to be effective and useful adjuncts to anesthesia

Fig. 35.3. A New Guinea crocodile physically restrained using a home-made restraint board. Note the use of a towel to cover the eyes and ears to reduce external stimuli.

in some, but not all, water turtles, lizards, and crocodylians.^{10–13} The effects of benzodiazepines can be reversed with flumazenil.

Opioids and nonsteroidal anti-inflammatory drugs are administered preoperatively when pain is present or likely to occur. Generally, the same drugs and dosages can be used as those used in mammals, but dosing is less frequent because of relatively prolonged drug clearance. Unlike birds, reptiles appear refractory to the analgesic effects of butorphanol, but responsive to morphine, meperidine, and buprenorphine.^{14–17} Further research to evaluate analgesic pharmacology and perianesthetic regimens in reptiles and amphibians is needed.¹⁸

Local Anesthesia

This approach can be an alternative to general anesthesia in reptiles restrained for procedures involving superficial and accessible sites (e.g., the limbs of lizards and chelonians). Small-volume syringes and small-gauge needles are used for accurate drug dosing. The toxic dosages of most local anesthetics do not appear to have been investigated in most nonmammalian species.

Parenteral Anesthesia: Administration Routes

Historically, IM injections into the muscles of the anterior body have been used to reduce drug passage through the kidneys via the renal portal system. However, studies in turtles and green iguanas demonstrate that only a small proportion of hind-limb venous return passes through the kidney.^{19,20} Consequently, it is unlikely the IM injection site has much influence on drug anesthetic activity.²⁰ Furthermore, posterior IM injection offers the advantages of increased personnel safety, a larger muscle mass for injection, and more injection-site options.²⁰ An exception is the circulation of the green iguana. Blood from the ventral caudal (coccygeal) vein of the green iguana does appear to enter the renal portal system. Consequently, drugs with a very high first-pass tubular excretory rate should not be administered by this route in this species. In snakes, IM injections are administered into the paravertebral musculature, whereas the pectoral and triceps muscles are used in chelonians and lizards, respectively. Distal limb injection is avoided because irritant solutions will cause tissue necrosis and sloughing. The forearms of chelonians appear particularly susceptible. Crocodylians have calcified cutaneous structures (osteoderms) concentrated on the dorsum and flanks that will block IM injection.²¹

Intravenous (IV) and intraosseous injection sites are described in Tables 35.1 and 35.2, respectively. Intravenous access in amphibians is primarily limited to the ventral abdominal vein. Vascular access is difficult in snakes, and jugular vein catheterization requires surgical dissection.²¹ In medium to large snakes, the palatine vein can be catheterized, but the palatine teeth preclude its use in the induction period (Fig. 35.4). Intracardiac injection is unnecessary, potentially traumatic, and delivers high drug concentrations directly to the endocardium and coronary flow. Ventral coccygeal vein injection using a 27-gauge needle is possible, but even in large snakes is difficult.

The jugular vein of tortoises and freshwater turtles is bilaterally located at the level of the auricular scale on the dorsolateral surface of the neck. The vein is catheterized using an over-the-needle catheter (18 to 24 gauge) either percutaneously or after surgical dissection. However, most awake chelonians resist extension of the neck and head required to access this vessel. Tame Galapagos tortoises may allow jugular vein injection through a 19- or 23-gauge butterfly catheter if they are first distracted with food, neck scratching, or a water spray. The subcarapacial vessels are composed of branches from the jugular vein. They are located in the midline underneath the carapace. The dorsal cervical sinuses of sea turtles can be used for catheterization with a through-the-needle catheter.²² The venous plexus on the inside of the forearm of tortoises is unsuitable for catheterization and anesthetic infusion. However, the dorsal coccygeal vein is readily accessible in small to large chelonians. To facilitate access, large tortoises and turtles are gently turned on their backs to cause them to tail curl. Care is taken to prevent being kicked by the hind legs, and the site is cleaned and disinfected to prevent bacterial contamination from feces. A 16- to 18-gauge over-the-needle catheter can be placed in this vessel in large tortoises and turtles (Fig. 35.5).

Fig. 35.4. Placement of an 18-gauge over-the-needle catheter in the palatine vein of an anesthetized Burmese python. The handler must take great care to avoid being injured by the palatine teeth that lie parallel to the vessel. After removal of the catheter, pressure and gauze must be applied for several minutes to provide hemostasis.

Intraosseous catheterization of the distal humerus has been described in sea turtles.²² Intraosseous catheterization of the femur, tibia, or humerus is performed in lizards following lidocaine infiltration of the cannulation site (Fig. 35.6). Correct placement is assessed by palpation, ease of injection, absence of subcutaneous edema at the injection site, and radiography. In lizards, either the ventral coccygeal (Fig. 35.7) or abdominal veins can be used for injection. The ventral coccygeal vein has been recommended for aggressive lizards and is approached from either the ventral or ventrolateral tail surface (Fig. 35.8). The cephalic vein is located on the dorsal surface of the forearm and may be catheterized after local anesthetic infiltration and surgical dissection. The ventral coccygeal vein can be catheterized percutaneously in larger lizards and crocodylians. The technique involves turning the tail to the side at an acute angle to enable placement of an over-the-needle catheter. The catheter can then be inserted at an acute angle in the ventral midline or from the ventrolateral aspect of the tail (Fig. 35.9).

Parenteral Drugs

Dissociative Anesthetics

The major disadvantages of ketamine include poor muscle relaxation, inadequate analgesia, prolonged recovery, the high dosage requirement for surgical anesthesia, and large injection volume.^{23–27} Repetitive administration may result in drug accumulation and prolonged recovery. Advantages to ketamine include a relatively brief effect and some analgesia, and it can be administered intramuscularly. In herptiles, ketamine produces hypertension and tachycardia, bradypnea, and hypoventilation.^{23,25,28} Ketamine dosage is reduced, and immobilization quality is improved by combining ketamine with either an α -adrenergic agonist or a benzodiazepine.^{10,21,29–32} The α -adrenergic agonists are typically reversed with the antagonist atipamezole to shorten re-

Table 35.1. Vascular access in amphibians and reptiles

Amphibians	<p>Ventral abdominal vein—Located in the midline immediately under the skin and may occasionally be identified by using transillumination. Use a 25- to 27-gauge needle and be careful to avoid penetrating the underlying viscera.</p> <p>Ventral coccygeal vein—Located in the ventral midline of the tail. Use a 22- to 27-gauge needle. Insert the needle less than one-third of the distance from cloaca to tail. Apply gentle aspiration until either bone or blood is encountered. If unsuccessful, reposition the needle either cranially or caudally.</p> <p>Heart—Indicated for emergencies. Not recommended for routine injection.</p>
Crocodylians	<p>Ventral coccygeal vein—Insert the needle in the ventral midline of the tail. Insert a 22- to 25-gauge, 1.5- to 3.0-inch needle (Fig. 35.9) less than one-third of the distance from cloaca to tail. Apply gentle aspiration until either bone or blood is encountered. If unsuccessful, reposition the needle either cranially or caudally. This vessel may also be approached laterally by directing the needle at the vertebral body and “walking” it to the vessel on the ventral aspect of the bone.</p> <p>Dorsal coccygeal vein—Located dorsal to the vertebrae in the midline. Insert a 22- to 25-gauge 1.5- to 3.0-inch needle less than one-third of the distance from cloaca to tail. Apply gentle aspiration until either bone or blood is encountered. If unsuccessful, reposition the needle either cranially or caudally.</p> <p>Supravertebral sinus—This vessel lies immediately dorsal to the spinal canal and is not recommended for anesthetic administration because of the potential for drug to be accidentally administered into the spinal fluid.</p>
Squamata Snakes	<p>Palatine vein (medium to large snakes)—Located medial to the palatine teeth in the roof of the mouth (Fig. 35.4). Take care to prevent injury to fingers.</p> <p>Jugular vein—The right is larger than the left. Make an incision four to seven scutes cranial to the heart at the junction of the ventral scutes and the right lateral body scales. Identify the vein by using blunt dissection just medial to the tips of the ribs.⁴⁹</p> <p>Coccygeal vein—Located on the ventral midline of the tail. Insert a 22- to 27-gauge needle less than one-third of the distance from cloaca to tail to avoid the hemipenes in males and the anal sacs. Apply gentle aspiration until either bone or blood is encountered. If unsuccessful, reposition the needle either cranially or caudally.</p> <p>Heart—Indicated for emergencies. Not recommended for routine injection.</p>
Lizards	<p>Cephalic vein—Located on the dorsal (anterior) surface of the distal foreleg. Make a skin incision from the elbow distal and medial over the dorsal forearm to enable visualization of the vein.⁴⁹</p> <p>Ventral abdominal vein—Located in the ventral midline, it may be entered percutaneously or following a small skin incision in the midline to visualize the vessel.</p> <p>Coccygeal vein—Located in ventral midline of tail (Figs. 35.8). Insert the needle sufficiently caudal to the cloaca to avoid the hemipenes in males and the anal sacs. The vessel is entered either directly from the ventral midline or laterally. The needle is inserted ventral to the transverse processes and advanced until the vertebral body is contacted. While gentle suction is applied with the syringe, the needle is “walked” ventrally around the vertebral body until the vessel is identified. It may also be approached laterally as described in crocodylians.</p>
Chelonia (tortoises and turtles)	<p>Jugular vein—Located on lateral surface of neck at the level of the auricular scale. In some animals, it may be percutaneously catheterized. In hypovolemic or hypotensive animals, a longitudinal skin incision is required for visualization. Positive-pressure ventilation may assist distension of the vessel for catheterization.</p> <p>Dorsal coccygeal vein—Located in midline, dorsal to the vertebrae (Fig. 35.5). To facilitate injection, turn the animal gently on its back to cause it to curl its tail onto its plastron. Clean the injection site of feces and other debris. Take care to avoid being kicked by large tortoises. Insert the needle in the midline and advance it until bone is contacted. Gentle suction will enable identification of the vessel.</p> <p>Dorsal cervical sinus (sea turtles)—Located on the dorsolateral surface of the neck just under the palpable dorsal neck muscles.</p>

covery time. In gopher tortoises, medetomidine-ketamine combinations produce marked hypertension, tachycardia, and prolonged apnea.³⁰ The latter results in hypoxemia and hypercapnia if the animal is not ventilated. Intravenous atipamezole administration is not recommended because of potential transient asystole, bradyarrhythmias, and profound hypotension.³⁰

Tiletamine and zolazepam (Telazol) is not indicated for use in most herptiles because of its long duration of effect (≥ 24 h). However, it does offer the advantage of potency and the ability to produce a high drug concentration, thereby reducing injection

dosage. This is useful when immobilizing large aggressive reptiles (e.g., pythons, monitor lizards, and crocodylians).

Propofol

This is the anesthetic induction agent of choice when preinduction vascular access has been attained. Its main advantage is that it is rapidly metabolized and thus has a relatively brief effect. In iguanas, propofol (10 mg/kg intraosseously) produces short-term immobilization, but is associated with prolonged apnea.³³ Subsequent clinical experience indicates this dosage is excessive.

Table 35.2. Techniques and sites for intraosseous catheterization in amphibians and reptiles.^a

Order	Site
Anura (frogs and toads)	Distal femur—Flex stifle, curve in the distal femur, usually enables the catheter to be introduced proximal to the joint.
Squamata (lizards)	Distal femur—Flex stifle, curve in the distal femur, usually enables the catheter to be introduced proximal to the joint (Fig. 35.6). Proximal tibia—Differentiate it from the lateral fibula. Pass the catheter through the tibial crest and pass the needle to the medial surface of the leg as it is passed into the bone. Proximal humerus—Place the catheter either into the greater tubercle or slightly medial to it.
Chelonia	
Tortoises and Turtles	Carapace-plastron bridge—Pass the needle at an acute angle through the bony bridge between the plastron and the carapace. The catheter usually enters the coelomic cavity rather than the intramedullary space.
Sea turtles	Distal humerus—Place the animal in sternal recumbency. From the front, grasp left or right foreflipper, insert the needle in the distal one-quarter of the medial aspect of the humerus at an angle of about 30° to 45° from parallel. Insert the needle as far distal as possible without entering the joint capsule. Turtle bone is very dense, so it is difficult to introduce a catheter.

^aIn all but the smallest patients, spinal needles are recommended to prevent blockage of the needle bore with a bone plug. Measuring half the length of the bone approximates needle length. All intraosseous catheter sites are cleaned and aseptically prepared for introduction of the needle. The bone selected for catheterization is firmly grasped in one hand, and the needle inserted with a twisting of the wrist. Successful placement is indicated by a sudden change in resistance and rapid advancement of the needle, a “grating” feeling as the needle passes through medullary bone, and ease of infusion of a test injection of heparinized saline. Intraosseous catheters can remain in place for 3 days before removal.

Fig. 35.5. A subadult Galapagos tortoise with a 16-gauge over-the-needle catheter placed in the dorsal coccygeal vein for administration of propofol.

Fig. 35.6. This radiograph of the femur of a bearded dragon demonstrates the placement of an intraosseous catheter for fluid administration.

Fig. 35.7. The ventral midline approach for accessing the ventral coccygeal vein in a physically restrained Tokay gecko.

Fig. 35.8A and B. An intravenous catheter placed in the coccygeal vein of a green iguana. This vessel can also be catheterized in other large lizard species and crocodylians.

To reduce the adverse cardiopulmonary effects, it is recommended that propofol be administered in small boluses to effect. In herptiles, time between boluses may need to be 2 to 5 min or more to allow sufficient time for maximum effect.

The muscle relaxants succinylcholine, gallamine, and rocuronium have been used to restrain and immobilize chelonians and crocodylians.^{34,35} The major advantages of succinylcholine are small injection volume, relatively short recovery, and low cost. A major disadvantage is that it produces muscle contractions that cause pain, distress, hyperkalemia, and myoglobinuria. Further, paralysis of the respiratory muscles produces apnea and hypoxemia. Since succinylcholine depends on hepatic and/or circulating pseudocholinesterases for metabolism and excretion, liver

Fig. 35.9. A lateral approach technique for accessing the ventral coccygeal vein in the tail of a New Guinea crocodile.

dysfunction makes duration of recovery unpredictable. Phallus prolapse, with associated trauma, is a frequent complication in male reptiles administered muscle relaxants. The nondepolarizing muscle relaxants offer the advantage of reversal with neostigmine. However, because there are alternative induction and immobilization regimens, neuromuscular blocking drugs are not recommended for immobilization of herptile species.

Inhalant Anesthesia

This is used for maintenance because of ease of control of anesthetic depth, reasonably rapid recovery, and predictability of effects across different species. Induction and recovery are generally slower in herptiles than mammals and often unpredictable. Low cardiac output that delays anesthetic removal from the alveoli would be expected to promote a rapid induction.⁸ However, this effect is counterbalanced by an inefficient respiratory system and low alveolar ventilation.³⁶ Furthermore, cardiac shunts (particularly in aquatic and semiaquatic species) may bypass either part or all lung tissue.^{8,36} To hasten inhalation anesthetic induc-

tion, it is recommended herptiles be at their preferred optimum body temperature, that they be ventilated after being intubated to improve alveolar ventilation, that high vaporizer settings be used initially until anesthetic depth is achieved, and that inhalant anesthetics with low tissue solubility be used. To promote rapid recovery, provide ventilation with room air, ensure the animal is at an appropriate temperature, begin lowering vaporizer settings 10 to 20 min before completion of the procedure, and use inhalant anesthetics with low tissue solubility.³⁷

Herptiles at their preferred optimum temperature appear to have similar anesthetic requirements as mammals.^{38,39} Hypothermic reptiles require a lower maintenance anesthetic setting than at their preferred optimum temperature. Since metabolic rates of reptiles are much lower than those of mammals, oxygen requirement and carbon dioxide production are also much less.³⁶ Nitrous oxide enhances the induction rate and reduces the requirement for other inhaled anesthetics.³⁸ As expected, sevoflurane administration to desert tortoises and black-throated monitors produces more rapid induction and recovery than does isoflurane.^{38,40} Both isoflurane and sevoflurane produce dose-dependent cardiopulmonary depression.^{17,40,41}

Manufactured masks or syringe cases are used for inhalant anesthetic induction in lizards and occasionally tortoises. Clear plastic endotracheal tubes (≥ 2 -mm internal diameter) are used for intubation in small reptiles (≥ 0.5 to 2.0 kg). For very small patients, tubes are constructed from either over-the-needle (18 to 20 gauge) or urinary catheters. However, mucous plugs may act as one-way valves allowing air into the lungs, but not back out, causing respiratory tract hyperinflation. Adequate time must also be allowed between breaths for effective exhalation through very small diameter tubes.

The herptile glottis is located at the base of the tongue and is closed except during exhalation and inspiration. The glottal opening of the green sea turtle is difficult to visualize because of caudally directed pharyngeal spines. The chameleon trachea is very short and flexible. Intubation is facilitated by direct application of local anesthetic to the glottis. Gentle ventral traction on the lower jaw will cause the mouth to open. Alternatively, aggressive herptiles will often open their mouth in response to gentle tapping on their rostrum. Once open, the mouth is prevented from closing with a mouth gag. In small to medium-sized herptiles, a rubber cooking spatula is used to prevent oral cavity and teeth damage. Time is allowed for the glottis to open before insertion of the endotracheal tube. Alternatively, the bevel of the lubricated endotracheal tube is used to gently open the closed glottis. After intubation, a mouth gag constructed of wrapped gauze squares is placed in the mouth. In small herptiles, attaching the animal's head, endotracheal tube, and breathing system to a tongue depressor reduces the possibility of the endotracheal tube accidentally being either twisted or removed.

In crocodylians, at the base of the tongue is a gular flap that must be ventrally displaced to visualize the glottis. After anesthetic induction, the animal's head is hyperextended, and the lower jaw gently pulled downward to enable placement of a mouth gag. A piece of pinewood makes a good mouth gag because the teeth can sink into it without causing damage.

Perioperative Monitoring and Supportive Care

Anesthetic Depth

Increasing depth toward a surgical plane of anesthesia is assumed when muscle tone (e.g., jaw muscle or cloacal sphincter) decreases, palpebral and corneal reflexes are obtunded, and there is no response to a noxious stimulus. In general, the corneal and cloacal reflexes are not lost at surgical anesthetic levels. Palpebral and corneal reflexes are not elicited in snakes and some lizard species because a spectacle protects the cornea. A fixed dilated pupil (unresponsive to light) and no corneal reflex (when previously present) are cross-species indicators of either excessive anesthetic depth or brain-stem hypoperfusion. Respiration rate and depth are not usually useful in assessing anesthetic depth because most herptiles become either apneic or bradypneic at a surgical anesthetic plane. During inhalant anesthetic induction, snakes relax from the head to tail and recover in the opposite direction. Hence, the absence of a response to either a tail or cloacal pinch suggests that an adequate surgical anesthetic plane has been achieved. Similarly, the toe and cloacal pinch response is used to monitor anesthetic depth in amphibians, lizards, and chelonians. The palpebral or corneal response can also be used in chelonians and most lizards. Heart rate and arterial blood pressure will increase in response to a painful stimulus, and sudden increases in these physiological variables often indicate decreased anesthetic depth.

Thermoregulation

During the perianesthetic period, herptiles have an impaired thermoregulatory ability. External heat sources include warm-water or forced-air blankets and radiant heat lamps. Although hypothermia prevention is important, hyperthermia is more likely to cause trauma and death. It is recommended that body temperatures not exceed 35°C. Burns may occur if a herptile is allowed to remain either on a hot surface or under a closely placed heat lamp. Thermal injury is more likely to occur in dehydrated animals with poor peripheral perfusion. Amphibians are prone to dehydration at higher temperatures ($>30^\circ\text{C}$), so their skin must not be allowed to dry out.

Cardiovascular Monitoring and Supportive Care

In herptiles, heart sounds are not usually externally auscultated. The electrocardiograms resemble those of mammals, with clearly defined P, QRS, and T components.³⁶ In reptiles, an SV wave may precede the P wave.³⁶ Standard lead positions are used. However, traditional positioning will not provide adequate wave deflections in herptiles with low signal voltages. Electrodes are placed in the cervical region in lizards with hearts located at the pectoral girdle.⁶ In snakes, the electrodes are placed two heart lengths cranial and caudal to the heart.⁶ In tortoises and turtles, the cranial leads are placed on the skin between the neck and the forelimbs.⁶ To improve signal detection, a stainless-steel suture is passed through the skin and attached to the electrodes.

Doppler flow-detection contact sites include the ventral aspect

of the tail base, the carotid and femoral arteries, and directly over the heart. The chelonian carotid artery is located ventral to the jugular vein on the lateral surface of the neck. It is covered by a layer of muscle and usually not visible. In chelonians, a pencil probe placed at the thoracic inlet will detect flow in either the heart or the major arteries. In an emergency, placement of a probe over the eye may detect ocular arterial flow in large chelonians. A probe placed either down the esophagus or into the cloaca and directed dorsally may also detect arterial flows.

Some reptiles have underdeveloped circulatory reflexes because they usually remain horizontal (e.g., aquatic and terrestrial snakes). To prevent orthostatic hypotension in these animals, positional changes are made slowly, normal body position (usually horizontal and sternal) is maintained, and hypovolemia and hypotension are aggressively treated.

Vascular access is described above and in Tables 35.1 and 35.2. Subcutaneous administration of fluids is not appropriate for correction of deficits or hemorrhage in the perianesthetic period. Balanced electrolyte solutions are used for routine fluid administration. An argument has been made against the use of lactated Ringer's solution in reptiles because of the prolonged half-life of lactate.⁴² It is suggested that a 1:1 combination of 5% dextrose and a nonlactated multiple-electrolyte solution such as Normosol-R (CEVA Laboratories, Overland Park, KS) or Plasma Lyte (Baxter Health Care, Deerfield, IL) be used.⁴² Isotonic dextrose solution (5%) or combinations are indicated when hypoglycemia is present or expected. When necessary for transfusion, blood is collected into heparinized syringes and administered soon after collection. Small-volume infusers are essential for accurate fluid infusion in small anesthetized patients.

Respiratory Monitoring and Supportive Care

Auscultation of the respiratory tract is made difficult by the presence of scales in squamates and the shell in chelonians. To improve sound transmission, use a good-quality stethoscope and place a moistened paper towel between the stethoscope diaphragm and the skin. An esophageal stethoscope will also detect respiratory sounds.

There are two schools of thought when analyzing ectotherm blood-gas samples.⁹ One believes the values should be corrected back to a common body temperature, usually 37°C. Arterial pH decreases consistently and systematically with increasing temperature in virtually all ectothermic vertebrates. Another group recommends analyzing and interpreting the sample at the animal's body temperature. Arterial blood samples are difficult to obtain in most herptiles. The preferable sampling site is the carotid artery because it reflects blood flowing to the brain.⁴³ Because of the presence of shunting and the multiple functional chambers, cardiac samples do not accurately reflect carotid arterial blood values.

Transmission pulse oximetry is made difficult by the lack of suitable placement sites. Reflectance pulse-oximeter sensors can be placed in either the esophagus or the cloaca of anesthetized animals. Diethelm et al.⁴⁴ evaluated pulse oximetry in green iguanas. Oxyhemoglobin and deoxyhemoglobin absorbencies at 660 and 940 nm were determined to be similar to those of human hemoglobin *in vitro*. A reflectance probe was placed in the esophagus and the measured saturation of peripheral oxygen (SpO₂) was

compared with arterial oxygen saturation (SaO₂) values calculated from arterial oxygen partial pressure (PaO₂) in blood samples obtained from the abdominal aorta. There were no significant differences between SpO₂ and SaO₂ values, and it was concluded that pulse oximetry is an excellent tool for monitoring pulse rate and oxygen saturation in iguanas. The study abstract does not mention how the SaO₂ values were calculated and does not address methemoglobin concentrations.⁴⁴ Another recent study in green iguanas showed no relationship between calculated hemoglobin saturations and those obtained from a pulse oximeter.¹⁷

Most reptiles appear to develop either apnea or marked bradypnea and hypoventilation when anesthetized. Hence, it is usually necessary to provide ventilation during anesthesia. The respiration rate required is very low (<4 breaths/min) and the tidal volume of reptiles is usually larger than that of mammals of a comparable size. Further research is necessary to determine optimum ventilation, whether spontaneous or assisted, in anesthetized reptiles. The presence of cardiac shunts in reptiles renders capnography inaccurate because end-tidal carbon dioxide partial pressure (ETCO₂) values do not reflect arterial carbon dioxide partial pressure (PaCO₂) levels.⁹

Resuscitation

This follows the same sequential guidelines used in mammalian patients. The low metabolic rates and low oxygen requirement of most herptiles allows a prolonged "window" of time in which resuscitation can be successful. The author (D.H.) has revived an iguana after 30 min of apparent asystole.

Anesthetic Recovery

Inhalant anesthetic administration is discontinued 15 to 20 min before the end of a surgical procedure. If indicated, additional analgesics are administered at this time. When a procedure is completed, the reptile is transported to the recovery site. Care is taken to prevent orthostatic hypotension by maintaining the animal horizontal and avoiding rapid changes in body position. The endotracheal tube is maintained in position until spontaneous respirations or attempts to remove the endotracheal tube are noted. The endotracheal tube is connected to a bag valve mask and ventilated with room air to facilitate return to spontaneous ventilation.³⁷ Amphibian patients are transferred with no anesthetic to clean tank water. The animal is provided with a heat source, and cloacal temperature is monitored. Hyperthermia and burns are prevented as discussed above. Prolonged recovery may be due to delayed hepatic biotransformation or renal excretion of parenteral anesthetic drugs, pulmonary shunting preventing removal of inhalant anesthetics, hypothermia, hypoglycemia, and severe metabolic disturbances (i.e., acidemia, hyperkalemia, hyponatremia, or hypocalcemia).

Selected Anesthetic Protocols

It is recommended that all amphibians and reptiles undergoing surgery and/or potentially painful procedures receive an analgesic(s) in the perioperative period.^{15,16} Anesthetic protocols are outlined in Table 35.3.

Table 35.3. Recommended anesthetic regimens for amphibians and reptiles.^a

Amphibians	<p>Tricaine methane sulfonate (MS-222).⁴⁵ Buffer a 0.02% to 0.2% (0.2 to 2 g/L) solution with sodium bicarbonate 1 to 3 g/L to a pH of 7.0 to 7.4. Immerse the animal until it is anesthetized (20 to 30 min) and then wash its surfaces with clean water. If supplemental anesthetic is required, immerse the animal in half-strength solution or drape it with towels soaked in solution. Alternatively, intubate it and maintain it with inhalant anesthetic in oxygen. Recovery should be in clean water from the animal's habitat.</p> <p>Topical isoflurane (3 mL of isoflurane + 3.5 mL of water-soluble gel + 1.5 mL of water, mixed thoroughly in a serum tube).⁴⁶ Apply dorsally (0.025 mL/kg for aquatic and 0.035 mL for terrestrial animals). Induce anesthesia in a clear plastic container and remove the animal from the container once the animal's righting response is lost. Wipe off all gel with a moist towel. The animal can be intubated and maintained with inhalant anesthetic in oxygen. Recovery should be in clean water from animal's habitat.</p> <p>Clove oil anesthetic bath.⁴⁷ Make it immediately before use: 0.30 mL of clove oil (eugenol: minimum, 85%; and specific gravity, 1.038 to 1.060) per liter of dechlorinated water and agitate for 4 min. Immerse the amphibian in a shallow tray for 15 min and then wash off the liquid. Gastric prolapse is common.</p>
Crocodylians	<p>Propofol (3 to 5 mg/kg IV). Intubate and ventilate (2 to 4 breaths/min) with either isoflurane (2% to 3%) or sevoflurane (4% to 5%) in oxygen (\pm nitrous oxide).</p> <p>Tiletamine-zolazepam (4 to 6 mg/kg IM). Wait 30 to 45 min and then intubate and ventilate (2 to 4 breaths/min) with either isoflurane (2% to 3%) or sevoflurane (4% to 5%) in oxygen (\pm nitrous oxide).</p> <p>Medetomidine-ketamine (100 to 200 μg/kg + 5 to 10 mg/kg IM, higher dosages in juveniles). Intubate and ventilate (2 to 4 breaths/min) with either isoflurane or sevoflurane in oxygen (\pm nitrous oxide).²¹ Reverse medetomidine with atipamezole (500 μg/kg IM).</p>
Lizards	<p>Propofol (3 to 5 mg/kg IV, IO). Intubate and ventilate (2 to 4 breaths/min) with either isoflurane or sevoflurane (4% to 5%) in oxygen (\pm nitrous oxide).</p> <p>Mask induction with isoflurane (5%) or sevoflurane (7%). Intubate and ventilate (2 to 4 breaths/min) with either isoflurane (2% to 3%) or sevoflurane (4% to 5%) in oxygen (\pm nitrous oxide).</p> <p>Lidocaine (1%) desensitization of the glottis. Wait 2 to 3 min and then intubate and ventilate (2 to 4 breaths/min) with either isoflurane (2% to 5%) or sevoflurane (4% to 7%) in oxygen (\pm nitrous oxide).</p> <p>Tiletamine-zolazepam (4 to 6 mg/kg IM, IV, IO). Intubate and ventilate (2 to 4 breaths/min) with either isoflurane (1% to 3%) or sevoflurane (3% to 5%) in oxygen (\pm nitrous oxide).</p> <p>Medetomidine-ketamine (150 μg/kg: 10 to 15 mg/kg IM, IV, IO). Intubate and ventilate (2 to 4 breaths/min) with either isoflurane (1% to 3%) or sevoflurane (3% to 5%) in oxygen (\pm nitrous oxide).</p>
Nonvenomous Snakes	<p>Lidocaine (1%) desensitization of glottis. Wait 2 to 3 min and then intubate and ventilate (2 to 4 breaths/min) with either isoflurane (5%) or sevoflurane (7%) in oxygen (\pm nitrous oxide); maintain with either isoflurane (2% to 3%) or sevoflurane (3% to 5%) in oxygen (\pm nitrous oxide).</p> <p>Large snakes (pythons and boas): tiletamine-zolazepam (3 to 5 mg/kg IM) or medetomidine-midazolam (30 μg/kg–0.3 mg/kg). Wait 45 min and then intubate and ventilate (2 to 4 breaths/min) with either isoflurane (3%) or sevoflurane (5%) in oxygen (\pm nitrous oxide); maintain with either isoflurane (2% to 3%) or sevoflurane (3% to 5%) in oxygen (\pm nitrous oxide).</p> <p>Propofol (3–5 mg/kg IV), ventral coccygeal vein. Intubate and ventilate (2 to 4 breaths/min) with either isoflurane (3%) or sevoflurane (5%) in oxygen (\pm nitrous oxide); maintain with either isoflurane (2% to 3%) or sevoflurane (3% to 5%) in oxygen (\pm nitrous oxide).</p>
Venomous Snakes	<p>Induction-chamber isoflurane (5%) or sevoflurane (7%). Intubate and ventilate (2 to 4 breaths/min) with either isoflurane (5%) or sevoflurane (7%) in oxygen (\pm nitrous oxide); maintain with either isoflurane (2% to 3%) or sevoflurane (3% to 5%) in oxygen (\pm nitrous oxide).</p>

IM, intramuscularly; IO, intraosseously; IV, intravenously.

^aThe inclusion of an analgesic is mandatory for surgery and painful diagnostic procedures.

Caecilians, Frogs and Toads, Salamanders, and Newts

The most commonly used chemical immobilization agent and anesthetic in amphibians is tricaine methane sulfonate (MS-222).^{45,46} This drug is dispensed as a white powder and, when dissolved in distilled water, produces a very acidic solution (pH \geq 3.0). Consequently, it is necessary to buffer the solution back to a physiological pH (7.0 to 7.4) with 1 to 3 g/L of sodium bicarbonate (NaHCO₃). The pH should always be checked before immersing an animal. Buffering of the solution has the added benefit of increasing the ionized drug (the active form of the drug). When using a buffered solution of MS-222, surgical anesthesia can be provided with concentrations as low as 0.02% (0.2 g/L).⁴⁵ The induction time is around 30 min. The animal should be confined in a clear container so that it cannot escape, but can be monitored (Fig. 35.1). Once the animal is anesthetized, it is removed from the solution and placed on a clean moist surface. If the animal begins moving, it can either be reimmersed in a half-strength solution or solution added to moist towels draped over the animal. Aquatic amphibian species have much more efficient transdermal absorption than terrestrial species and thus may require a lower dosage. Similarly, larvae and tadpoles appear to require a lower dosage. Clove oil is an alternative to MS-222.⁴⁷ Ketamine produces immobilization and anesthesia, but results in prolonged recoveries. Similarly, tiletamine and zolazepam combinations produce very prolonged recoveries.

Inhalant anesthetics administered into solution are cumbersome and difficult to scavenge. A technique using a topical mixture of isoflurane and K-Y Jelly has been used to immobilize frogs.⁴⁶ A viscous isoflurane solution (1.5 mL of water plus 3.5 mL of K-Y Jelly) is produced in an empty serum container that is shaken vigorously until the contents mix. The liquid/gel is drawn into a syringe with a 16-gauge needle and then applied directly to the animal's dorsum. Dosages vary from 0.025 to 0.035 mL/g of body weight, depending on the species.⁴⁶ Lower dosages are used for frogs, newts, and salamanders, compared with toads. Once the solution is applied, the animal is placed in a small sealed container until induction occurs (5 to 15 min). When the animal has lost its withdrawal and righting reflexes, a saline-soaked gauze is used to wipe the dermis free of anesthetic solution. The animal will remain anesthetized for 45 to 80 min. These methods provide general anesthesia or can be used for intubation prior to gas anesthesia.

Nonvenomous Snakes

Small to medium-sized snakes (<20 kg) are manually restrained, their mouths are opened using a spatula, and 1 to 2 drops of a 1% lidocaine (without epinephrine) solution is applied directly into the glottal opening. A period of 2 to 3 min is allowed for the lidocaine to desensitize the mucosal surfaces before a lubricated endotracheal tube is passed through the glottal opening. Although large snakes (\geq 20 kg) can be manually restrained, it is preferable that an induction agent be administered first to facilitate handling and intubation. In large pythons, a tiletamine-zolazepam combination (Telazol, 3 to 4 mg/kg) is administered intramuscularly 45 min before the animal is intubated. Alter-

natively, a combination of medetomidine (30 μ g/kg) and midazolam (0.3 mg/kg) may be used. These injections are given through the cloth bag restraining the snake. Ventral coccygeal vein administration of propofol is difficult even in large snakes, but can be attempted using small-gauge needles. Snakes can also be induced by placing them in an induction chamber and administering high inhalant anesthetic concentrations in oxygen. Once intubated, the snake can be connected to an anesthetic breathing system, maintained with isoflurane in oxygen, and ventilated one to six times per minute.

Venomous Snakes

The main difference between venomous and nonvenomous snake anesthesia is the importance of careful physical restraint during the perianesthetic period. Although parenteral anesthesia is never relied on to produce complete immobility, a low IM dose (3 to 4 mg/kg) of tiletamine-zolazepam 30 to 40 min before inhalation anesthesia will decrease the responsiveness of the snake and may contribute to analgesia. The authors prefer to induce anesthesia in venomous snakes in either an induction chamber or snake tube with isoflurane. Alternatively, the animal is intubated while awake while restrained in a snake tube. The snake is allowed to advance to a position just before the end of the tube. A long pair of tongue forceps or a vaginoscope is then used to open its mouth and manipulate the endotracheal tube through the glottis. Once the animal is restrained, the fangs are covered with either a syringe case or urine cup and taped in place to prevent accidental envenomation. During recovery, the endotracheal tube is removed with forceps when spontaneous respiration is present but before struggling occurs.

Lizards

Lizards may be induced with an inhalant anesthetic administered into a plastic bag, induction chamber, or mask. Breath holding, though sometimes present, is not as large a problem as some authors suggest and does not preclude its use. Gently running fingers along a lizard's chest wall will usually elicit a respiration. Some lizards may also be intubated while awake, as with chelonians and snakes. The preferred induction agent is propofol (3 to 6 mg/kg) administered into the ventral coccygeal vein. Tiletamine-zolazepam (4 to 8 mg/kg) can be given intramuscularly to facilitate handling of large lizards.

Chelonians

Some tortoises and turtles can be intubated while awake. Once intubated, they are ventilated with isoflurane in oxygen (with or without nitrous oxide). In animals in which a parenteral anesthetic is required for intubation, the authors prefer propofol (3 to 5 mg/kg) administered into the dorsal coccygeal vein (Fig. 35.5). Alternatively, small IV boluses (1 to 2 mg/kg) of ketamine may be used. If vascular access is not possible, a combination of IM ketamine and medetomidine can be used for induction.^{29,31,32} The dosage is lower in land tortoises than in aquatic turtles. Atipamezole is administered intramuscularly to reverse the medetomidine and hasten recovery. Mask induction is possible with either isoflurane or sevoflurane in oxygen, but is likely to be

prolonged because of breath holding and pulmonary shunting in aquatic species.

Anesthesia of sea turtles is similar to that of other chelonians.^{29,48} However, they tend to be large, powerful, and sometimes more aggressive. The sea turtle glottis may be very difficult to visualize because it is hidden in the folds and spines of the pharynx. Pulmonary shunting is a problem for inhalation anesthesia in sea turtles and probably explains some of the prolonged recoveries observed in animals that appear lightly anesthetized during a procedure.^{48,49} Unfortunately, there appears to be no mechanism for avoiding this problem.

Crocodylians

Crocodylian anesthesia usually requires a combination of physical restraint (Fig. 35.3) and anesthetic drugs.^{4,35} Muscle relaxants have commonly been used for chemical immobilization of medium to large crocodylians. In addition to the lack of analgesia, the therapeutic index of these drugs is very low. An alternative to muscle relaxant-induced immobilization is using the combination of tiletamine and zolazepam. A recent study that also assessed medetomidine with ketamine in alligators concluded that this combination provided good reversible restraint.¹⁶ However, the dosages used were much higher than those needed to immobilize chelonians and other reptiles. When IV access can be attained, propofol is a valuable agent for induction and maintenance of anesthesia. Dosages vary from 2 to 5 mg/kg. Once the crocodile or alligator is intubated, it can be ventilated and maintained on an inhalant anesthetic.

Fish Anesthesia

As with other veterinary patients, a solid understanding of anesthetic agents and procedures will greatly enhance the diagnostic and treatment options available to veterinarians working with fish. Although the topic of fish anesthesia may be new to most veterinarians, the concepts and procedures are relatively easy to master. With a basic understanding of fish physiology and anatomy, practitioners should be able to sedate and anesthetize a variety of fish species for both medical and surgical procedures. This discussion focuses primarily on anesthesia of teleost fish (bony fish) and contrasts differences to cartilaginous fish (sharks and rays).

Anatomy and Physiology

There are more than 24,000 species of fish. In comparison, there are only 4,000 species of mammals. Because of this tremendous diversity of species, there are many species-specific responses. Accordingly, when working with a new fish species one should anesthetize and recover a few individuals before applying a particular anesthetic protocol or technique to a large number of individuals.

Fish are vertebrates that are uniquely adapted to the aquatic environment. While they do not have lungs, they do respire and require oxygen for routine metabolic processes. Fish use their gills for respiratory gas exchange and can remove oxygen from the water and transfer carbon dioxide and other metabolic by-

products back into the water. For this reason, adequate oxygen levels in the animal's aquatic environment are critical for normal respiration and safe anesthesia. During fish respiration, water enters the mouth, passes over the gill filaments, and travels out through the opercular opening. Movement of this opercular flap is a good method to grossly evaluate respirations.⁵⁰⁻⁵⁴ The gill filaments are anatomically designed for water flow from cranial to caudal, therefore it is recommended that anesthetic-delivery systems provide water flow in a similar direction.

Depending on the procedure, the patient may remain either in its water environment or be removed for prolonged periods of time. In general, fish can be safely removed from water for periods of 1 to 4 min in order to perform routine diagnostic procedures (e.g., blood collection, biopsy, radiography, etc.).⁵¹⁻⁵⁴ For longer procedures (i.e., surgical intervention), the patient can remain out of water for much longer periods, but must be kept moist to prevent desiccation.⁵¹⁻⁵⁴ Placing the patient in a shallow water bath or on a wet foam block and intermittently dripping or spraying water over the animal can accomplish this. The gills must be kept wet for adequate oxygen exchange. If the fish is placed in a shallow water bath, the water level should be adjusted to cover the gills. If the animal is maintained on a wet foam block, water flow must be provided into the oral cavity and over the gills.

Fish are poikilothermic and their body temperature is directly influenced by their external environment. It is important to know the general water temperature ranges for different species and maintain their water anesthetic solutions in a similar temperature range.

Anesthetic Protocols

Most commonly, the anesthetic agent can be dissolved in water which is used to deliver the drug to the fish. This is a form of inhalation anesthesia since the anesthetic agent is delivered via the respiratory system. While there are some injectable anesthetic agents that are effective, difficulty with controlled delivery combined with their very different species-specific dosages makes the use of injectable agents generally more problematic.^{51,53,54}

Adding an anesthetic agent to the water is a relatively simple and safe method of anesthesia. Inhalant water anesthesia allows the animal to remain in its normal environment during induction and does not require direct patient handling or knowledge of the animal's body weight. It is critical to have adequate and appropriate water for anesthetic induction, maintenance, and patient recovery. When available, it is recommended that the anesthetic water source be the animal's own environmental water (i.e., tank or pond). There are many water quality variables that have direct impact on fish physiology, and abrupt changes of water parameters can have deleterious implications.

Water quality testing should be performed prior to any anesthetic attempt. The specific tests conducted are dictated by the size of the system, the water quality history and whether it is fresh water or marine. In general, the following basic parameters should be evaluated: temperature, pH, nitrate, nitrite and ammonia.^{52,54} If water from the tank is not being used, it is important that both tank water and anesthetic water are tested, and that

anesthetic water quality parameters closely resemble those of the home tank. Water quality testing and maintaining appropriate parameters is more critical for longer anesthetic procedures. For short anesthetic events (i.e., less than 10 min), the equipment needs are minimal and require only an induction system and a recovery system. This “system” is usually a water filled container, the size of which will be dictated by the size of the patient. Small plastic containers or buckets work well for animals less than 1 kg, and larger plastic food coolers for larger fish. This setup is ideal for short diagnostic evaluations, including skin scrapes, gill biopsies, blood collection, body weight measurement, and diagnostic imaging. The patient is placed in a container filled with the anesthetic containing water for induction. Once the fish has become recumbent, it can be evaluated either by elevating the area of interest out of the water or by removing the whole patient to a shallow water bath. After completion of the procedure(s), the fish is placed in a container with anesthetic-free water for recovery.

As with anesthesia of other animals, appropriate oxygen supplementation is critical. Air stones can be attached to the oxygen tubing of an anesthetic machine or directly to an air tank for delivery. In general, the air stone should follow the patient through each tank system (induction, maintenance, and recovery).

For longer anesthetic procedures (e.g., more than 5 to 10 min), the patient should be removed from the induction system and placed in a container of water with a lower maintenance anesthetic concentration. For these procedures anesthetic and oxygen delivery is enhanced by an active flow of water over the gills. This can be accomplished either through the use of a gravity-fed, elevated water container or a small water pump.^{51,52,54} The elevated container can easily be constructed using empty IV fluid bags and associated IV drip sets. A corner at the top of the IV bag is cut away, the bag is emptied, and the anesthetic solution poured in. An air stone is placed into the bag through the opening at the top. The IV drip set is attached to the bag and the solution directed into the patient’s mouth. The flow can be adjusted using the adjustable valve on the fluid line. In general, the author uses 1-L bags with a corresponding small animal drip set for smaller patients (<200 g) and 3- to 5-L IV bags with higher flow equine drip sets for larger patients. A plastic Y piece can be attached to the end of the IV line and placed in the animal’s oral cavity. The Y piece helps direct water flow directly over the gills and out through the operculum. This helps prevent water flow into the GI tract. This system is easy to create, but does require continual refilling of the bag for longer procedures.

Another option is to create a closed system with a water pump. This is much more convenient for longer procedures or if several anesthetic events are scheduled. A submersible pump is placed within the anesthetic water container and water is pumped from the tank into the patient’s mouth via a flexible tube.⁵² The water pump and the outflow tubing should be adjusted to allow a steady, gentle flow of water through the opercular flaps. Excessive water velocity or placement of the tube in the caudal portion of the oral cavity can cause gastric dilation and poor oxygenation. The patient should be positioned on a fenestrated platform that allows the water to drain back into the anesthetic water tank.

Perioperative Considerations

Although not required, it is generally recommended that patients be fasted 12 to 24 h prior to anesthesia. Fish do not have lungs and cannot aspirate. They can however regurgitate and digesta can become trapped in the gill arches. Fasting also helps decrease the likelihood of fecal contamination of the anesthetic and recovery water systems.

In practice, preoperative hematologic evaluation is not commonly performed in fish although the merits of a preanesthetic evaluation still apply. In many cases large numbers of animals are sedated and preanesthetic blood work may not be realistic. In addition, normal hematological blood parameters have not been documented and values for many species can be difficult to interpret.

Anesthetic Levels and Monitoring

Anesthetic monitoring is important to ensure the patient is at the appropriate anesthetic level for the procedure being conducted. As with other animals, fish pass through anesthetic stages as they become sedated and anesthetized (Table 35.4). Depending on the species, the agent, and the concentration, each stage of anesthesia may not be recognized.¹ In general, sedation is characterized by slower swimming and reduced reaction to stimuli. As the fish becomes anesthetized, it becomes ataxic, loses its righting reflex, and does not respond to stimuli. At a surgical plane of anesthesia the animal is recumbent, has decreased respiration, and does not respond to noxious stimuli (e.g., pinprick).

Fish respiration is observed by noting the rate and quality of opercular movements. As the depth of anesthesia increases, respiration rate will decrease and may eventually become nonexistent. A lack of respirations should not be cause for alarm, but the clinician should reduce the anesthetic concentration and ensure that well-oxygenated water is flowing over the gills. Gill color is also a useful method of grossly evaluating oxygenation and anesthetic depth in fish. In a critical situation, anesthetic-free water can be flushed over the gills using a large syringe. The gills should be dark pink to light red. Pale gills are an indicator of hypotension, hypoxemia, or anemia.^{51,52} For longer anesthetic procedures, other anesthetic monitoring equipment including ECG, a Doppler flow detector, or ultrasonography can be used. When using these monitors in fish to evaluate heart rate, trends are more important than specific rates. Normal heart rates are not known for many species, but in general, fish have a significantly slower heart rate than similar sized mammals. The fish myocardium uses local glycogen stores rather than circulating glucose. The fish heart contracts independently of nerve impulses from the brain. It is important to note that a clinically dead fish may still have a heart beat; therefore, pulse should not be used as the sole method of anesthetic monitoring. In the author’s experience, pulse oximetry has little practical application in fish.

Waterborne Anesthetics

MS-222

This anesthetic agent has several common names, but is often referred to as Tricaine-S, Fiquel, or tricaine methane sulfonate. MS-222 is the most commonly used fish anesthetic agent and is the only product approved by the Food and Drug Administration

Table 35.4. Anesthetic stages of fish.^{50,53,56}

Stage 0	Normal	Reacts to external stimuli Normal opercular respirations
Stage 1	Light sedation	Decreased opercular movement Decreased response to visual and tactile stimuli
Stage 2	Deep sedation	Only reactive to gross stimulation
Stage 3	Light anesthesia	Loss of equilibrium Loss of muscle tone Reactive only to strong tactile stimuli
Stage 4	Deep anesthesia	Total loss of reactivity and loss of reflexes Respiratory and heart rate diminished
Stage 5	Medullary collapse	Cardiac and respiratory arrest Death Overdose

Center for Veterinary Medicine for use in fish intended for human consumption.^{50,51,54–56} The agent is supplied as a white powder that is easily soluble in water. It is an acidic compound and can cause significant pH changes when added to water. This is especially true in fresh water with a low buffering capacity.^{51,52} For this reason, it is important to buffer the pH of the anesthetic water with sodium bicarbonate. Baking soda, a readily available form of sodium bicarbonate, can be added to the anesthetic water until saturation occurs (i.e., until the baking soda no longer dissolves). Adequately buffered solutions will maintain a neutral pH (7.0 to 7.5) after MS-222 has been added. MS-222 is very safe and effective in a wide variety of species and can be used for light sedation (e.g., shipments), surgical anesthesia or, at very high concentrations, for euthanasia.^{50–54,56}

The desired concentration of MS-222 will depend on the desired depth of anesthesia, the water temperature, the water hardness, and the animal's species, age, and overall health.⁵³ In general, MS-222 is more potent and has a narrower safety margin in warmer, softer water and with young fry.^{51–53} Published dosages vary widely for fish and range from 25 to 300 mg/L. Induction concentrations between 75 and 125 mg/L, and maintenance solutions of approximately 50 to 75 mg/L are usually effective.⁵⁴ Euthanasia can be achieved by placing animals in a concentration of 1000 mg/L for 5 to 10 min (Tables 35.5 and 35.6).⁵⁴

MS-222 has no anesthetic effects in mammals, and exposure is generally considered safe for people, although there have been reports in the literature of chronic exposure to high levels of MS-222 causing reversible retinal lesions in humans.⁵⁷ For this reason, inhalation of the powder should be avoided, gloves worn, and hands washed after handling.

Clove Oil (Eugenol)

The active ingredient in clove oil is eugenol, which is available from health food stores (90% active ingredient) or from pharma-

cies as 100% eugenol.^{52,57} Eugenol has become a popular anesthetic for freshwater species, including koi and trout. In New Zealand and Australia, a commercially available form of iso-eugenol is marketed under the trade name Aqual-S.⁵⁵ Eugenol oil is commonly diluted 1:10 with ethanol before being mixed with water.^{51,52} It has been compared with MS-222 in a limited number of species and appears to be an effective fish anesthetic.^{51,52,54,55,57–60} Eugenol has a narrower margin of safety than MS-222 and is more likely to cause respiratory failure at higher concentrations.⁵⁷ Published dosages for eugenol range from 40 to 200 mg/L, with those at the higher end being associated with longer recoveries and an increased need for manual resuscitation.^{52,54,55,57–60} Fish anesthetized/immobilized with higher concentrations of eugenol appear to react more vigorously to hypodermic needle injections when compared with fish anesthetized with MS-222.⁵⁵

Isoflurane

This technique has had limited use in fish. It is effective, but administration and safe scavenging of waste anesthetic gas is problematic. Although vaporized isoflurane can be easily bubbled into water, this method can take a long time to reach anesthetic concentrations. A much more rapid and effective method is to mix liquid isoflurane directly into the water. Since isoflurane is hydrophobic, it beads up in water. To enhance distribution into water, it can be applied by injecting the liquid isoflurane through a small-gauge needle under the water's surface. When added in this manner, small droplets of isoflurane mix in the water. Although this method of administering gaseous anesthesia is effective, a major concern is the difficulty of scavenging waste anesthetic gases. A small "fume hood" can be created by attaching a funnel to a vacuum scavenger system and inverting the funnel over the anesthetic-water mixture. Induction concentrations range from 0.4 to 0.75 mL of liquid isoflurane/L of water. Maintenance concentrations are approximately 0.25 to 0.4 mL of isoflurane/L of water.^{54,58}

Other Water-Based Anesthetic Agents

Quinaldine, metomidate, and benzocaine have all been used as anesthetic immobilizing agents in fish.^{51–53} Like MS-222 and eugenol, these agents are mixed with water to create an anesthetic solution that is passed over the gills of the fish. In the United States, these agents are not approved for fish intended for human consumption, are less available, and are not commonly used.

Injectable Anesthetics

Propofol

This lipid-based anesthetic emulsion has been demonstrated to be effective in several fish species.^{51,61} Its major disadvantage is that it must be given intravenously. It has a rapid induction rate and provides light anesthesia for 60 to 200 min.^{51,61} Similar to mammalian species, propofol produces cardiac and respiratory depression in fish. Dosages range from 3.5 to 7.5 mg/kg, and specific dose requirements will likely vary widely among species.^{51,61}

Table 35.5. Tricaine methane sulfonate (MS-222) concentration dosing chart.

Gallons of Water	Liters of Water	Grams of MS-222									
		25 mg/L ^a	40 mg/L	50 mg/L	60 mg/L	70 mg/L	80 mg/L	90 mg/L	100 mg/L	125 mg/L	150 mg/L

^amg/L = ppm.

Ketamine-Medetomidine

Ketamine in combination with medetomidine is usually reserved for larger fish that cannot be manually placed in an anesthetic bath. This is common in large aquarium systems or in free-ranging open-water situations.⁶² The drug combination can be delivered via a spring-loaded pole syringe if the animal is swimming in the water, or via hand injection if the animal is in a net.^{52,54,62}

Teleost (bony) fish are more refractory to these agents and require fairly high dosages. Elasmobranchs (sharks, rays, and skates) are more susceptible to ketamine-medetomidine effects, and this has become the regimen of choice for immobilizing large sharks.^{52,62} Teleost dosages range from 1 to 7 mg/kg ketamine plus 30 to 100 µg/kg medetomidine injected intramuscularly.⁵² This combination can be partially reversed with atipamezole administered at fivefold the medetomidine dose (on a milligram basis). Elasmobranch dosages range from 1 to 5 mg/kg ketamine combined with medetomidine at 50 to 100 µg/kg administered intramuscularly.^{52,54,62}

Nonchemical Methods of Immobilizing Fish

In the aquaculture and fisheries industries, there are several methods of slowing or immobilizing fish that may not traditionally be considered anesthetic techniques. These include hypothermia, electroshock, and application of carbon dioxide.

Hypothermia

This is commonly used when transporting large numbers of fish. Since fish are poikilothermic, reducing their environmental temperature will slow their metabolism and reduce movement. In general, slow gradual cooling is preferred and causes less deleterious physiological changes. It should be noted that hypothermia results in immobilization only and is best reserved for transportation of fish and not used for invasive surgical procedures.⁵³

Electroshock or Electroimmobilization

These methods inhibit the fish's ability to swim due to a current-induced tetany.⁵³ They are primarily used in freshwater animals

Table 35.6. Anesthetic agents commonly used in fish.

Agent	Method of Administration	Dose Concentration	Comments
MS-222	Supplied as a powder that is dissolved in bath water	Induction concentration: 75 to 125 mg/L Maintenance concentration: 50 to 75 mg/L	Buffer solution with sodium bicarbonate. Use a lower concentration for subadults (i.e., fry and fingerlings).
Clove oil (eugenol)	A liquid agent that is placed in bath water	40 to 100 mg/L	Eugenol is poorly soluble in water and should be dissolved in ethanol at a ratio of 1 part eugenol to 10 parts ethanol. Eugenol is commonly supplied as clove oil.
Isoflurane	Liquid isoflurane is placed in bath water	Induction concentration: 0.4 to 0.75 mL/L Maintenance concentration: 0.25 to 0.4 mL/L	Liquid isoflurane can be drawn into a syringe and injected into the water by using a 25-gauge needle.
Propofol	Intravenous	3.5 to 7.5 mg/L	Rapid onset on induction. Provides 60 to 200 min of sedation/anesthesia.
Ketamine-medetomidine	Intramuscular	Teleosts (bony fish) 1 to 7 mg/kg ketamine combined with 30 to 100 µg/kg medetomidine Elasmobranchs (sharks and rays) 1 to 5 mg/kg ketamine combined with 50 to 100 µg/kg medetomidine	Atipamezole can be used to reverse medetomidine at fivefold the medetomidine dose. Not generally recommended for teleosts because of slow recovery rates. Commonly used with large sharks.

MS-222, tricaine methane sulfonate.

and typically reserved for collecting and/or sampling fish from large bodies of water (e.g., ponds or lakes). A high-voltage, direct current is applied to the water, and the fish within range that have been shocked will float to the surface. This provides enough time for fish to be processed (weighed, tagged, blood sampled, etc.) before they are recovered and returned to the water unharmed.

Carbon Dioxide

The use of carbon dioxide to induce a state of narcosis is common in many aquatic facilities. Either gaseous carbon dioxide can be bubbled into, or sodium bicarbonate dissolved in, the water. Sodium bicarbonate requires an acidic pH for adequate carbon dioxide release and thus may require the addition of acidic agents to help lower the water pH. In general, this method is reserved for transporting or culling large groups of fish and is not routinely used for individual veterinary procedures.

Cardiac Dysrhythmias

Introduction

The anesthetic management of a patient with cardiovascular dysfunction can be very challenging, because most preanesthetic and anesthetic agents capable of depressing the central nervous system can also produce cardiovascular depression. Patients with cardiovascular dysfunction may be more prone to fluid overload and dysrhythmias. Extremes in heart rate may cause severe problems, including heart failure. Patients with cardiovascular dysfunction may lack sufficient cardiac reserve to compensate for anesthetic-induced depression. Because of the diversity of pathophysiological conditions, no single anesthetic management technique or protocol can be recommended for all animals with cardiovascular dysfunction.¹ Appropriate patient monitoring with arterial blood pressure, central venous pressure, electrocardiogram, end-tidal carbon dioxide, pulse oximetry, and other parameters is essential to reduce anesthetic and surgical risk.

Cardiovascular Physiology

The function of the myocardial cell is to contract and relax rhythmically with other myofibers so that the heart will act as a pump. The basic contractile unit of heart muscle is the sarcomere, which is composed of interdigitating protein filaments of actin and myosin. Muscle shortening begins in the myocardial muscle when the actin and myosin filaments are activated. This activation is regulated by tropomyosin and troponin. Tropomyosin prevents the interaction of actin and myosin during diastole. When tropomyosin is no longer at its blocking position, systole is initiated. The availability of ionized calcium in the area of the troponin-tropomyosin protein unit acts as an immediate catalyst for the contraction-relaxation cycle. The contraction of

the heart muscle depends on the amount of free calcium ions available around the myofibril. Part of the contractile-dependent calcium originates from superficial sites on cell membranes that are in equilibrium with extracellular calcium and therefore can be affected by drugs that do not penetrate the myocardial cell.

Few clinically used drugs affect the actin and myosin proteins, but many drugs can alter the availability of calcium for activation of the contractile process.¹ Digitalis increases calcium movement to the troponin-tropomyosin protein unit and thus increases contractile strength. Barbiturates and inhalant anesthetic agents seem to disrupt calcium movements and thus cause reduced contractile strength. Myocardial intracellular acidosis also inhibits the binding of calcium to the troponin-tropomyosin unit, causing decreased myocardial contractile strength. Disease conditions or drugs that produce metabolic or respiratory acidosis may decrease contractility. Most anesthetics depress respiration and predispose patients to respiratory acidosis.

Blood pressure is the product of peripheral vascular resistance and cardiac output. Cardiac output is the product of heart rate and stroke volume. Drugs that alter any or all of these parameters may greatly affect blood pressure and tissue blood flow. Preanesthetic and anesthetic agents can alter vascular resistance (e.g., phenothiazine tranquilizers, α_2 -adrenergic agonists, barbiturates, and inhalant agents), heart rate (e.g., opioids, α_2 -adrenergic agonists, dissociative agents, and inhalants), and stroke volume (e.g., inhalant anesthetics). Patients that suffer from diseases causing impaired cardiac output, patients with congenital heart disease, and those suffering from hypotension, hypovolemia, anemia, and/or heartworms are at a higher anesthetic risk.

Impaired Cardiac Output

Anesthetic management of patients with impaired cardiac output depends greatly on the underlying pathology, which may require echocardiography for accurate diagnosis. General guidelines are to avoid bradycardia and tachycardia, decreased preload, and hypovolemia, as well as unnecessarily high left-atrial pressures and volume overload. The decreased tolerance of these patients for improper fluid therapy and anesthetic management emphasizes the need for adequate perioperative monitoring and support. These patients should be preoxygenated for 5 to 7 min prior to anesthetic induction. If cardiovascular function is adequate, the choice of anesthetic drugs may not be specific for these patients; however, drugs that may produce tachycardia (anticholinergics

and dissociative agents) or large changes in vascular resistance should be used judiciously.

Narcotics are often used as preanesthetic medication because of their minimal effects on the myocardium, and they can be readily antagonized. Indeed, opioids are the mainstay of cardiac anesthesia. Opioids tend to maintain, and may even indirectly improve, myocardial function. They can be used in combination with acepromazine or a benzodiazepine tranquilizer for additional sedation. Use of acepromazine may be contraindicated in some forms of cardiovascular diseases (e.g., hypertrophic cardiomyopathy) but may be beneficial in others (e.g., mitral valve insufficiency) because of the potential for decreased afterload. Opioids can increase vagal afferent activity, which may decrease heart rate. If significant bradycardia occurs, atropine or glycopyrrolate should be given as needed.

If only tranquilization is needed, a low dose of acepromazine (e.g., 0.02 mg/kg) may be administered intramuscularly. Acepromazine decreases peripheral vascular resistance and very often leads to arterial hypotension and reduced preload. Acepromazine can have significant negative inotropic effects. Because of direct myocardial depression, and prominent vasodilatation and hypotension, the value of inducing sedation/tranquilization must be weighed against the potential adverse effects. Phenothiazines must be used cautiously in most cardiac patients.² If acepromazine is administered, patients must be monitored closely and appropriate supportive care used should adverse effects become significant.

The use of α_2 -adrenergic agonists should be avoided in patients with impaired cardiac output. These drugs can produce significant dysrhythmias, including severe sinus bradycardia and sinoatrial and atrioventricular nodal blocks. Bradycardia, reduced contractility, and increased afterload are particularly disadvantageous effects of α_2 -adrenergic agonists in many cardiac patients.^{2,3}

Cardiomyopathy

Cardiomyopathy can be classified as hypertrophic or congestive. Hypertrophic cardiomyopathy is characterized by ventricular hypertrophy, decreased ventricular compliance, and impaired ventricular filling, which result in reduced cardiac output. Ventricular contractility (pump function) is usually not impaired.⁴ Congestive (dilated) cardiomyopathy is characterized by marked ventricular dilation, increased ventricular end-diastolic and systolic volumes, and poor myocardial contractility. Often, congestive heart failure is present.⁴ Since most anesthetic drugs worsen existing myocardial performance, to reduce the risk during the preanesthetic period, treatment of cardiomyopathy is warranted prior to anesthesia. Commonly employed cardiovascular medications used for treatment of congestive heart failure are listed in Table 36.1. In dogs with dilated cardiomyopathy, anesthesia is best induced with agents that have minimal direct myocardial depressant effects. Etomidate or alphaxalone would be preferable induction agents over either thiopental or propofol. The direct depressant effects of ketamine on the myocardium may be clinically significant if sympathetic nervous system efferent activity is already maximal or exhausted. The lowest possible concentra-

tion of an inhalant should be used for maintenance of anesthesia. Anesthesia is less depressing to myocardial performance when an opioid is coadministered, resulting in lower inhalant anesthetic requirements.

Pericardial Tamponade and Constrictive Pericarditis

These are associated with impaired cardiac output caused by reduced stroke volume secondary to reduced end-diastolic ventricular volume. There is limited expansion of the cardiac chambers, resulting in decreased ventricular filling such that heart rate must increase to maintain cardiac output. Pulse pressure is usually decreased, and peripheral pulses may feel abnormal. Myocardial contractility might not be impaired.⁵

Valvular Heart Disease

The heart contains four valves: mitral, tricuspid, aortic, and pulmonary. Valve changes usually can be classified as insufficiency or stenosis. Valvular heart disease is associated with impaired cardiac output and, when severe, can cause congestive heart failure. When a murmur is ausculted or valvular heart disease is suspected, the preanesthetic evaluation should include thoracic radiographs and possibly an echocardiogram in addition to the routine preanesthetic screening. The value of these diagnostic tests is to facilitate anesthetic planning and intraoperative responses to abnormal monitored parameters since the management of valvular disease can vary significantly depending on which valve (valves) is (are) affected.

Although both mitral and tricuspid insufficiencies are often clinically insignificant, ventricular ejection fraction is reduced. It is useful to maintain heart rate, maintain contractility, and avoid arteriolar constriction.⁶ Antimuscarinics should be used conservatively, but lower doses of atropine or glycopyrrolate are often used to inhibit anesthetic-associated bradycardia. α_2 -Adrenergic agonists are contraindicated in patients with valvular insufficiency, because they can affect heart rate and peripheral vascular resistance. Opioids are a principle component of balanced anesthesia for these patients and are generally chosen based on analgesic and sedative requirements. If these patients are stable, anesthesia may be induced with ketamine and diazepam or propofol. Less stable patients may be anesthetized by induction with etomidate or high doses of opioids in combination with a benzodiazepine. To avoid pronounced vasodilatation and hypotension, lower doses of inhalants are used. Use of the inhalants helps to prevent arteriolar vasoconstriction and increased afterload. Fluid therapy should be conservative and based on continual monitoring of central venous pressure and arterial blood pressure. As with other aspects of anesthetic care, postoperative monitoring and support are individualized.

Hypertrophic Cardiomyopathy

This is the most commonly diagnosed cardiac disease of cats.⁷ An inherited form of the disease has been identified in humans and in Maine coon cats. Hypertrophic cardiomyopathy (HCM) is characterized by a stiff left ventricle with poor diastolic function. As

Table 36.1. Chronic therapy for congestive heart failure

Classes	Trade Name	Mechanism of Action	Effects on		Maintenance Dose
			Contractility	Afterload	
Nitrovasodilators					
Na nitroprusside	Nitropress	Activation of EDRF or NO. These drugs act as substrates for the formation of NO. Nitroprusside is primarily an arterial dilator, whereas nitroglycerin is a venodilator.	—	↓	2–5 µg/kg/min IV (monitor pressure) CRI suggested Protect drug from light
Nitroglycerin	Nitrostat; Nitropaste	Preload-reducing agent.	—	↓	1–5 µg/kg/min IV recommended only for acute-care situations with continuous blood pressure monitoring. Available in oral and transdermal paste formulations, but oral is rarely if ever used in animals. Pastes are considered third-line therapy. More likely to use oral hydralazine acutely. <i>Dog:</i> ¼–½ inch/kg QOD <i>Cat:</i> ⅛ inch/kg QOD
Isosorbide dinitrate	Many formulations available	Formation of NO.	—	↓	0.5–2.0 mg/kg PO, BID; also available as an ointment; uncommonly used in animals
Hydralazine	Apresoline	Hydralazine interferes with Ca ²⁺ transport in smooth muscle; acts as an afterload-reducing agent.	—	↓	<i>Dog:</i> 0.5–2.0 mg/kg PO, BID <i>Cat:</i> not commonly recommended
ACE inhibitors					
Captopril	Capoten	Prevents conversion of angiotensin I to angiotensin II, which decreases blood pressure and produces some venodilation. Produces balanced vasodilation, prevents renal fluid retention, reverses cardiac fibrosis, and slows heart rate through decreased β-adrenergic stimulation.	—	↓	This drug is rarely used in VM and is less reliable than are the other ACE I agents below. <i>Dog:</i> 0.5–2.0 PO, TID <i>Cat:</i> the same
Enalapril	Enacard		—	↓	<i>Dog:</i> 0.5 mg/kg PO, SID-BID <i>Cat:</i> 0.25–0.5 mg/kg PO, SID-QOD
Benazepril	Lotensin Foretaker		—	↓	<i>Dog:</i> 0.25–0.5 mg/kg PO, SID-BID <i>Cat:</i> 0.25–0.5 mg/kg PO, SID
Lisinopril	Zestril Prinivil	ACE I, as above for captopril		↓	<i>Dog:</i> 0.5 mg/kg PO, SID <i>Cat:</i> 0.25 mg/kg PO, SID
Diuretics					
Acetazolamide		Inhibits Na ⁺ from passing into the proximal tubule. The osmotic effect is at the glomerulus.	—	↓	<i>Dog:</i> 10 mg/kg q 6 h Rarely used in cardiovascular medicine
Aminophylline		Increases the vascular perfusion of the glomerulus.	↑	↓	<i>Dog:</i> 11 mg/kg PO, BID-TID <i>Cat:</i> 5 mg/kg PO, BID-TID
Spirolactone	Aldactone	Inhibits the aldosterone receptor in collecting tubule (CT). Prevention of ACE escape is the principal use of this agent now.	—	↓	<i>Dog:</i> 0.25 mg/kg SID for preventing ACE escape. Higher dosages may be considered as a diuretic. <i>Cat:</i> the same
Furosemide	Lasix	Inhibits the Na ⁺ , K ⁺ , and Cl ^{−2} cotransporter in the thick ascending loop of Henle.	—	↓	<i>Dog:</i> 1–4 mg/kg PO, SC, IM, IV, SID-QID <i>Cat:</i> 1–2 mg/kg PO, SC, IM, IV, SID-QID

(continued)

Table 36.1. Chronic therapy for congestive heart failure (*continued*)

Classes	Trade Name	Mechanism of Action	Effects on		Maintenance Dose
			Contractility	Afterload	
Hydrochlorothiazide	Hydrodiuril	Blocks resorption in the distal convoluted tubule by inhibiting the Na ⁺ and CT cotransporter.	—	↓	<i>Dog:</i> 2–4 mg/kg PO, SID-BID <i>Cat:</i> 1–2 mg/kg PO, SID-BID
Inotropes					
Digitalis	Cardoxin; Lanoxin	Inactivates the Na ⁺ /K ⁺ ATPase pump, increasing Ca ⁺² intracellularly.	↑	↑	<i>Dog:</i> 0.005–0.008 mg/kg PO, BID in smaller dogs and 0.22 mg/m ² ; also twice daily in larger dogs <i>Cat:</i> ¼ to ½ 0.125-mg tablet PO q 48–72 h, based on size and clinical response
T3	Tristat	Increases Ca ⁺² adenosine ATPase activity; upregulates beta-receptor activity.	↑	—	Not likely to be used and not a primary inotrope but may be part of the protocol along with traditional agents in the event of a low thyroid value
“Inodilators”					
Amrinone	Inocor	Class III phosphodiesterase enzyme inhibitors (PDEIs) prevent breakdown of cAMP, which results from the stimulation of β-adrenergic receptors.	↑	↓	1–3 mg/kg IV slow to effect, then CRI at 10–100 µg/kg/min
Milrinone	Primacor		↑	↓	1–3 mg/kg/min IV slow, then CRI at 10–100 µg/kg/min to effect
Pimobendan	Vetmedin	Ca ⁺² sensitization and PDE inhibition.	↑	↓	<i>Dogs:</i> 0.3–0.6 mg/kg PO, SID <i>Cats:</i> not known if applicable
Beta blockers					
Metoprolol	Lopressor; Toprol XL	Upregulates damaged beta sites; reduces the adrenergic barrage; slows the cardiac rate.		↓	<i>Dogs:</i> 0.25–1.0 mg/kg PO BID-TID; begin low and titrate upwards slowly. <i>Cats:</i> very low dosages used usually for heart rate control and not CHF
Carvedilol	Coreg	Beta-blocking agent and peripheral vasodilator (blocks β ₁ , β ₂ , and α ₁).	↑	↓	<i>Dogs:</i> 0.05 mg/kg PO initially once daily; slowly titrate weekly to maximum 0.3 mg/kg

ACE, angiotensin-converting enzyme; CRI, constant-rate infusion; EDRF, endothelium-derived relaxing factor; IV, intravenous; NO, nitric oxide; PO, per os (orally); and SC, subcutaneously.

This table enlists a variety of classes of medications including digitalis, “inodilators,” vasodilators, ACE inhibitors, and diuretics. Dosages taken from *Textbook of Veterinary Internal Medicine*, 6th ed.¹⁶

ventricular wall thickness increases, end-diastolic volume and ventricular function are decreased. Congestive heart failure develops as ventricular stiffness increases, end-diastolic ventricular volume decreases, and mitral regurgitation and hypertension develop. Early HCM is often asymptomatic. Signs of progressive HCM (murmurs, arrhythmias, dyspnea, and thromboembolic disease) are consistent with the development of heart failure. Sudden death during the stresses of hospitalization, anesthesia, and medical or surgical procedures can occur with more advanced HCM.

For patients with early signs of cardiomyopathy, anesthesia can be induced by using propofol, etomidate, or a neuroleptanalgesic combination. Mask induction using one of the potent volatile inhalant anesthetics is also an acceptable technique, although the stress of induction may be detrimental to patients with

impaired cardiac function. Inhalant anesthetics are most often the maintenance agents for these patients. Isoflurane is one of the preferred inhalants because of preservation of a near-normal cardiac index and minimal dysrhythmic effects in healthy animals, when compared with the effects of halothane. However, in animals with diastolic dysfunction (e.g., HCM) isoflurane may be associated with reduced preload and afterload leading to reduced end-diastolic ventricular volume and increased end-systolic ventricular to aortic pressure gradients when dynamic outflow-tract obstruction is present. Sevoflurane minimally reduces cardiac output and is associated with less vasodilation than is isoflurane at typical anesthetic doses in healthy animals. Animals may maintain a lower heart rate when anesthetized with sevoflurane than with isoflurane, although preanesthetic drugs may alter the

cardiovascular responses to inhalant anesthetics. Based on the lower blood solubility and reduced pungency, sevoflurane may provide for a less stressful inhalant induction compared with either halothane or isoflurane. When a lower heart rate is desired (e.g., for cats with HCM), sevoflurane may be preferred over isoflurane.⁸ Among the injectable general anesthetics, etomidate is unique in maintaining cardiac output without increasing myocardial oxygen consumption.

Congenital Heart Disease

When considering the anesthetic management of patients with congenital heart disease, the problems encountered are often similar to those in patients with congestive heart failure. The most common surgically correctable problems are patent ductus arteriosus (PDA) and persistent right aortic arch (PRAA).

PDA is usually recognized early in life before patients develop signs of heart failure. Typically, if diagnosed early, shunt blood flow is from the systemic circulation to the pulmonary artery (left-to-right shunt). However, when systemic vascular resistance decreases after induction of anesthesia, shunt flow may reverse, especially when significant pulmonary hypertension is present. Pulse oximetry is useful for rapid detection (rapid reduction in arterial hemoglobin saturation) of this reversion to a right-to-left shunt. Phenylephrine can be useful in this situation to increase systemic pressure and reestablish left-to-right flow. If the patient is normal in other respects, the anesthetic protocol is designed for the pediatric patient undergoing a thoracotomy with attention toward maintaining heart rate and cardiac output. Surgical manipulation around the heart may cause ventricular ectopic beats. These are usually transitory and do not require treatment. When the PDA is ligated, increased blood pressure may cause a reflex slowing of the heart rate. This is a normal physiological response.⁸ In some instances, antimuscarinic drugs (e.g., atropine or glycopyrrolate) may be needed to counteract the sinus bradycardia. To minimize the potential for bradycardia, an anticholinergic may be administered as a preanesthetic medication. Because of the size of some patients, intraoperative hypothermia is often a problem when they undergo PDA surgery. Every effort should be made to minimize the loss of body heat.

PRAA is also usually recognized and corrected early in life. If a patient is normal in other respects, the anesthetic protocol is designed for the pediatric patient undergoing a thoracotomy. It is important to remember that a patient with PRAA may be suffering from aspiration pneumonia. As with a PDA, surgical manipulation around the heart may cause ventricular ectopic beats, and intraoperative hypothermia is of concern.

Hypotension, Hypovolemia, or Shock

Patients with hypotension and hypovolemia should be stabilized with intravenous fluids and/or whole blood prior to anesthesia. Many preanesthetic and anesthetic drugs are potentially hypotensive; therefore, these drugs can exacerbate preexisting hypotension.

Shock can be defined as an acute clinical syndrome character-

ized by progressive circulatory failure that leads to inadequate capillary perfusion and cellular hypoxia.⁹ Shock is a complex, multisystem disorder that may be caused by a variety of insults. Shock may be classified as hypovolemic, cardiogenic, or vasculogenic. If one thinks of the cardiovascular system as a pump, fluid, and pipes to carry the fluid, then the three classifications reflect which component of the cardiovascular system is affected.

Hypovolemic shock occurs when there is an inadequate volume of fluid (blood) being pumped through the cardiovascular system. Hemorrhage, fluid loss, and trauma can all cause hypovolemic shock.

Cardiogenic shock, which occurs when the heart is no longer an effective pump, can be caused by a failure in ventricular filling (cardiac tamponade, tension pneumothorax, or collapse of the vena cava caused by inadvertent closure of the pop-off valve, resulting in airway pressure buildup) or by a failure of ventricular ejection (ruptured chordae tendineae, cardiac dysrhythmias, severe myocardial depression, or severe and prolonged increase in systemic vascular resistance).

Vasculogenic shock occurs when there are changes in venous capacitance or peripheral resistance. Numerous causes can lead to vasculogenic shock, including sepsis (vasodilation is caused by release of vasoactive substances such as histamine, prostaglandins, and bradykinin), anaphylaxis (vasodilation occurs because of histamine release), neurogenic factors (loss of vasomotor tone caused by excessive general anesthesia, trauma of the central nervous system, and spinal anesthesia), and a severe and prolonged increase in peripheral resistance.

Regardless of the underlying cause, a common pathway of circulatory failure is present in shock. Reflex mechanisms may compensate for early circulatory failure and result in recovery of a patient with mild or moderate shock. However, reflexive compensatory mechanisms may become deleterious to a patient if they are prolonged and may result in microcirculatory changes and further cellular hypoxia.

All forms of shock eventually result in decreased blood flow and hypoperfusion of the body tissues. Baroreceptors in the aorta and carotid artery and low-pressure receptors in the atria respond to the decreased cardiac output and blood pressure. This results in activation of the sympathoadrenal system. Hypothalamic sympathetic nerve centers increase release of norepinephrine from postganglionic sympathetic nerve endings and increase liberation of epinephrine and norepinephrine from the adrenal medulla into the blood. This results in splenic contraction and a release of blood into the circulation. Epinephrine and norepinephrine stimulate alpha and beta receptors. Alpha-receptor stimulation results in vasoconstriction of both arteries and veins. Beta-receptor stimulation causes vasodilation in skeletal muscle and increased force and rate of cardiac contraction. This results in a redistribution of blood flow to the heart and brain. Blood flow to the splanchnic, renal, and cutaneous vessels is markedly decreased. The catecholamines produce tachycardia, increase myocardial contractility, and stimulate hepatic glycogenolysis. Venous constriction causes decreased vascular capacity. The decreased vascular capacity improves venous return and thus cardiac output.

An important compensatory mechanism in shock is the ex-

travascular fluid shift. Owing to vasoconstriction, there is decreased capillary blood flow and thus capillary pressure. The decreased capillary pressure allows extravascular fluid to enter the blood vessels. This is very important in expanding circulating fluid volume. Endocrine factors are also important in the compensatory mechanism of shock. Renin is released from the ischemic kidney to activate the renin-angiotensin-aldosterone system. This results in vascular constriction; renal absorption of sodium, chloride, and water; and renal excretion of potassium. Antidiuretic hormone is released because of hypovolemia, and this also promotes water retention. The overall effect is to increase extracellular fluid volume.

These compensatory mechanisms cause a significant redistribution of blood flow to the heart, brain, and adrenal glands, and may aid recovery of patients in mild to moderate shock. However, they may not be adequate in severe shock, and it may become irreversible. Irreversibility is characterized by inadequate tissue perfusion to vital organs that results in cardiac failure, disseminated intravascular coagulation, depression of the reticuloendothelial system, and peripheral vascular failure. Hypotension and decreased capillary perfusion lead to cellular hypoxia, decreased delivery of energy substrates to the cell, and increased concentration of cellular metabolites.

Glucose is first used anaerobically by the cells as an energy source with production of pyruvate and limited amounts of adenosine triphosphate (ATP). Pyruvate is then aerobically utilized to produce large amounts of ATP, or it may be released into the circulation after being reduced to lactic acid. Large amounts of oxygen are needed by cells to produce the ATP. In shock, cellular hypoxia occurs, and although ATP can be produced anaerobically, it may not be produced in adequate amounts.⁹ The establishment of membrane ionic gradients depends on adequate ATP generation. Cellular edema may result if ionic gradients are not maintained. The lactic acidemia that occurs in shock results from the release of anaerobic energy in tissues unable to support adequate oxidative processes. Individual cells and then organs begin to die.

Increased cellular metabolites (lactic acid) in the capillary bed cause precapillary sphincters to relax, but postcapillary sphincters remain constricted. Blood flows into the capillary bed but is slow to leave, resulting in an increased hydrostatic pressure with net flow into the tissues and further volume deficits. Decreased perfusion of the splanchnic vasculature results in pancreatic ischemia and the release of myocardial depressant factor. Myocardial depressant factor decreases myocardial contractility.¹⁰ Splanchnic vasoconstriction and decreased capillary perfusion depress the reticuloendothelial system in the spleen and liver. With impaired function of the reticuloendothelial system, endotoxins, bacteria, and microemboli accumulate and produce further circulatory failure. Slow-moving (stagnant) acidic blood is hypercoagulable. Clot-initiating factors are common in shock and include bacterial toxins and thromboplastin of red cells (released by hemolysis).¹¹ These factors result in disseminated intravascular coagulation, which results in a consumption of clotting factors, bleeding, and focal tissue infarcts due to microthrombi. Multiorgan failure (multiorgan dysfunction syndrome)

occurs, and the patient dies. Induction of anesthesia in patients with any level of shock is ill-advised.

Anemia

Anemic patients are at higher risk from an anesthetic standpoint because the oxygen-carrying capacity of the cardiovascular system is diminished. Either packed red blood cells, whole blood, or hemoglobin-based oxygen-carrying solutions should be considered if the dog or cat has a packed cell volume (PCV) of less than 25% to 30% before surgery or less than 20% after surgery. Patients with chronic anemia seem to be able to cope better with the problem than those with acute anemia. Whole blood, packed red blood cells, or a hemoglobin-based oxygen-carrying solution (e.g., Oxyglobin) should be readily available. The rate and total amount of blood administered should be tailored to the requirements of the patient. Patients with acute blood loss and hypovolemia can usually tolerate faster rates of colloid administration than can normovolemic patients that are anemic.

Anemic and/or hypoproteinemic patients should have serial PCV and total plasma protein concentration measurements during and after surgery. If an animal is anemic, supplemental oxygen may be beneficial in the preanesthetic period as well as the postoperative period to maintain maximal hemoglobin saturation. Although dissolved oxygen content is very minor compared with hemoglobin-bound oxygen content, a high inspired oxygen tension will enable more oxygen to be dissolved into the plasma and thus help counteract the decreased oxygen-carrying capacity due to low red blood cell numbers. A mask, nasal catheter, or oxygen cage can be used to deliver 40% to 100% oxygen to patients.

A pulse oximeter should be used during anesthesia and during recovery when patients are anemic. One of the periods of greatest risk for anemic patients is when anesthesia is discontinued and the fraction of inspired oxygen suddenly decreases from near 1.0 to 0.21 (room air) in the presence of anesthetic drug-related respiratory depression. In addition, as a hypothermic patient recovers, shivering will occur, dramatically increasing oxygen demands. Since approximately 5 g/dL of desaturated hemoglobin is needed for visible cyanosis to develop, anemic patients (PCV less than 15%) would not be expected to appear cyanotic even though hemoglobin oxygenation is dangerously low. Pulse oximeters are more sensitive at detecting hemoglobin desaturation in anemic patients, although a particular model's accuracy under these conditions may vary.

Hypoproteinemia

Many preanesthetic and anesthetic drugs are reversibly bound to plasma proteins, especially albumin. If plasma protein concentration is decreased, a greater fraction of highly protein-bound drug (i.e., protein binding in excess of 80%) is pharmacologically active and therefore will have an increased effect. Plasma protein, primarily albumin, is also required to maintain plasma oncotic pressure. Hypoalbuminemic patients are less tolerant of crystalloid fluid administration and more prone to volume overload and

pulmonary edema. Total plasma protein concentration should be maintained above 3.5 to 4.0 g/dL. If the plasma protein concentration falls below this number, the administration of plasma or colloidal fluid substitutes should be considered.

Heartworm Disease

A positive heartworm test in itself does not contraindicate any particular anesthetic regimen or protocol. If the patient is not exhibiting clinical signs, any standard anesthetic protocol is probably satisfactory, provided patient monitoring is appropriate. One should be aware that patients with heartworms may be more prone to spontaneous and catecholamine-induced cardiac dysrhythmias while under anesthesia.¹² Additionally, pulmonary hypertension and/or pulmonary embolic disease may be present, affecting pulmonary and cardiovascular function. If a significant number of heartworms are present, cardiac output may also be decreased.

Cardiac Dysrhythmias

Ventricular dysrhythmia is relatively common in dogs and cats during anesthesia, and its incidence is increased with certain anesthetics (e.g., halothane) and diseases (e.g., splenic neoplasia). Arrhythmia is more common with inappropriate levels of inhaled anesthetics.^{13–15} Ventricular tachyarrhythmia can be resolved through use of antiarrhythmics (typically lidocaine or sotalol), by providing deeper anesthesia if the patient is inadequately anesthetized, or by changing to a less arrhythmogenic anesthetic (e.g., changing from halothane to isoflurane). Catecholamine-induced arrhythmia may be more common during illness, after injury, and with other stressors.

Chapter 37

Pulmonary Disease

Robert R. Paddleford and Stephen A. Greene

Introduction
Physiology of Ventilation
Effects of Preanesthetic and Anesthetic Drugs on Ventilation
Anesthetic Considerations in Patients with Respiratory Dysfunction
Controlled Ventilation

Introduction

Patients with pulmonary dysfunction are often difficult to anesthetize safely. Most preanesthetic and anesthetic drugs depress respiratory function, further compromising patients with pulmonary disease and/or dysfunction. Knowledge of normal respiratory physiology and effective techniques for respiratory support is essential to provide favorable anesthetic outcomes.

Physiology of Ventilation

The primary function of the lungs is to exhale carbon dioxide generated by body metabolism and oxygenate venous blood. Alveolar ventilation can be assessed by measuring arterial carbon dioxide partial pressure (PaCO_2) or end-tidal carbon dioxide partial pressure (ETCO_2). Many factors can alter the ventilatory pattern (Table 37.1): (a) arterial carbon dioxide tension, (b) arterial pH, (c) arterial oxygen tension, (d) pulmonary stretch and upper airway receptors, (e) thermoregulation, (f) sensory input, and (g) emotional factors.¹ No conscious control is necessary to sustain ventilation.

The ventilatory control system is an integrated series of complex feedback loops made up of sensors, controllers, and effectors. The principal ventilatory receptors or sensors are (a) the peripheral carotid-body chemoreceptors (located at the bifurcations of the carotid arteries), (b) the central chemoreceptors (located near the surface on the ventrolateral aspect of the medulla oblongata), and (c) receptors sensing stretch, irritation, and proprioception in the lungs, airways, and muscles of respiration. The carotid-body chemoreceptors are responsive to oxygen and stimulate respiration when hypoxemia is present. The central chemoreceptors respond to carbon dioxide and stimulate ventilation when hypercarbia (respiratory acidosis) is present. Increased ventilation caused by metabolic acidosis may be mediated through either the central or peripheral chemoreceptors or the controllers of the ventilatory feedback loop located in the brain.² Automaticity of breathing is governed by specialized regions in the brain stem. The cortex controls voluntary and behavioral modifications of ventilation, and respiratory rhythm is controlled

by the medulla. Control functions are integrated both centrally (brain stem) and peripherally (spinal cord). The effectors of ventilation are the muscles of respiration and include the intercostal muscles, the diaphragm, and the muscles of the upper airways.

Many preanesthetic and anesthetic agents can alter a patient's ventilatory pattern. Most preanesthetic and anesthetic agents alter ventilation by altering either the threshold or sensitivity of the respiratory centers to carbon dioxide and/or by relaxing the muscles of ventilation.³

Effects of Preanesthetic and Anesthetic Drugs on Ventilation

Most preanesthetic and anesthetic drugs depress respiratory function, thereby further jeopardizing a patient with respiratory dysfunction. Drugs depress or stimulate ventilation by acting directly or indirectly on one or more of the elements of the ventilatory control system.⁴ Drugs used to treat respiratory disease may have significant interactions with anesthetics and anesthetic adjuncts.⁵

Atropine and glycopyrrrolate decrease airway resistance by causing direct dilation of the airways. Atropine also increases respiratory dead space by dilating the larger bronchi. Both drugs will increase the viscosity of airway secretions.

Phenothiazine tranquilizers have minimal effects on ventilation at therapeutic doses, although large doses can depress ventilation. They decrease respiratory rate, but this is usually compensated for by an increase in tidal volume. Phenothiazines do not delay the central respiratory center response (threshold) to increases in arterial carbon dioxide, although the maximum ventilatory response (sensitivity) may be decreased.³

The α_2 -adrenergic agonists (e.g., xylazine, detomidine, and medetomidine) vary in their pulmonary depressant effects and are somewhat unpredictable. Their depressant effects may range from mild to significant, depending on dose and individual patient response.⁶ As with all general central nervous system (CNS) depressants, this effect is more pronounced in patients already suffering from respiratory distress caused by pneumonia, hydrothorax, or pneumothorax. When used in higher doses, α_2 -adrenergic agonists may cause mucous membrane color to darken or appear cyanotic. Whereas cyanotic mucous membranes are normally interpreted as arterial hypoxemia and severe respiratory insufficiency, with α_2 -adrenergic agonists the mechanism (and significance) is different. Arterial oxygen partial pressure is usually normal or near normal in these patients. The origin of the

Table 37.1. Factors affecting the ventilatory pattern

Arterial carbon dioxide tension
Arterial pH

Heat regulation
Sensory input
Emotional factors

increased concentration of desaturated hemoglobin in the mucous membranes is increased oxygen extraction during capillary transit rather than arterial hypoxemia. Oxygen extraction increases due to decreased tissue blood flow and increased capillary transit time. Vital organ blood flow (e.g., in the kidney, liver, and brain) may not decrease to the same extent as flow to superficial tissues (e.g., skin, mucous membranes, and skeletal muscle); therefore, the degree of darkening of the mucous membranes may not represent vital organ hypoxia. When α_2 -adrenergic agonists are administered, the term *cyanosis* may not accurately reflect the true physiological status of the patient.

The benzodiazepine tranquilizers (diazepam and midazolam) usually produce minimal respiratory depression at therapeutic doses. However, both drugs have produced significant respiratory depression in isolated cases. This may be especially true when higher doses are administered intravenously.

Opioids are potentially respiratory depressant. The depression is drug and dose dependent, and may occur at doses that do not produce marked CNS depression or analgesia. The opioids directly depress the pontine and medullary centers, causing a decrease in respiratory rate and tidal volume. They also produce a delayed response (altered threshold) and a decreased response (altered sensitivity) to increases in arterial carbon dioxide.³ The panting observed in some dogs after opioid administration (e.g., hydromorphone or oxymorphone) may be caused by an initial stimulation of the respiratory centers and/or alteration of the thermoregulation center.

The barbiturates are respiratory depressants. At anesthetizing doses, the respiratory centers of the brain are depressed. The barbiturates can depress both the respiratory rate and tidal volume, and thus minute ventilation. Barbiturates also produce a delayed response (altered threshold) and a decreased response (altered sensitivity) to increases in arterial carbon dioxide and depress the carotid-aortic chemoreceptors.

Dissociative anesthetics (ketamine and tiletamine) may have a dual effect on ventilation. They may affect ventilation at two or more anatomical sites, causing stimulation at one and depression at another. Both drugs can produce apneustic ventilation; that is, a ventilatory pattern characterized by a prolonged pause after inspiration. Although the respiratory rate may decrease, the tidal volume usually remains normal. In general, these respiratory alterations do not affect gas exchange or transport of gases to and from the lungs. However, in some patients, the dissociative agents can produce marked hypoxia and hypercarbia, especially when additional CNS-depressant drugs, such as tranquilizers,

sedatives, or opioids, are used in combination with them. Dissociative agents do not depress the pharyngeal or laryngeal reflexes, and they may be activated with stimulation. Therefore, patients may be more prone to laryngospasm, bronchospasm, and coughing. Dissociative agents increase salivation and respiratory secretions, sometimes resulting in aspiration and respiratory obstruction. For this reason, the use of an antimuscarinic in combination with these drugs may be indicated.

Propofol is an injectable anesthetic that produces respiratory depression in much the same manner as the barbiturates. The incidence of apnea with propofol is comparable to that with barbiturates, but the duration of apneic episodes may be slightly longer. Etomidate is a carboxylated imidazole that can produce mild to moderate dose-dependent respiratory depression. Apnea following administration of propofol or etomidate can usually be avoided by limiting the rate of administration to achieve tracheal intubation.

The inhalant anesthetics halothane, isoflurane, sevoflurane, and desflurane depress ventilation by decreasing tidal volume. These anesthetics typically increase respiratory rate but not adequately to compensate for the decrease in tidal volume. Potent inhalation anesthetics increase the set point at which arterial carbon dioxide initiates spontaneous ventilation (i.e., the *apneic threshold*). The degree of elevation in apneic threshold is directly related to the depth of anesthesia. Inhaled anesthetics decrease the slope of the carbon dioxide response curve. There is both a delayed response (altered threshold) and a decreased response (altered sensitivity) to increases in arterial carbon dioxide. Inhaled anesthetics also depress the ventilatory response to hypoxemia, and the interaction between hypoxemia and hypercarbia in stimulating ventilation is greatly attenuated or eliminated by even moderate concentrations of these agents.

Nitrous oxide induces minimal respiratory depression. However, because of its low potency requiring high inspired concentrations and to prevent hypoxemia, this agent should be used cautiously, if at all, in patients with pulmonary dysfunction.

Anesthetic Considerations in Patients with Respiratory Dysfunction

Patients with pulmonary dysfunction may lack the ability to expand their lungs properly (extrapulmonary dysfunction) and/or may have impairment of oxygen and carbon dioxide transfer across the alveolar membranes (intrapulmonary dysfunction). Examples of extrapulmonary dysfunction include diaphragmatic hernia, pneumothorax, hydrothorax, space-occupying lesions of the thorax, flail chest, and any condition that restricts chest wall expansion. Examples of intrapulmonary dysfunction include pneumonia, pulmonary edema, intrapulmonary hemorrhage (contusions), atelectasis, interstitial disease, and upper-airway, tracheal, or bronchial obstruction.

Patients with respiratory dysfunction can be placed in one of four categories:

Category I: Dyspnea does not occur with exertion.

Category II: Dyspnea occurs with moderate exertion.

Category III: Dyspnea occurs with mild exertion.

Category IV: Dyspnea occurs at rest.

Patients in categories III and IV are at higher anesthetic risk. A thorough preanesthetic evaluation should be done on all patients with respiratory dysfunction. The thorax should be physically examined, and thoracic radiographs should be taken if the patient can tolerate handling and positioning without experiencing distress. Radiographs are valuable for arriving at a diagnosis, but the magnitude of the functional impairment is best measured with arterial blood-gas analysis. An ECG, arterial blood-gas analysis, baseline complete blood count, serum biochemistry panel, and serum electrolyte concentrations should be obtained.

Blood-gas analysis on an arterial sample obtained while the patient is breathing a low fraction of inspired oxygen (F_{iO_2}), such as room air ($F_{iO_2} = 0.21$), and a high F_{iO_2} is used by some to assess the ability of supplemental oxygen to improve arterial partial pressure of oxygen and calculate a pulmonary shunt fraction before administering anesthetic drugs. The oxygen partial pressure (PaO_2)- F_{iO_2} ratio is a simple way to quantify the ability to oxygenate at different levels of F_{iO_2} . Dividing the value for PaO_2 by the decimal value of F_{iO_2} yields the ratio. A normal ratio is 500 (i.e., PaO_2 of 100 mm Hg divided by F_{iO_2} of 0.21). A PaO_2 - F_{iO_2} ratio of 300 to 500 is consistent with mild disease, whereas a value of 200 represents significant pathology. This value is less accurate than the traditional alveolar-arterial gradients because it does not reflect the influence of PCO_2 .⁷ If a patient experiences cyanosis or respiratory distress when breathing a low F_{iO_2} , supplemental oxygen should not be withheld to obtain a measurement that can be estimated using an arterial sample collected during oxygen supplementation (e.g., alveolar-arterial gradient).

If possible, surgery and anesthesia should be delayed in patients with pneumonia, pulmonary edema, lung contusions, atelectasis, pneumothorax, and/or hydrothorax to allow time for these problems to be addressed and the condition of the patient to improve. A thoracentesis should be done in patients with moderate to severe pneumothorax or hydrothorax prior to anesthesia, and in some cases a chest tube may be needed.

Patients with respiratory dysfunction should be preoxygenated for 5 to 7 min prior to anesthetic induction.⁸ A mask, nasal catheter, or oxygen chamber may be used. Supplemental oxygen should be immediately available both preoperatively and postoperatively.

Mild preanesthetic sedation may be necessary to enable the patient to be handled without causing stress and exacerbating dysfunction. Preanesthetic drugs that induce minimal respiratory depression should be considered. Several preanesthetic drugs or combinations may be used, such as the combination of acepromazine and butorphanol. Acepromazine is a phenothiazine derivative tranquilizer that produces minimal respiratory depression, especially in low doses. Butorphanol is a synthetic, opioid agonist-antagonist. Butorphanol can produce a dose-related respiratory depression similar to morphine; however, butorphanol seems to reach a ceiling beyond which higher doses do not cause significantly more depression.

After a patient has been sedated, rapid induction of anesthesia

may be needed to gain quick control of the airway to enable positive pressure ventilation. Rapid anesthetic induction may be accomplished by intravenous administration of thiopental, propofol, etomidate, or ketamine. A rapid mask induction using desflurane, isoflurane, or sevoflurane may be used; however, because of the patient's inability to ventilate properly, this technique may result in delayed anesthetic induction and excessive struggling. Whichever induction technique is used, the trachea must be intubated rapidly and accurately.

Anesthesia is best maintained with an inhalant anesthetic and controlled or positive pressure ventilation. Nitrous oxide should be used with care in patients with respiratory dysfunction. It can increase the severity of a pneumothorax, and it should be discontinued if cyanosis is evident. Even if a patient with respiratory compromise seems to have adequate spontaneous ventilation, assisted or controlled ventilation is desirable unless a resolving pneumothorax is present and the patient's $PaCO_2$ and PaO_2 can be maintained at an acceptable level with spontaneous ventilation. High airway pressures from positive pressure ventilation in these patients may result in rapid development of a tension pneumothorax that requires immediate thoracentesis. Pulse oximetry, $ETCO_2$, and arterial blood-gas monitoring should be used to monitor respiratory status in these patients.

Controlled Ventilation

In spontaneously ventilating patients, the respiratory muscles increase the size of the thoracic cavity, the volume within it increases, and the pressure in the thorax falls. Thus, the intrapulmonary pressure falls, and the difference between the intrapleural pressure and alveolar pressure overcomes the elasticity of the lungs while the difference between the alveolar pressure and the pressure at the oral-pharyngeal area overcomes the airway resistance. There is a great difference between the intrapleural and alveolar pressures, and a small difference between the oral-pharyngeal pressure and airway resistance. The net effect is movement of air into the alveoli from the upper airway.

In contrast, controlled ventilation is usually *positive pressure* ventilation. Air is forced into the alveoli under pressure. Intrapleural pressure and intrapulmonary pressure increase during controlled ventilation. Controlled ventilation may be provided manually (by squeezing the rebreathing bag) or mechanically (using a ventilator).

One of three methods can be used to control a patient's ventilation and take over ventilatory effort: The patient can be hyperventilated to decrease the arterial carbon dioxide levels and decrease the stimulus for ventilation; the patient's anesthetic level can be increased (deepened); or the patient can be paralyzed by using peripherally acting muscle relaxants. Of the three methods, hyperventilating the patient (i.e., manually or mechanically increasing the patient's respiratory rate and depth) is the easiest and is usually quite effective.

Five components can be adjusted in the ventilatory cycle during controlled ventilation (Table 37.2): (a) peak airway pressure, (b) mean airway pressure, (c) length of inspiratory phase, (d) length of expiratory phase, and (e) the inspiratory-expiratory

Table 37.2. Adjustable components of the respiratory cycle during mechanical ventilation

Peak airway pressure
Mean airway pressure
Length of inspiratory phase
Length of expiratory phase
Inspiratory-expiratory ratio

ratio. Peak airway pressures are measured by a pressure manometer in the anesthesia circuit. Peak airway pressures of 15 to 20 cm water are necessary to overcome lung resistance to expansion in dogs and larger species. In cats, slightly higher pressures may be needed. Decreased lung compliance will increase the peak airway pressures needed to expand the lungs. An increase in airway resistance will increase the peak airway pressure needed to expand the lungs.

The mean airway pressure is the average pressure generated during the inspiratory and expiratory phases of positive pressure ventilation. Mean airway pressure should be kept low by minimizing the duration of positive airway pressure. Mean airway pressure most closely correlates with decreases in cardiac output.

To produce minimal cardiovascular alteration, the inspiratory phase should be shorter than the expiratory phase. Typically, the inspiratory phase should last 1 to 1.5 s. Prolonged holding of the tidal volume at peak airway pressure will not increase tidal exchange but will increase mean airway pressure and intrathoracic pressure, thereby decreasing venous return and cardiac output. The expiratory phase should begin as soon as the inspiratory phase is complete. The increased pressure within the lung must be allowed to return to 0 cm water pressure as soon as possible to prevent this preload impairment. The inspiratory-expiratory (I-E) ratio is very important during controlled or positive pressure ventilation. The inspiratory phase should be at least one-third and no more than one-half of the total ventilatory cycle. An I-E ratio of 1:2 or 1:3 will help provide an adequate period for proper cardiac filling. A 1:2 ratio will provide for a ventilatory rate of approximately 20 cycles per minute. A 1:3 or 1:4 ratio provides for a rate of 15 or 12 breaths per minute, respectively.

Although controlled or positive pressure ventilation is usually safe and effective, if it is done improperly, harmful side effects can occur.^{9,10} As already described, interference with cardiac output can occur during controlled or positive pressure ventilation. During spontaneous ventilation, the intrapleural pressure at the height of inspiration is approximately a negative 8 to 10 cm water. This augments the movement of blood in the great veins into the chest (thoracic pump). However, during controlled or positive pressure ventilation, the intrapulmonary pressure increases and may reach plus 3 to 5 cm water pressure. Only during expiration is the intrapulmonary pressure the same in spontaneous ventilation and controlled ventilation. Increased alveolar pressure will also decrease pulmonary blood flow. This is why maintenance of proper peak and mean airway pressures and a proper I-E ratio is critical during ventilatory support of anesthetized patients.

Lung damage or *volutrauma* is a potential complication during positive pressure ventilation. Volutrauma (e.g., overextension or expansion of the lung tissue by excessive pressure) can range from mild trauma producing minimal alveolar hemorrhage to severe trauma producing airway rupture and a tension pneumothorax. Maintaining proper peak and mean airway pressures will help minimize pulmonary trauma.¹¹ A major airway blowout that occurs during positive pressure ventilation is often caused by excessive peak airway pressures and/or preexisting lung pathology. Vigilant monitoring of the anesthetic circuit's adjustable pressure limiting (e.g., pop-off) valve is crucial to preventing this type of misadventure.

Acid-base balance will be altered in accordance with changes in alveolar ventilation. Hyperventilation will cause a decreased arterial carbon dioxide level and an increased pH (alkalemia). Hyperventilation can also lead to cerebral vasoconstriction and may reduce cerebral perfusion pressure such that cerebral hypoxia occurs.¹² Hypoventilation will lead to increased arterial carbon dioxide and a decreased pH (acidemia), which may adversely increase intracranial pressure and lead to brain ischemia and/or herniation.

Introduction

Veterinary patients frequently require anesthesia for diagnostic evaluation or surgical correction of neurological disorders. Diagnostic procedures that require either general anesthesia or heavy sedation include electroencephalography (EEG), myelography, other imaging techniques, and electrodiagnostic testing. Veterinary neurosurgical anesthesia is more often required in patients with spinal cord rather than intracranial disorders. The most frequently performed neurosurgical procedure in veterinary medicine is used in the treatment of intervertebral disk disease. However, the increased use of advanced imaging techniques, such as computed tomography and magnetic resonance imaging (MRI), has led to a greater frequency of intracranial operative procedures in small animal patients where these imaging modalities are available. In patients with neurological disease, consideration of the dynamics of intracranial pressure (ICP), cerebral blood flow (CBF), and cerebrospinal fluid (CSF) production and flow is important in preventing patient morbidity or death.

Physiology

In normal awake animals, blood supply to the central nervous system (CNS) is controlled by autoregulatory mechanisms. Alteration in CBF can result from a variety of changes in arterial

oxygenation, carbon dioxide partial pressure, mean arterial pressure, and venous outflow. The brain and spinal cord are protected by encasement within the bony skull and vertebral column. Increases in blood flow within the noncompliant cranial vault cause an increase in the intracranial volume.¹⁻³ Once increases in CBF cause the intracranial volume to exceed the limits of effective compliance, ICP increases sharply. When clinical findings suggest ICP is already increased by intracranial masses, trauma, or derangement of autoregulation, extreme care is required, because slight changes in intracranial volume greatly increase ICP.² Significant ICP increases may lead to cerebral ischemia and brain herniation.¹

Autoregulation of Cerebral Blood Flow

Autoregulation of brain blood flow is usually very effective in a systemic mean arterial blood pressure range of approximately 60 to 140 mm Hg. Within this range of blood pressure, many factors—including intracranial tumors, hypercapnia, severe hypoxia, and many anesthetics—interfere with autoregulation and cause changes in ICP (Fig. 38.1).^{1,4,5} Blood vessels in the brain supplying diseased or neoplastic tissues may be fully dilated and unaffected by normal autoregulation mechanisms.

The CNS depression of general anesthesia is usually accompanied by a decrease in cerebral metabolic rate and cerebral metabolic requirement for oxygen (CMRO₂). This decrease in oxygen requirement is thought to be protective in the possible event of relative ischemia during anesthesia and neurosurgery. There are conflicting reports on the efficacy of various anesthetics in reducing CMRO₂, just as there are with regard to the relative effects of the anesthetics on CBF and ICP. Isoflurane, sevoflurane, etomidate, and the barbiturates are generally recognized as contributing substantially to reduction of CMRO₂, affording some cerebral protection.⁵

In patients with preexisting elevated ICP, further increases can be caused by gravitational or positional interference with drainage of venous blood from the head. Obstruction by occlusion of jugular veins through surgical positioning of the head, use of a neck leash, or venous occlusion to obtain blood samples or placement of jugular vein catheters can rapidly cause dangerous increases in ICP.⁶ For intracranial neurosurgery, a slight elevation of the head above the level of the heart (with the neck in a neutral position) will facilitate venous drainage, lowering ICP. Extreme elevation is avoided to minimize the risk of venous air embolization.³

Fig. 38.1. Alterations in cerebral blood flow (CBF), in milliliters per 100 g of brain tissue per minute, caused by changes in arterial tension of oxygen (PaO_2), carbon dioxide (PaCO_2), and mean arterial blood pressure (MAP). Redrawn from Shapiro.¹

Only at very low arterial oxygen tensions does the CBF change in response to oxygen partial pressure. When arterial oxygen partial pressure (PaO_2) decreases below a threshold of 50 mm Hg, CBF increases (Fig. 38.1). The relationship between arterial carbon dioxide partial pressure (PaCO_2) and CBF, on the other hand, is linear. CBF increases by about $2 \text{ mL} \cdot \text{min}^{-1} \cdot 100 \text{ g}^{-1}$ of brain tissue for every 1-mm Hg increase in arterial carbon dioxide over the range of PaCO_2 from 20 to 80 mm Hg.⁷ Hyperventilation has been used extensively in neuroanesthesia to reduce CBF (via cerebral vasoconstriction). This maneuver decreases tissue bulk, facilitating intracranial surgery. Although quite effective, this technique is somewhat controversial in some situations, because a potential exists for the diversion of remaining blood flow preferentially to diseased tissues lacking autoregulation at the expense of normal brain tissue.⁸ Deliberate hyperventilation to decrease ICP may be risky when mean arterial blood pressure is reduced to less than 50 mm Hg. The ensuing ischemia could be deleterious to normal brain tissues if a “steal” of CBF diverts remaining blood flow.^{8,9} The rapid and substantial reduction in CBF and ICP achieved by hyperventilation makes it a valuable tool for the immediate reduction in brain bulk to facilitate intracranial surgery and to reduce acute brain swelling.

Although controversial, restriction of intravenous fluids to only that volume necessary to maintain adequate circulating volume and cardiac output is usually recommended in neurosurgical patients with increased ICP.^{10,11} Excessive fluid volume has been associated with increased central venous pressure, decreased venous outflow, and increased risk of compounding cerebral edema. Diuretic therapy is frequently indicated in the medical management of patients with intracranial masses and elevated ICP or cerebral edema.⁶ Dextrose administration is somewhat

controversial and must be individualized to the situation. Hyperglycemia is associated with adverse outcome in animals with cerebral ischemia, and cerebral edema can be exacerbated by administration of isotonic dextrose. However, intravenous dextrose administration decreases the incidence of seizures in patients after metrizamide myelography and is indicated in hypoglycemic seizures or hypoglycemic coma.^{1,12,13}

Glucocorticoids are effective in the treatment of some forms of cerebral edema¹⁴ and have been shown to be effective in reducing the increased ICP that is caused by brain tumors and hydrocephalus. Glucocorticoid therapy may be considered in the management of patients with cerebral edema associated with primary or metastatic brain neoplasia. Since dexamethasone administration has been shown to reduce the rate of CSF formation in dogs, steroid administration may be of some value in the preanesthetic management of hydrocephalic patients considered at risk of further increases in ICP.^{14,15} Corticosteroids are now known to be contraindicated in cases of CNS trauma.

Pharmacological Considerations

Sedatives, Tranquilizers, and Analgesics

For many years, the suspected increased seizure activity associated with administration of the phenothiazine (e.g., acepromazine) and possibly butyrophenone (e.g., droperidol) tranquilizers contraindicated their use in seizure-prone patients and in patients for diagnostic EEG.¹⁶ A more recent retrospective study indicates that acepromazine does not potentiate seizure activity.¹⁷ Control of seizures with benzodiazepine tranquilizers (e.g., diazepam or midazolam) is desirable in the management of seizure-prone patients but can obscure characteristic patterns in diagnostic EEGs. In addition, benzodiazepines appear to decrease CBF and ICP.¹⁸

Use of xylazine in dogs and cats is controversial, yet clinical evidence for or against its use in patients with neurological disease is lacking. In healthy conscious horses, xylazine (1.1 mg/kg IV) decreased CSF pressure measured at the lumbosacral space.¹⁹ Horses anesthetized with pentobarbital and subsequently given xylazine (1.1 mg/kg IV) had no change in either lateral ventricle or lumbosacral CSF pressure.²⁰ Horses given detomidine (20 $\mu\text{g}/\text{kg}$ IV) also had a reduction in CBF.²¹ Medetomidine administered to isoflurane-anesthetized dogs had no effect on ICP measured using a fiberoptic transducer, whereas antagonism of medetomidine by using atipamezole was associated with a dramatic transient increase in ICP.²² Dexmedetomidine, the pharmacologically active stereoisomer of medetomidine, decreased CBF in both halothane and isoflurane anesthetized dogs.^{23,24} Thus, although the effects of α_2 -agonists on ICP may differ in horses and dogs with head trauma or neurological disease, they appear to be rational choices to provide sedation for examination or as a preanesthetic medication. Venous congestion in the head, when positioned below the level of the heart, may be associated with an increase in ICP. Therefore, the dose of xylazine or detomidine should be titrated to prevent excessive head lowering and possible resultant increased ICP in horses or other species.

Table 38.1. Effects of anesthetics and anesthetic adjuncts on cerebral blood flow (CBF), intracranial pressure (ICP), blood pressure (BP), and cerebral perfusion pressure (CPP).

^aIndirectly, respiratory depression caused by morphine (and other opioids) may result in hypercapnia with raised CBF and ICP.

Opioids or neuroleptanalgesic combinations are sometimes used in anesthetic management of patients with increased ICP. The direct effects of opioids on CBF and ICP are minimal. However, opioids may indirectly increase CSF pressure and should be used cautiously in patients with cerebral trauma or space-occupying tumors. Increases in pressure within the cranium may aggravate the underlying condition. The elevation in CSF pressure is caused by accumulation of carbon dioxide, which in turn is caused by opioid-induced hypoventilation. If a patient is ventilated to prevent hypercapnia, the increase in CSF pressure does not occur when opioids are administered.²⁵ When opioids are used in these cases, the respiratory status must be assessed through arterial blood-gas analysis or end-tidal carbon dioxide levels, and when necessary, the patient should be ventilated to prevent hypercapnia. The judicious use of opioids for pain management in the postoperative period often does not cause as much respiratory depression as does pain itself.²⁶ Thus, opioid analgesic medication is based on the relative severity of pain in each animal.

Injectable Anesthetics

Most of these cause significant reductions in CMRO₂, CBF, and ICP (Table 38.1).^{1-3,5,6,12} Recognition of barbiturate-induced reductions in CMRO₂, CBF, and ICP has contributed to the concept of *barbiturate coma* therapy for cerebral resuscitation after periods of cerebral ischemia as occurs in near-drowning and in cardiopulmonary resuscitation. The value of barbiturates as a therapy for cerebral ischemia/hypoxia is controversial at best. It is likely that barbiturates are protective if administered prior to the insult but of relatively little value if administered after clinical signs of brain ischemia have developed. Propofol or barbiturates may be of value in avoiding postoperative sequelae to sur-

gical trauma. It must be recognized, however, that barbiturate anesthesia often prolongs anesthetic recovery. In neurosurgical patients, the CNS depression associated with residual barbiturates can seriously obscure postoperative evaluation and prevent meaningful neurological evaluation.

The dissociative anesthetics represent a notable exception to the reduction in CBF, ICP, and CMRO₂ characteristic of most injectable anesthetics.^{1-3,6,12} EEG activity also increases with dissociative anesthesia. Convulsant activity ranging from muscle twitching to seizures occurs as an infrequent adverse effect of the dissociatives. Patients with a history of seizure-related disorders and those with intracranial masses, closed-head traumatic injuries, and other conditions potentially increasing ICP should not receive dissociative anesthetics. Because benzodiazepine tranquilizers may decrease CBF and ICP, their combination with dissociative anesthetics may attenuate cerebrovascular and neurological effects of the dissociative agent.²⁷

Volatile Anesthetics

Inhalant anesthetics increase CBF and alter CMRO₂ to varying degrees.^{7,10,12,28-31} Since increased CBF and ICP are also highly influenced by carbon dioxide retention, respiratory depression associated with volatile anesthesia can be responsible for increases in ICP that are clinically significant in neurosurgical patients. There is evidence that regional changes in the distribution of CBF result from administration of the volatile anesthetics such that our understanding of cerebrovascular effects may not be accurately based on global estimates of CBF in animals.⁴

Among the volatile anesthetics clinically used in veterinary medicine, halothane dramatically blocks autoregulation, increasing CBF and ICP.^{29,30} Methoxyflurane, enflurane, and isoflurane all interfere with autoregulation in a more limited extent than halothane.³ At 1.1 minimum alveolar concentration levels of anesthesia, CBF increases almost 200% with halothane but by only about 40% with enflurane and is unchanged with isoflurane.^{2,28} Higher concentrations of isoflurane cause increases in CBF. The loss of cerebral autoregulation with halothane is implicated in the greater degree of brain swelling noted during neurosurgery with this anesthetic. The increase in CBF occurs rapidly upon halothane administration and is independent of changes in arterial blood pressure, implicating halothane's direct cerebrovascular effects.

Fortunately, modest hyperventilation, reducing arterial carbon dioxide to 30–35 mm Hg, often eliminates the volatile anesthetic-induced increase in CBF.²⁹ Hyperventilation is rapidly effective in reducing elevated CBF and ICP or in preventing their rise in patients at risk. It is easy, rather cost free, and the safest method available. Excessive hyperventilation should be avoided because cerebral perfusion pressure may decrease, resulting in cerebral ischemia. In light of the respiratory depression of general anesthesia and the potential rise in CBF and ICP, ventilation to prevent hypercapnia should be incorporated into the anesthetic technique for animals with intracranial masses or other disorders of autoregulation. Values between 35 and 40 mm Hg of PaCO₂ are recommended in anesthetized patients at risk of increased morbidity associated with raised ICP.

Nitrous oxide has substantial cerebrovascular effects. Although there are conflicting reports and a minority opposing opinion, adverse effects of nitrous oxide have been well documented in animals undergoing neurosurgery.^{5,31} Nitrous oxide causes the most profound increase in both CBF and ICP of all the inhalant anesthetics. Owing largely to the limited potency of nitrous oxide in veterinary patients, its use is primarily in combination with other general anesthetics. The combination of volatile anesthetic gases and nitrous oxide can produce greater increases in CBF and ICP. In rabbits, nitrous oxide administration produced a consistent increase in CBF and ICP regardless of whether it was combined with halothane, isoflurane or fentanyl-pentobarbital anesthesia.¹⁶ Furthermore, these potentially adverse effects were not blocked by hyperventilation. In dogs, nitrous oxide increases CMRO₂ by 11%. In animal models of regional cerebral ischemia, the use of nitrous oxide worsens the neurological outcome.⁵ The disadvantages of nitrous oxide would appear to be substantial for many neurosurgical patients.

Anesthetic Management of Specific Neurological Problems

Myelography and Intervertebral Disk Disease

For the relatively common surgical procedures to decompress cervical or thoracolumbar intervertebral disk herniation, anesthetic management should address (a) protection from possible seizures and other potential complications associated with administration of myelographic contrast agents, (b) perioperative pain relief, (c) maintenance of adequate spontaneous ventilation, and (d) management of concurrent disorders such as urinary incontinence or other factors predisposing patients to adverse recovery.

Radiographic contrast myelography is frequently performed in the immediate preoperative period to localize the lesion(s) and to identify the proper site(s) for surgical decompression. As this procedure is often performed during the same anesthetic period, patient management is designed to optimize conditions for both the diagnostic (radiographic) and the therapeutic (surgical) procedures. Dural puncture for sampling of CSF and/or for administration of myelographic contrast agent requires a depth of anesthesia at less than a surgical plane but adequate to prevent patient movement with subsequent trauma. Considerations for an anesthetic protocol suitable for spinal cord surgery are listed in Table 38.2.

Avoiding the use of potent respiratory depressants and using a light surgical plane of anesthesia will optimally maintain spontaneous ventilation during myelography. Among the less frequent complications associated with myelography are respiratory depression or respiratory arrest and cardiac arrhythmias.³² Preoperative administration of an anticholinergic will reduce the incidence of bradycardia. Respiratory depression is probably referable to effects of the contrast agent at the level of brain stem and medullary respiratory centers. As such, respiratory effects are most likely to be associated with “high” myelograms, typically those showing contrast agent ascending to the brain and brain stem. The incidence of seizure activity and the other potential adverse side effects of myelography appears to be greatly re-

Table 38.2. Anesthetic management for intervertebral disk disease.

1. Benzodiazepine tranquilization (e.g., diazepam, 0.2 mg/kg IV)
2. Low-dose opioid (e.g., hydromorphone, 0.2 mg/kg IV or IM)
3. Anticholinergics if needed, especially before myelography (atropine, 0.04 mg/kg IM)
4. Induction with thiopental (15 mg/kg IV) or propofol (3 mg/kg IV) administered to effect
5. Avoid hyperextension of the neck in cases of cervical trauma, instability, or disk disease
6. Maintenance of protected airway during the procedure
7. Judicious fluid therapy
8. Positioning of the patient to avoid venous occlusion
9. Use of intraoperative and postoperative opioids for pain management

IM, intramuscularly; and IV, intravenously.

duced with use of newer contrast agents such as iopamidol and iohexol rather than metrizamide.^{33,34} Hyperflexion of the cervical spine for cisternal CSF collection and for cervical administration of myelographic contrast can easily kink most endotracheal tubes, causing airway obstruction. Endotracheal tubes that are armored or contain spiral wire are quite resistant to kinking. Metal or other radiopaque reinforcement in the armored tubes makes them unsuitable for use in cervical and cranial radiographic studies. Close attention to adequacy of the airway and spontaneous ventilation is of paramount importance when flexing the neck.

In addition to the precautions and considerations appropriate for thoracolumbar disk disease, cervical disk disease can be associated with increased risk of cardiac arrhythmias and respiratory arrest.³ Vagal stimulation during ventral approaches to the cervical spine may increase with retraction of the carotid sheath. Frequently, there appears to be greater postoperative pain with cervical as opposed to thoracolumbar surgical repair, possibly indicating a neuropathic component to the postoperative pain. Patient positioning for a ventral cervical approach often is dorsal recumbency with the neck extended. Patients should be observed carefully during and after positioning, because overextension may lead to respiratory arrest or cardiac arrhythmias.

Patients having lost deep-pain perception are surgical emergencies. Rapid-sequence induction, using intravenous general anesthetics rather than inhalation induction of anesthesia, is indicated if the animal has or may have a full stomach. Additional management related to the emergent nature of their distress may be indicated. The fact that these animals do not feel painful stimuli to the rear limbs suggests that these areas preferentially can be used for placement of injections and intravenous catheters without contributing additional pain to an already highly stressed patient.

Anesthesia for Horses with Cervical Vertebral Instability (Wobbler Syndrome)

The preanesthetic dose of xylazine administered to a horse with wobbler syndrome should be decreased to prevent the horse from becoming recumbent prior to induction of anesthesia. Xylazine should not be administered until the horse is moved to the induc-

tion area. Horses that are severely ataxic prior to drug administration may be anesthetized in the stall and returned there for recovery after the procedure.

Horses with wobbler syndrome may require anesthesia for myelography. For premedication, a low dose of xylazine (0.2 to 0.4 mg/kg IV) can be used. Anesthesia may be induced by using guaifenesin in combination with thiopental. Anesthesia can be maintained with halothane, isoflurane, sevoflurane, or an injectable anesthetic mixture such as guaifenesin-thiopental. Some clinicians prefer to administer guaifenesin alone until the horse becomes unsteady and then administer a bolus of thiopental (2 to 3 g/450 kg body weight). The total dose of anesthetic should be kept to a minimum so that recovery from anesthesia is optimized. As a rule of thumb, a total dose of 2 L of the guaifenesin-thiopental combination is not exceeded (5% guaifenesin with 0.3% thiopental). Horses can be expected to have an acceptable recovery when anesthesia is limited to less than 1 h. Controlled ventilation during the procedure is recommended. Assisted recovery using a tail rope or other method of assistance may be desired; however, experience and extreme caution are required because of the danger of being crushed by an ataxic horse.

Myelography or withdrawal of CSF may precipitate changes in cerebrospinal pressure, which can adversely affect function of the respiratory center in the brain stem.³⁵ Following administration of a contrast agent, the head should be elevated to minimize the agent's migration toward the brain. In one study, 32% of the horses with significant gait abnormalities that underwent myelography (using metrizamide as the contrast agent) had significant worsening of clinical signs after the procedure.³⁶ Equine myelography with iopamidol or iohexol as the contrast agent may be associated with less toxicity and fewer side effects than metrizamide.^{37,38} Regardless of the contrast agent used, a sudden drop in arterial blood pressure may occur at the time of injection. Monitoring of blood pressure is recommended during the procedure. At the end of the procedure, the horse is returned to spontaneous ventilation and remains anesthetized for at least 30 min after the last injection of contrast agent. Following prolonged lateral recumbency, it is advised to allow the horse to recover with the same side down. Turning horses to the opposite side after long procedures in lateral recumbency does not improve, and may worsen, arterial oxygenation.^{39,40} Recovery from anesthesia for myelography is often characterized by several hours of ataxia, which may be more severe than prior to anesthesia. Measures to observe and support recovering horses should be available. Some horses benefit from being placed in a sling for a few hours after anesthesia. To promote a smooth recovery (and possibly to decrease the incidence of post-myelogram seizure or muscle-tremor activity), a low dose of xylazine (25 to 100 mg IV) or diazepam (0.03 mg/kg intramuscularly) may be administered to adult horses. Some clinicians use phenylbutazone to minimize postmyelogram muscle-tremor activity. Because phenylbutazone is highly protein bound and may displace anesthetic from protein-binding sites, it has been recommended that phenylbutazone be administered before anesthetic agents are given. Phenylbutazone administration to horses that already are induced and/or maintained with injectable anesthetics may deepen anesthesia or prolong recovery.

Intracranial Masses and Elevated Intracranial Pressure

Patients with intracranial masses, dysfunctional CBF autoregulation, and/or increased ICP are at risk of rapid decompensation under anesthesia. Preoperative assessment should include measurement of arterial blood pressure, because many patients with elevated ICP will have an accompanying increase in systemic arterial blood pressure (Cushing's response). Systemic hypertension is an attempt to compensate and maintain adequate cerebral perfusion pressure. If mean arterial pressure is significantly elevated prior to drug administration, arterial blood pressure should not be allowed to drop to normally acceptable levels under anesthesia (e.g., a mean arterial pressure of 60 mm Hg), because cerebral ischemia can result despite an "acceptable" mean blood pressure.

Manual or mechanical positive-pressure ventilation should be immediately available and instituted at induction. Mechanical ventilation should be continued until extubation. In some cases, allowing PaCO₂ to rise in order to stimulate spontaneous ventilation, before the respiratory depressant effects of the anesthetics wane, may cause serious elevations in ICP and possibly herniation. Anesthetic monitoring should address the physiological variables associated with altered ICP. Venous and arterial blood pressures and airway or arterial sampling for carbon dioxide analysis should be included, if possible. Intravenous mannitol (0.5 to 1.0 g/kg IV slowly) may be useful to reduce ICP before, during, or after anesthesia. Optimal anesthetic management can substantially improve patient status and the outcome of intracranial surgical procedures. A recommended anesthetic technique is summarized in Table 38.3.

Management of Seizures in the Perianesthetic Period

Seizures are most commonly observed in animals with other signs of brain disease. Thus, animals anesthetized for diagnosis or treatment of CNS disease are more likely to exhibit seizure activity during the perianesthetic period. The animal with seizure activity should be medically treated to control standard recom-

Table 38.3. Anesthetic technique for patients with elevated cerebral blood flow and/or intracranial pressure.

1. Preanesthetic critical care management and stabilization
2. Fluid therapy limited to minimize cerebral edema but adequate to support circulation
3. Avoid severe respiratory depression, jugular venous occlusion, and coughing at induction or during recovery
4. Avoid dissociative anesthetics, halothane, enflurane, and nitrous oxide
5. Thiobarbiturate or propofol induction of anesthesia preferred
6. Minimal inhalant anesthetic supplemented with opioids for maintenance
7. Modest hyperventilation to reduce cerebral blood flow and intracranial pressure
8. Postoperative critical care with support of ventilation and circulation as indicated

mendations before anesthesia is attempted. In horses, treatments for status epilepticus include use of anticonvulsants such as diazepam, midazolam, pentobarbital, phenobarbital, phenytoin, primidone, chloral hydrate, and the combination of guaifenesin with a thiobarbiturate.⁴¹ Foals exhibiting seizure activity may be treated with diazepam (5 to 10 mg IV), phenytoin (5 to 10 mg/kg IV, intramuscularly, or orally), or phenobarbital (with plasma-level monitoring).⁴² A complication associated with treatment of seizures in neonatal foals is the altered disposition of drugs. Functional hepatic microsomal enzymes and renal function in neonates is immature. Thus, concurrent medication with other drugs may cause unexpected interactions or changes in elimination, necessitating careful patient monitoring and alteration of the anticonvulsant dosage regimen.

Phenothiazine tranquilizers have been shown to augment epileptiform activity on the electroencephalogram of dogs.⁴³ Intrathecal injection of radiographic contrast agents is frequently associated with seizures.⁴⁴ Therefore, the use of acepromazine and other phenothiazine tranquilizers has usually been avoided in animals with preexisting seizures and in animals undergoing myelography (Table 38.4).

Horses sedated with xylazine demonstrate electroencephalographic slowing with irregular waveforms.⁴⁵ Xylazine (0.1 to 0.2 mg/kg IV) and diazepam (0.2 mg/kg IV) have both been suggested as effective injectable treatments for seizures in horses recovering from anesthesia.⁴⁶ Seizures occurring after myelography that are not controlled by injections of xylazine or diazepam may be treated by reanesthetizing the horse with guaifenesin and a thiobarbiturate. Anesthesia with an inhalation anesthetic may be necessary for up to 1 or 2 h until seizure activity wanes.

In horses, the accidental intracarotid injection of drugs such as xylazine may seriously irritate neural tissues, causing a violent reaction and seizures. Management of this potentially dangerous situation should be directed toward manual and, preferably, chemical restraint to prevent injury. Intravenous injection of thiopental alone or guaifenesin combined with thiopental is recommended as soon as accidental intracarotid injection is recognized. The preplacement of an indwelling intravenous catheter is recommended to help prevent the accidental perivascular injection of any drug. Inspired oxygen should be supplemented, and intravenous fluids should be administered. In the case of intracarotid injection of xylazine, pharmacological antagonism is not recommended. Horses given intracarotid drug injections can be sedated for 30 min by using the combination of guaifenesin and thiopental and often recover uneventfully. The accidental intracarotid injection of larger doses may have severe neurological sequelae (presumably caused by brain edema) requiring additional symptomatic treatment.

Anesthesia for Electrodiagnostic Techniques

Electrodiagnostic procedures are those that involve recording spontaneous or evoked electrical activity from tissues or organs. Although consistent with the definition, electrocardiography is usually not considered under this rubric. In veterinary medicine,

clinical electrodiagnostic techniques are used to record potentials from muscle, peripheral nerves, spinal cord, brain stem, cortex, and retina. In humans, these procedures are performed without the use of general anesthetics, tranquilizers, or analgesics. With adequate instruction, most adults will tolerate some degree of discomfort or boredom to achieve good test results. Some procedures, such as nerve-conduction studies or electromyography, cause some pain, whereas others, such as visual or auditory evoked potentials, may simply require human patients to concentrate or refrain from movement. A fundamental problem encountered in the use of electrodiagnostic techniques in veterinary medicine is that of patient cooperation. Even during those procedures in which the stimulus is innocuous, artifacts caused by movement may render the technique ineffective. Therefore, many of these procedures must be performed in anesthetized or tranquilized animals. This approach is usually less stressful to the animals, insures a minimum of recording artifacts, and often gives the examiner an opportunity to collect more useful data. The obvious trade-off is nervous system function that has been chemically altered to some degree.

The effects of anesthetics on the outcome of electrodiagnostic procedures range from insignificant to dramatic. In some instances, the use of anesthetic agents altogether precludes recording certain types of potentials. The order of increasing anesthetic effects on recordings is peripheral nerve and skeletal muscle, spinal cord and retina, brain stem, and cerebral cortex. Even so, as long as the effects are understood, the benefits of the recordings may still provide valuable diagnostic data and information.

Today, intraoperative monitoring has become standard practice when a physician desires direct and prompt feedback about neural function during surgical procedures. The use of intraoperative electrodiagnostic monitoring in veterinary medicine is not widespread, but many electrodiagnostic laboratories judiciously use anesthetics for their procedures. Certainly, the precautions will vary between animal species and the physical condition of patients. An exhaustive review of anesthetic effects on these diagnostic techniques is not possible here, but some examples from the literature underscore the relevance of this information.

Electroencephalogram and Electromyography

There are two procedures in which electrical activity is recorded from spontaneously, reflexively, or volitionally active tissue. The first is the electroencephalogram (EEG), activity produced by the

cerebral cortex, and the second is the electromyogram, electrical activity produced by skeletal muscle. Most other electrodiagnostic procedures require a stimulus to evoke activity from excitable tissue. The evoking stimulus may be electrical, visual, auditory, or mechanical.

The effects upon the EEG depend on the anesthetic type and depth. Anesthesia initially causes an increase in the voltage and a decrease in the frequency of cortical potentials when compared with the record of an awake alert dog. Spikes and spindles may also riddle the EEG of lightly anesthetized dogs and cats.^{47,48} As anesthesia deepens, the overall voltage begins to diminish. A dose-response decrease in cerebral oxygen consumption (CMRO₂) accompanies the use of isoflurane in dogs and causes the EEG to become isoelectric at an end-expired concentration of 3%.⁴⁹ The same type of cortical alteration in electrical activity, sometimes referred to as *burst suppression*, has been reported in swine.⁵⁰ Isoflurane anesthesia may thereby interfere with acquisition of diagnostic information. A recommended anesthetic technique for diagnostic EEG evaluation and for procedures other than EEGs in seizure-prone patients is summarized in Table 38.4.

Dose-dependent CNS depression of EEG activity by most anesthetics is characteristic and has led to the development of EEG-based anesthetic-monitoring techniques.⁵¹ Use of computer-analyzed *quantitative* EEG in isoflurane-anesthetized dogs has been reported.⁵² Notable exceptions to the general rule that anesthetics decrease EEG activity include the dissociative anesthetics and the volatile anesthetic enflurane. Enflurane anesthesia can be accompanied by increased EEG activity extending to seizures, particularly if a patient is hyperventilated and hypocarbic.^{3,12} Alterations in normal PaCO₂ are associated with significant changes in the quantitative EEG of dogs during halothane anesthesia.⁵³ Methoxyflurane and halothane anesthetics cause a progression of cerebral depression in dogs, with the latter more likely to promote burst suppression than the former.⁵⁴ Similar results in dogs have been reported for sodium pentobarbital. In dogs, barbiturate anesthesia is accompanied by reduced EEG amplitude and burst suppression.⁵⁵

Monitoring CNS depression by using EEG during anesthesia has been the focus of study for decades. However, direct interpretation of the EEG has not proven adequately reliable or time responsive for use in operative circumstances. Processed EEG monitoring has evolved as a way to provide immediate feedback to anesthetists in regard to patients' CNS activity. Spectral edge frequency, total power, beta to delta frequency ratios, and other specific parameters derived from computer-processed EEG have been correlated to varying degrees with anesthetic depth, but interpretation can vary depending on the selection of anesthetic agents. Intraoperative EEG processing has been developed with significant improvement in reliability. For example, the bispectral index (BIS) monitor is a proprietary device that provides information related to anesthetic depth and is readily interpreted. In addition, the BIS has proven to be reliable as an indicator of anesthetic depth in people given a variety of anesthetic agents and adjuncts.^{56,57} The BIS is a unitless number between 0 and 100 derived from the processed EEG.⁵⁸ People undergoing surgery are typically maintained at a depth of anesthesia that yields

a BIS value between 40 and 60, which reliably prevents intraoperative awareness.^{59–63}

In animals, a few reports have evaluated use of the BIS as an indicator of anesthetic depth. In dogs, isoflurane and sevoflurane anesthetic depth has been correlated to BIS.^{64,65} Anesthetized cats had a nonlinear relationship of BIS with increasing multiples of sevoflurane minimum alveolar concentration.⁶⁶ The change in BIS values following stimulation in isoflurane-anesthetized cats provided a useful measure of anesthetic depth.⁶⁷ In goats anesthetized with isoflurane, BIS values significantly changed in response to intubation and noxious stimulation.⁶⁸ One study in unstimulated pigs did not demonstrate reliable correlation between isoflurane anesthetic depth and BIS, whereas others have demonstrated correlation of BIS values to anesthetic depth during surgery or with other noxious stimulation.^{69–72}

Nerve-Conduction Studies

Nerve-conduction velocity has been successfully recorded in dogs while using a variety of anesthetic protocols. Because these procedures have not been done in unanesthetized animals, the effects of anesthetics on these procedures are largely unknown. Studies in dogs have been successful using thiamylal sodium and methoxyflurane for assessment of motor and sensory nerve function.^{73,74}

Auditory and Visual Evoked Potentials

These may be altered by anesthetic agents, depending on the location of signal generators. Generally, cortical potentials are more likely to be affected than brain-stem potentials. In cats, administration of pentobarbital (20 mg/kg intraperitoneally) was shown to increase latency, area, and amplitude of auditory potentials.⁷⁵ In another study, brain-stem auditory evoked potentials recorded from cats were unaffected by sodium pentobarbital, ketamine, halothane, or chloralose administration.⁷⁶ Similar results were obtained from rats when ketamine or pentobarbital were used.⁷⁷ The use of ketamine in rats does, however, affect photic and field potentials recorded directly from various sensory relay nuclei when using implanted microelectrodes.⁷⁸ The use of ketamine and xylazine in cats produces only minimal changes (latency increases) in the brain-stem auditory evoked responses (BAERs) compared to xylazine alone.⁷⁹ The use of thiamylal sodium alters the BAER in dogs by increasing the latencies and decreasing the amplitudes of certain peaks.⁸⁰ The same dose of thiamylal sodium, however, completely obliterates middle-latency components of the BAER in dogs.⁸¹ Light pentobarbital anesthesia in cats produces an increase or no change in cortical auditory evoked responses (AERs), moderate levels cause some increases in amplitude, and deep anesthesia causes all waves to disappear.⁸² Although paraldehyde, ether, and ethyl chloride produce effects similar to those of pentobarbital, chloralose and chloroform are associated with an earlier and more profound period of enhancement.

In rats, the use of halothane (0.25% to 2.0%) affects AERs in a dose-related fashion.⁸³ These potentials are more sensitive to halothane than are visual evoked responses, especially in the auditory cortex. Pentobarbital, given to rats in sufficiently high doses to cause coma, progressively depresses and then abolishes

all peaks of the auditory brain-stem potential.⁸⁴ The use of atropine and xylazine in dogs in combination with ketamine or pentobarbital produces only slight changes in the latency of BAER wave VI when compared with xylazine and atropine alone.⁸⁵ When BAER waves in dogs anesthetized with methoxyflurane are compared with those in unanesthetized dogs, all waves have significantly longer latencies.⁸⁶ In gerbils, ketamine-xylazine anesthesia induces only minor changes in the low-frequency and high-frequency components of the auditory brain-stem response.⁸⁷

Visual evoked potentials (VEPs) have been successfully recorded in dogs and cats administered halothane, and in cats administered halothane and thiamylal sodium.^{88–90} In dogs, a comparison of VEPs from dogs anesthetized with chloralose with VEPs from dogs anesthetized with halothane or halothane and thiopental did not reveal any differences in the waveform.⁹¹

Electroretinogram and Oscillatory Potentials

These can be recorded from small animals under a variety of anesthetic conditions.^{92–94} The effects of clinical anesthetic protocols in animals is not well documented. Methoxyflurane, halothane, enflurane, ether, and chloroform anesthesia retards cone adaptation curves in monkeys.⁹⁵ Pentobarbital anesthesia in cats enables visual evoked responses to be recorded with only minor fluctuations over an 80-min period.⁹⁶ Barbiturate anesthesia has no effect on the maturation of the visual evoked response during the first 2 weeks of life.⁹⁷ Beyond 2 weeks of age, anesthesia causes an increase in the amplitude of early components while eliminating later components altogether.

Somatosensory Evoked Potentials

Somatosensory evoked potentials (abbreviated as SSEPs, SEPs, or SERs [somatosensory evoked responses]) are also affected by anesthesia. Isoflurane at 1% produces a sustained latency change in SSEP in newborn piglets.⁹⁸ Halothane administration does not affect peak latencies of lumbar spinal cord evoked potentials, but amplitudes are reduced.⁹⁹ In cats, increasing levels of pentobarbital can be used to achieve therapeutic coma levels.¹⁰⁰ The early brain-stem components are relatively unaffected, whereas late brain-stem and initial cortical responses show progressive latency increases. Late cortical waves are abolished at relatively low doses; central conduction is unaffected, and late waves of the visual evoked response are abolished even though a single potential survives massive doses. Components of sheep SSEPs have been shown to be differentially sensitive to barbiturate anesthesia.¹⁰¹

Motor Evoked Potentials

The effects of isoflurane on motor evoked potentials (MEPs) in rats has been examined using concentrations ranging from 0.2% to 1.5%.¹⁰² There is a progressive increase in onset latency of the compound muscle action potentials and a decrease in the peak-to-peak amplitude and duration. Spinal cord MEPs have been reported in dogs with the use of a combination of fentanyl, droperidol, sufentanil, and nitrous oxide. Halogenated gas anesthetics raised the stimulus threshold for recording MEPs as compared with narcotic/nitrous oxide anesthesia.¹⁰³ Peripheral nerve MEPs

have been successfully recorded from dogs when using thiopental sodium, isoflurane, and oxymorphone.¹⁰⁴

Considerations for Magnetic Resonance Imaging

Anesthetic concerns during MRI examination center on the potentially dangerous environment of a strong magnetic field. Ferromagnetic projectiles have had serious, even lethal, consequences in MRI suites. Anesthetic management of animals undergoing MRI exam can most simply be accomplished by means of injectable agents.^{105–107} Inhalant anesthetics have been used in MRI suites by distancing the vital ferromagnetic components of the anesthesia machine from the magnetic field. Use of an extended non-rebreathing circuit, such as the Bain circuit, has been described.¹⁰⁸ One drawback of this technique is the higher fresh-gas flow rates required for larger animals (>50 kg). Another modification of anesthetic technique for MRI involves the use of extended rebreathing hoses with the anesthetic machine placed near the magnet, yet just beyond the critical point of magnetic attraction. For equine MRI, a large animal machine suitable for delivering inhalant anesthetics to horses can be used in this manner. There is anecdotal evidence that prolonged exposure (more than 2 h) in a 3- to 5-gauss magnetic field begins to affect vaporizer (Isotec; Datex-Ohmeda, Helsinki, Finland) output such that higher vaporizer settings are required to maintain adequate anesthesia (S. Greene, personal observation). In human patients, this effect has been reported for Fortec vaporizers (Cyprane, Keighley, U.K.).¹⁰⁹ Although many vaporizers are mainly constructed from nonferrous materials, many do contain components attracted or affected by magnetic fields.¹¹⁰

Anesthesia in MRI suites can be monitored by using MRI-compatible equipment to measure the electrocardiograph, blood pressure, pulse oximetry, and airway gases.¹¹¹ Less expensive alternatives include use of remotely placed monitors with specialized cabling designed to avoid interference with the magnetic field and induction of electric currents leading to burns. Simple systems can be used to measure direct arterial blood pressure, such as the aneroid manometer placed beyond the magnetic field or several feet of extension tubing placed between the transducer and patient. Some dampening and degradation of the arterial pulse wave may occur, but often direct measurement or arterial blood pressure is invaluable to assure maintenance of adequate cerebral perfusion pressure.

Because the magnetic fields vary considerably among various MRI units in clinical practice, consultation with a knowledgeable biomedical engineer is advised prior to implementing a monitoring system or novel means of anesthetic delivery.

Introduction

Anesthetic Effects on Renal Function

Effects of Renal Insufficiency on Anesthesia

Tests of Renal Function

Postoperative Oliguria

Urethral Obstruction

Ruptured Urinary Bladder

Introduction

The kidneys have three primary functions: filtration, reabsorption, and secretion. To accomplish these functions, they receive about 25% of the cardiac output. The renal tubules and collecting ducts reabsorb up to 99% of filtered solutes, indicating that the total filtration volume is much greater than daily urine production. Neurohumoral substances and physiological factors that affect reabsorption of the filtered water and sodium include aldosterone, antidiuretic hormone (ADH), arterial blood pressure, atrial natriuretic factor, catecholamines, prostaglandins, renin-angiotensin, and stress.

Renal blood flow (RBF) is regulated by extrinsic nervous and hormonal control and by intrinsic autoregulation. Renal vasculature is highly innervated by sympathetic constrictor fibers originating in the spinal cord segments between T4 and L1. The kidneys lack sympathetic dilator fibers and parasympathetic innervation. Intrinsic autoregulation of RBF is demonstrated by a constant flow when mean arterial blood pressure ranges from 80 to 180 mm Hg. When the mean arterial blood pressure is between 80 and 180 mm Hg, the kidney can control blood flow by altering resistance in the glomerular afferent arterioles. Although the exact mechanism of renal autoregulation is not known, the significance of this phenomenon relates to protection of glomerular capillaries during hypertension and preservation of renal function during hypotension. However, even within the range of blood pressure described for function of renal autoregulation, extrinsic forces (e.g., neural, hormonal, and pharmacological) and intrinsic forces (e.g., renal insufficiency/failure) may cause alterations in RBF and glomerular filtration rate (GFR). Catecholamines are the major hormonal regulators of RBF. Epinephrine and norepinephrine cause dose-dependent changes in RBF and the GFR. Low doses increase arterial blood pressure and decrease RBF with no net change in the GFR. Higher doses cause decreased RBF and GFR. The renal vascular anatomy is unique in its distribution to cortical and medullary zones. Because of this vascular dichotomy, local tissue ischemia and hypoxia may occur

even though total organ blood flow is normal. Oxygen delivery to the kidney is complex, and selective regional hypoxia is a possible source of renal injury during renal hypoperfusion. Experimental evidence indicates that the medullary thick ascending limb of Henle's loop, because of its high metabolic rate associated with active transport of electrolytes, is selectively vulnerable to hypoxic injury.¹

Anesthetic Effects on Renal Function

Effects of anesthetics on RBF can be summarized with the following generalization: All anesthetics are likely to decrease the rate of glomerular filtration. Anesthetics may directly affect RBF, or they may indirectly alter renal function via changes in cardiovascular and/or neuroendocrine activity. Most anesthetics decrease the GFR as a consequence of decreased RBF (Table 39.1). Anesthetics that cause catecholamine release (e.g., ketamine, tiletamine, and nitrous oxide) have variable effects on RBF. Inhalation anesthetics tend to decrease RBF and GFR in a dose-dependent manner. Light planes of inhalation anesthesia preserve renal autoregulation of blood flow, whereas deep planes are associated with depression of autoregulation and decreases in RBF. Although isoflurane has little effect on RBF, it decreases GFR and urine output.² Nitrous oxide in combination with halothane does not appear to alter autoregulation of RBF.³ Desflurane has no effect on RBF at concentrations up to twice the minimal alveolar concentration (MAC); however, it decreases renal vascular resistance at concentrations greater than 1.75 MAC.⁴

Thiobarbiturates increase systemic vascular resistance but decrease renal vascular resistance with no net change in RBF. In contrast, ketamine increases RBF and renal vascular resistance.⁵ Most anesthetics cause less disruption of renal autoregulation of blood flow at lower doses (lighter anesthetic planes). Different responses to anesthetics may occur in controlled studies of RBF compared with clinical use of anesthetics. Renal responses to anesthetics also depend on the preexisting hydration status and quantity of perioperative fluids administered, as well as preexisting renal insufficiency/failure.

Due to systemic hypotension or renal vasoconstriction, renal ischemia may occur during anesthesia. Systemic hypotension may be caused by excessive depth of inhalation anesthesia, as all potent halogenated anesthetics cause peripheral vasodilation. Inhalant anesthetics also depress myocardial contractility and cardiac output in a dose-dependent manner. Hypotension may also be induced by phenothiazine or butyrophenone tranqui-

Table 39.1. Effects of anesthetics on renal blood flow (RBF) and glomerular filtration rate (GFR)^a.

Drug	RBF	GFR
Desflurane	No change	Decrease
Enflurane	Decrease	Decrease
Etomidate	No change	No change
Halothane	Slight decrease	Decrease
Isoflurane	Slight decrease	Decrease
Ketamine	Increase	Decrease or no change
Propofol	No change	No change
Sevoflurane	Slight decrease	Decrease
Thiopental	No change	No change or slight decrease

^aInjectable anesthetics administered as a single intravenous bolus.
Halogenated inhalants administered for maintenance of anesthesia.

lizers. Phenothiazine and butyrophenone tranquilizers block α -adrenoceptors and dopamine receptors. α -Adrenergic blockade may induce peripheral vasodilation and hypotension. Dopamine receptor blockade by acepromazine premedication may prevent dopamine-induced increases in RBF during surgery.

Intraoperative administration of epinephrine for hemostasis will increase renal vascular resistance and may reduce RBF significantly.⁶ Renal failure may occur occasionally in animals that have been given epinephrine for hemostasis during otherwise uneventful anesthesia.⁷ Following the initial ischemic insult, renal perfusion may remain altered because of other mechanisms. In experimental dogs injected intrarenally with norepinephrine, saline administration restored RBF but did not correct oliguria.⁸ Necropsy of animals following acute renal failure may not detect renal damage because histological evidence may not be evident until 3 or 4 days after injury.⁹

Anesthesia and the stress associated with surgery cause release of aldosterone, vasopressin, renin, and catecholamines. Thus, RBF and GFR (and therefore urine production) are generally decreased with surgery in any patient. For most patients, the effects of inhaled anesthetics on renal function are reversed at the termination of anesthesia. Some patients, however, may not regain the ability to regulate urine production for several days.¹⁰ Postanesthetic oliguria should be evaluated as soon as is feasible.

Some drugs used in the perianesthetic period have a significant effect on urine production. α_2 -Adrenergic agonists can dramatically increase urinary output and reduce urinary osmolality.¹¹ Xylazine is believed to decrease ADH concentration in mares, accounting, in part, for increased urine production.¹² Detomidine-induced diuresis has also been reported in horses.¹³ Because α_2 -adrenergic agonists can induce diuresis, they should not be used in animals that have urethral obstruction. Reports on the effects of opioids on ADH secretion are confusing. The anti-diuresis following morphine administration in animals has been attributed to increased release of ADH.¹⁴ Others suggest this is a response to stress associated with surgical stimulation.¹⁵ Opioids

may cause urine retention when administered systemically or as an epidural injection.

Nephrotoxic drugs administered during anesthesia may cause oliguria (Table 39.2). Methoxyflurane is the only anesthetic known to cause nephrotoxicity as a consequence of biotransformation to oxalate and free fluoride ion.¹⁶⁻¹⁸ Methoxyflurane anesthesia combined with flunixin meglumine precipitates renal failure in dogs.¹⁹ Aminoglycoside antibiotics are potentially nephrotoxic and also enhance the renal toxicity of methoxyflurane.²⁰

Effects of Renal Insufficiency on Anesthesia

Renal insufficiency/failure and renal azotemia in patients with renal insufficiency can alter the response to anesthetics. Azotemia may be associated with changes in the blood-brain barrier, leading to increased drug penetration into the central nervous system. Patients with renal insufficiency/failure may be acidotic, which will increase the fraction of unbound barbiturate and other injectable drugs in the plasma. Thus, lower doses of highly protein-bound injectable anesthetics may be required in acidotic patients.

Hyperkalemia may be present in animals with renal insufficiency/failure, obstructed urethra, or rupture of the urinary bladder. Acidosis may be associated with a concurrent increase in serum potassium. Patients in renal failure with hypocalcemia are at even greater risk, because hypocalcemia potentiates the myocardial toxicity of hyperkalemia. Further, administration of succinylcholine will transiently increase serum potassium concentration.²¹ Succinylcholine-induced increases in potassium are potentially life threatening in animals with hyperkalemia. In contrast, elevation in serum potassium is not observed after administration of nondepolarizing neuromuscular blocking agents. It should be remembered that patients with hypermagnesemia associated with chronic renal failure may have prolonged recovery from nondepolarizing neuromuscular blocking agents.²² In general, patients having a serum potassium concentration greater than 5.5 or 6.0 mEq/L should not be anesthetized until the hyperkalemia can be addressed. Electrocardiographic (ECG) abnormalities are commonly observed with potassium concentrations exceeding 7 mEq/L. The resting membrane potential of cardiac muscle depends on the permeability and extracellular concentra-

tion of potassium (Fig. 39.1). During hyperkalemia, the membrane's resting potential is raised (partially depolarized), and fewer sodium channels are available to participate in the action potential. As the serum potassium concentration increases, repolarization occurs more rapidly and automaticity, conductivity, contractility, and excitability are decreased. These changes produce the classic ECG appearance of a peaked T wave with a prolonged PR interval progressing to wide QRS complexes and loss of P waves. Mild chronic hyperkalemia may not require treatment prior to anesthesia. If treatment is instituted for chronic hyperkalemia, serum potassium should be lowered gradually to allow intracellular potassium time to reestablish physiological transmembrane concentration gradients. If hyperkalemia is acute or ECG abnormalities are noted, treatment should be initiated prior to induction of anesthesia. The most rapid treatment for the cardiac effects associated with hyperkalemia is 10% calcium chloride (0.1 mg/kg IV). Calcium will increase the membrane's threshold potential, resulting in increased myocardial conduction and contractility. Because increased serum potassium concentration causes the resting potential to be less negative (partially depolarized), the calcium ion-induced increase in threshold potential temporarily restores the normal gradient between resting and threshold potentials. It should be recognized that administration of calcium will not affect the serum potassium concentration, and its effects will therefore be short-lived. Regimens to decrease the serum potassium concentration by shifting potassium intracellularly include bicarbonate administration and combined infusion of glucose and insulin. Because acidemia favors extracellular movement of potassium and worsens hyperkalemia, intermittent positive pressure ventilation may be required to prevent anesthetic drug-induced hypercapnia and respiratory acidosis.

Patients with chronic renal failure may be anemic because of bone marrow suppression, chronic gastrointestinal tract blood loss, reduced red blood cell life span, and decreased erythropoietin production. In response to anemia, the cardiovascular system may become hyperdynamic in an attempt to maintain oxygen delivery. Chronic renal disease may be associated with hypertension and increased cardiac output but reduced cardiac reserve. Patients undergoing anesthesia should have a red blood cell transfusion if the hematocrit is less than 18% (cats) or 20% (dogs). Additionally, pulse oximetry can be used to rapidly detect hemoglobin desaturation and alert one to the potential for a decrease in tissue oxygen delivery.

In dogs and cats with mild renal insufficiency, a rapid intravenous induction of anesthesia may be accomplished with thiobarbiturates, propofol, etomidate, diazepam-ketamine, or diazepam-opioid combinations. Severely depressed patients can be mask induced with isoflurane or halothane. Anesthesia may be maintained with isoflurane or sevoflurane. The use of medications, including nonsteroidal anti-inflammatory drugs (NSAIDs), that are potentially nephrotoxic should be avoided (Table 39.2).

When renal function is questioned, the urinary bladder can be catheterized and urine production monitored via a closed, sterile urine-collection system. Urine production is an indirect measure of renal perfusion. Normal urine output for dogs is 0.5 to 1.0 mL · kg⁻¹ · h⁻¹. In normal horses, daily urine production has been

Fig. 39.1. Relationships between extracellular concentrations of potassium (K⁺) and calcium (Ca²⁺) and the resting potential (RP) and threshold potential (TP). An action potential is generated when there is sufficient depolarization to reach the TP. Increased extracellular potassium will result in raised (less negative) RP, whereas increased extracellular calcium will result in raised TP.

estimated to be about 15 L; horses that are denied feed and water for 24 h produce about 6 L.²³ Empty intravenous fluid bags can be saved for the purpose of collecting urine from catheterized patients.

If the urinary tract is not obstructed or the patient is anuric, intravenous fluids should be administered during anesthesia at the rate of 20 mL/kg for the first hour. A rate of 10 mL · kg⁻¹ · h⁻¹ is used thereafter. Lower fluid rates should be used if the patient has mild hypoproteinemia or cardiovascular disease. The choice of intravenous fluid is based on the animal's electrolyte and acid-base status. In general, animals with mild to moderate renal insufficiency/failure that are well prepared for surgery or anesthesia are given lactated Ringer's solution. Arterial blood pressure must be measured to detect systemic hypotension and decreased renal perfusion pressure. The mean arterial blood pressure should be maintained above 70 to 80 mm Hg. The central venous pressure (CVP) can be measured via a jugular catheter to evaluate the rate of intravenous fluid administration. Normal CVP should be between 3 and 5 cm of water. If the CVP rises more than 10 cm of water, the fluid administration should be slowed or stopped. If the CVP falls in response to the fluids being stopped, they may be resumed at a slower rate. An elevated CVP of more than 10 cm of water indicates inadequate myocardial function or volume overload. Myocardial function may be improved by infusion of dopamine (1 to 3 μg · kg⁻¹ · min⁻¹). Low doses of dopamine will also improve RBF either through increased cardiac output, dopaminergic diuretic effects, or both. Doses of dopamine above approximately 10 μg · kg⁻¹ · min⁻¹ may cause α-adrenergic renal vasoconstriction and decreased RBF. Improvement in renal perfusion in cats given dopamine is less well documented, but may involve α-adrenoceptor stimulation rather than dopamine receptor agonism.²⁴ Putative renal dopamine receptors (DA1) in cats appear to differ from those identified in kidneys of other species.²⁵ Other DA1 agonists, such as fenoldopam, may prove useful in improving RBF and diuresis in this species.

Tests of Renal Function

Measurements of the GFR and renal tubular function, such as urine specific gravity and blood urea nitrogen (BUN), are not specific for renal disease. Serum creatinine is a more specific indicator of the GFR than BUN because it is influenced by fewer extrarenal variables. It is important to keep in mind that greater than 75% nephron loss is necessary for most patients to become persistently azotemic. Thus, patients with mild renal insufficiency may not have elevated serum creatinine. Persistent proteinuria and/or cellular or granular cylinduria may indicate renal damage prior to the onset of renal azotemia.

In addition to BUN, serum creatinine concentrations, and urinalysis, patients with renal insufficiency should be evaluated to determine acid-base balance, electrolyte concentrations (especially potassium), exercise intolerance, hematocrit, hydration, and urine production.

Postoperative Oliguria

Postoperative oliguria ($<0.5 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$) should be investigated. If the animal does not have congestive heart failure or pulmonary edema, a fluid challenge of 5 mL/kg isotonic sodium chloride may be given. If urine production increases, the animal was hypovolemic and fluids should be continued. If not, dopamine may be infused at a rate of 1 to 3 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. Dopamine improves renal function when used at low doses by increasing RBF, GFR, urine output, and sodium excretion, and by decreasing renal vascular resistance.²⁶ At moderate doses (approximately 5 to 10 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$), dopamine activates β -adrenoceptors in addition to DA1 receptors, which may dilate renal arterial beds and increase cardiac output. As previously mentioned, dopamine doses above approximately 10 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ can cause α -adrenoceptor stimulation, vasoconstriction, and decreased RBF even though systemic arterial blood pressure may increase. Dopamine may also be beneficial because it inhibits intrarenal norepinephrine release and has an antialdosterone effect.¹ Recall that, in patients medicated with acepromazine, low-dose dopamine may be ineffective at increasing RBF, because of dopaminergic receptor blockade.

The use of diuretics in the perioperative period is controversial. In a study of human patients, acute renal failure treated with diuretics such as mannitol and furosemide was not resolved.²⁷ In a dog model of uranyl nitrate-induced acute renal failure, a combination of furosemide and dopamine was effective in restoring RBF and creatinine clearance, whereas either drug alone was not.²⁸ In a more recent study, greater diuresis, natriuresis, and calciuresis and less kaliuresis occurred in normal dogs given a constant rate infusion of furosemide (0.66 mg/kg IV loading dose followed by 0.66 mg/kg/h) when compared with intermittent bolus administration.²⁹ Furosemide is used to promote diuresis in patients with pulmonary edema but should not be used when a patient is known to be hypovolemic. In hypovolemia, furosemide may increase nephrotoxicity of other drugs by increasing their contact time in the renal tubules.³⁰ Mannitol, an osmotic diuretic, can be given (0.25 to 0.5 g/kg slowly IV) to prevent pulmonary

edema or hyponatremia if the kidneys do not respond to fluid administration and the patient becomes volume overloaded.

Urethral Obstruction

Patients with urethral obstruction may become hyperkalemic, azotemic, acidotic, and hyperphosphatemic. Cats may also develop hyperglycemia, hypocalcemia, and hyponatremia. Hyponatremia is associated with leakage of urine into the peritoneal cavity.³¹ Any metabolic abnormalities should be evaluated and addressed prior to anesthesia, if possible. Hyperkalemia is the primary concern in most cases of urethral obstruction, and a pre-anesthetic electrocardiogram assessment is warranted. Treatment of hyperkalemia has been discussed in preceding paragraphs.

In small animals with urethral obstruction, fine-needle centesis of the urinary bladder may be performed prior to anesthesia, although bladder injury is a potential concern. Rupture of the urinary bladder during induction of anesthesia in a horse has been described.³² Perineal urethrostomy may be performed in stallions with urethral blockage by using standing restraint and epidural anesthesia. If general anesthesia is required while the bladder is distended, every attempt should be made to assist the horse into sternal or lateral recumbency during induction.

Anesthesia may be induced by using injectable or inhalation anesthetics. In many animals, distension of the urinary bladder is associated with increased heart rate. Cats that are chamber induced should not be induced with halothane due to its arrhythmic effects. Chamber induction with isoflurane or sevoflurane is preferred for small animals. Intravenous ketamine with a benzodiazepine has been used in obstructed cats even though active metabolites of the drug are excreted by the kidney. The rationale is that, once the obstruction is relieved, excretion of the anesthetic will proceed normally. However, cats with a long-term urethral obstruction may develop metabolic disturbances and renal insufficiency such that elimination of drugs is slowed even after the obstruction has been removed. Thus, if dissociative anesthesia is used, low doses of ketamine (1 to 2 mg/kg IV) can be used in combination with diazepam (0.2 mg/kg IV). With low doses, anesthetic action will be reduced after redistribution of the drug into body tissues. More commonly, injectable anesthetic induction in cats with renal disease is performed by administering propofol (2 to 5 mg/kg IV) or etomidate (1.0 mg/kg IV) slowly to effect.

Ruptured Urinary Bladder

Rupture of the urinary bladder is a surgical emergency. Animals may become hyperkalemic, hyponatremic, hypochloremic, and acidotic after urinary bladder rupture.³³ Intravenous fluids, such as 0.9% sodium chloride, should be given to aid in correcting electrolyte imbalances. Potassium enters the abdominal cavity from the ruptured bladder and is reabsorbed into the circulation, causing an increased serum potassium concentration. An electrocardiogram should be evaluated prior to induction of anesthesia to determine whether cardiac arrhythmias or evidence of hyperkalemia are present. Acute hyperkalemia (serum $[\text{K}^+] > 5.5$

mEq/L) should be treated prior to anesthesia. Anesthesia may be induced by face-mask administration of isoflurane or sevoflurane. Young foals (weighing < 200 kg) may be nasotracheally intubated while awake and then induced rapidly with an inhaled anesthetic. In larger foals, xylazine (1.1 mg/kg IV) or diazepam (0.1 mg/kg IV) in combination with ketamine (2.2 mg/kg IV) can be used for induction.³⁴ Isoflurane and sevoflurane are preferred over halothane because they possess less myocardial depressant action and potentiation of catecholamine-induced cardiac arrhythmias.³⁵ Administration of dextrose-containing solutions with or without insulin may be desired to counter hyperkalemia. Positive-pressure ventilation may be used to prevent anesthetic-associated hypercapnia and accompanying respiratory acidosis. Appropriate monitoring should be used, including end-tidal carbon dioxide, pulse oximetry, arterial blood-gas analysis, arterial blood pressure, and electrocardiogram assessment.

Hepatic Blood Supply

About 20% of cardiac output is continually being delivered to the liver. Of this, the hepatic artery supplies 30% of the blood flow and 90% of the oxygen, and the remainder is supplied by blood flowing through the portal vein. Anesthetics may affect hepatic blood flow by altering vascular tone in the hepatic artery, the portal vein, or both (Table 40.1). Methoxyflurane decreases both portal vein and hepatic arterial blood flow. Halothane decreases portal vein blood flow but has only a slight effect, if any, on hepatic arterial blood flow. Isoflurane decreases portal vein blood flow but increases hepatic artery blood flow with a net overall increase in flow. Nitrous oxide has no direct effect on liver perfusion. Sevoflurane and desflurane maintain hepatic artery and portal vein resistance and are associated with decreased portal vein and total hepatic blood flow.¹ Hypercarbia has also been associated with decreased hepatic perfusion during anesthesia. Decreased blood flow may occur in cirrhotic livers or patients with portocaval shunt syndrome. Detrimental effects of decreased blood flow are likely to be more significant when an animal is hypotensive. Significant decreases in blood flow may be associated with decreased hepatic extraction and, ultimately, elimination of drugs.²

Hepatic Insufficiency

Clinical signs of hepatic insufficiency include ascites, depression, seizures, jaundice, hepatic encephalopathy, anorexia, and weight loss. Horses with colic have an increased incidence of concurrent hepatic disease.³ Tests of substrate metabolism may give an indication of hepatic function. Low values for albumin, urea nitrogen, glucose, and cholesterol are associated with poor hepatic function. Coagulation defects such as prolonged prothrombin time, prolonged partial thromboplastin time, and in-

creased fibrinogen values may also indicate decreased hepatic function. Bilirubin is formed by metabolism of degraded hemoglobin by macrophages and carried by albumin to the liver for conjugation to a diglucuronide. In the horse, fasting for more than 24 h causes fatty acids to compete with bilirubin for hepatic metabolism. In this way, hyperbilirubinemia frequently causes icterus in anorexic horses. In dogs and cats, hyperbilirubinemia may be due to prehepatic, hepatic, or posthepatic causes.

Blood ammonia concentration and retention of dyes such as sulfobromophthalein (BSP) or indocyanine green (ICG) indicate liver dysfunction as evidenced by the liver's inability to eliminate these substances in a normal manner. The dyes, like bile acids, are more sensitive indicators of liver dysfunction than is a change in bilirubin concentration.⁴ Bile acids are produced by the liver and excreted in the bile. They undergo a process termed *enterohepatic circulation*. Following biliary excretion, bile acids are reabsorbed by the ileum and enter the portal circulation. Bile acids are then removed by the hepatocytes, leaving only a low concentration to enter the systemic circulation during normal circumstances. Fasting does not affect bile acid concentration. Normal fasting bile acid concentrations are below 5 mmol/L for cats, below 10 mmol/L for dogs, and below 15 mmol/L for horses.

Postprandial blood samples will demonstrate an elevation in bile acid concentration caused by gallbladder contraction. Within 2 h, as a result of gallbladder emptying, the liver can remove most of the bile acids presented to it. Thus, a marked increase in postprandial bile acid concentration indicates decreased hepatic function or the presence of a portocaval vascular shunt. Normal 2-h postprandial concentrations of bile acids are below 15 mmol/L in cats and below 25 mmol/L in dogs. Because horses lack a gallbladder, postprandial elevations in bile acid concentrations are not expected. Use of bile acid concentrations to aid in assessment of hepatic disease in horses is best when combined with other tests of hepatobiliary function.⁵ Tests of cell membrane integrity (i.e., alanine aminotransferase, γ -glutamyltransferase, sorbitol dehydrogenase, and lactate dehydrogenase) and serum alkaline phosphatase indicate hepatocellular damage but may not reflect altered hepatic function.

Pharmacological Considerations for Patients with Hepatic Disease

Tranquilizers/Sedatives

The use of acepromazine, droperidol, and α_2 -adrenergic agonists should be avoided in patients with moderate to severe liver dis-

Table 40.1. Effect of inhaled anesthetics on hepatic blood flow

Agent	Portal Vein	Hepatic Artery
Desflurane	Decrease	No change
Halothane	Decrease	Decrease or no change
Isoflurane	Decrease	Increase
Nitrous oxide	No direct effects	
Sevoflurane	Decrease	No change
Methoxyflurane	Decrease	Decrease

ease. Hypotension may occur after administration of phenothiazine (acepromazine) or butyrophenone (droperidol) tranquilizers because of peripheral vasodilation mediated by α -adrenergic blockade. Phenothiazine administration has also been associated with thrombocytopeny and may exacerbate coagulopathy associated with hepatopathy. Dysrhythmias such as bradycardia or atrioventricular block and alterations of plasma glucose concentration may occur after administration of xylazine or detomidine. Diazepam is generally considered safe when used in intravenous doses of less than 0.2 mg/kg because it causes minimal changes in cardiovascular function. However, in animals with severe liver dysfunction, the duration of action of benzodiazepines may be significantly prolonged because of decreased hepatic biotransformation. Diazepam may not consistently tranquilize healthy young animals but frequently produces tranquilization in animals with liver disease. When diazepam is administered intravenously, it should be injected slowly to decrease vessel irritation and prevent hypotension associated with the propylene-glycol carrier. Use of benzodiazepines in animals exhibiting signs of hepatic encephalopathy is controversial.

Opioids

These can be used in patients with liver disease. Morphine and meperidine can cause release of histamine, which may cause hypotension and a decrease in total hepatic blood flow. Morphine also constricts the sphincter of Oddi in people, yet the significance in obstructive biliary disease in animals is unknown. Opioid side effects should be treated if they appear to affect cardiac or respiratory function. Opioid-induced bradycardia may decrease cardiac output and should be prevented by administration of an anticholinergic agent. Respiratory depression from opioids may lead to decreased oxygen delivery to all body tissues, including the liver. Careful dose titration of the opioid antagonist naloxone can relieve depression of respiration while maintaining some of the analgesic and sedative effects of the opioid agonist. Butorphanol and buprenorphine are associated with less respiratory depression than other opioid agonists and may be reasonable choices for patients with hepatic disease when maximal opioid analgesia is not required. Fentanyl, delivered by continuous-rate intravenous infusion, enables rapid individual patient dose titration and is an effective and reasonably safe method for providing opioid analgesia to patients when liver function is unknown.

Thiobarbiturates

These should be used in low doses or their use avoided in patients with liver disease. A single, intubating dose of thiobarbiturate is not necessarily contraindicated because it will be redistributed from the brain to less well perfused tissues, terminating the anesthetic effect. However, liver disease may affect the duration and depth of thiobarbiturate-induced anesthesia because of increased sensitivity of the central nervous system or hypoalbuminemia and decreased protein binding of the anesthetic. Anesthesia should not be maintained by redosing thiobarbiturates in patients with liver disease.

Methohexital is a methylated oxybarbiturate, and although it is more rapidly metabolized than thiobarbiturates, it is associated with excitation and possible seizures during the recovery period. For this reason, methohexital should be avoided in patients with hepatic encephalopathy.

Propofol and Etomidate

Propofol is an alkylphenolic compound used for induction of anesthesia that is supplied in a lecithin emulsion, giving it a milky white appearance. Redistribution and metabolism of propofol after a single injection are extremely rapid. The total body clearance of propofol exceeds hepatic blood flow, indicating sites other than the liver (e.g., lung) may play a role in its elimination. Propofol is about 90% excreted by the kidneys as glucuronate-conjugated metabolites.⁶ Because of its dependence on glucuronidation for biotransformation, cats appear to have a more prolonged duration of propofol-induced sedation and hypnosis compared with dogs, especially following large or repeated doses. Indications for use of propofol are similar to those for the thiobarbiturates. The major advantage of propofol over a thiobarbiturate is the rapid rate of propofol elimination. In dogs, the incidence of apnea immediately after injection seems to be greater than that associated with thiobarbiturates.

Etomidate is an imidazole compound used for induction of anesthesia. It is supplied as a weak base in a propylene-glycol vehicle. As with other drugs formulated with propylene glycol, it can be irritating when injected intravenously.⁷ Etomidate does not decrease hepatic perfusion. It has a short duration of action, primarily because of rapid redistribution from the brain to muscle tissue. Etomidate is metabolized by the hepatic microsomal enzyme system, as well as by plasma esterases. The total body clearance rate for etomidate is five times as fast as for thiopental, although clinically the duration of action is similar after a single dose.⁴ Etomidate has been shown to cause adrenocortical suppression with repeated administration.⁸ The importance of etomidate-associated inhibition of steroidogenesis after single-bolus administration in patients with hepatic disease is unknown. In both humans and dogs, etomidate continuous-rate intravenous infusion has been associated with hemolysis.^{9,10} Hemolysis appears to be caused by the propylene-glycol vehicle in which etomidate is formulated. In dogs, red blood cell counts during and 10 min after termination of a 60-min infusion of etomidate were not significantly different from preinfusion values.¹⁰ All dogs in the aforementioned study appeared normal after recovery from anesthesia maintained with etomidate. Thus, the clinical signifi-

cance of etomidate-induced or propylene-glycol-induced hemolysis in dogs is not clear. Etomidate appears to be a reasonable drug choice for induction of anesthesia in patients with cardiac and/or hepatic disease.

Dissociative Anesthetics

Dissociative anesthetics such as tiletamine (Telazol) or ketamine are generally acceptable for induction of anesthesia in patients with hepatic disease. Intravenous administration is preferred in order to minimize the dose required for tracheal intubation. In dogs, these drugs are largely metabolized by the liver, so maintenance of anesthesia should be with an inhalant. Dissociative anesthetics may induce seizures in dogs or cats. In cats, ketamine is metabolized to a lesser extent by the liver to form norketamine, which has about 10% of the activity of ketamine.

Zolazepam, the benzodiazepine tranquilizer in Telazol, has been suspected of causing the prolonged recovery after intramuscular injection in cats. Flumazenil has been used intravenously (0.1 mg/kg) to antagonize midazolam in cats anesthetized with a combination of ketamine and midazolam.¹¹ Zolazepam's effect in cats is similarly antagonized by flumazenil, providing an alternative to the apparently slow hepatic metabolism of the benzodiazepines in this species.

Inhalation Anesthetics

Inhalation anesthetics are the best choices for maintenance of anesthesia in patients with severe liver disease. Halothane decreases hepatic blood flow and is metabolized up to 20% by the liver.¹² Halothane anesthesia in ponies is associated with decreased bile acid excretion and increased conjugated bilirubin excretion.¹³ It is recommended that halothane be avoided, if possible, in patients with liver disease. However, the presence of hepatic disease does not necessarily result in increased hepatotoxicity when a patient is subsequently exposed to an unpredictable hepatotoxin such as halothane.¹⁴ Halothane has been implicated in causing liver disease in people and possibly in animals. This is a problem in about one of every 6000 to 10,000 people and is probably genetically related.^{15,16} Halothane is metabolized to trichloroacetic acid, which may undergo reductive metabolism to produce hepatotoxins during hypoxic conditions. Studies indicate that the trifluoroacetate metabolite of halothane combines with a hepatic protein, resulting in the formation of a hapten.¹⁷⁻¹⁹ The trifluoroacetate hapten is subsequently attacked by serum antibodies, causing hepatitis. A clinical test for this hapten is not yet available for animals. In a study of goats hyperimmunized for production of anti-human-lymphocyte serum that were subsequently exposed to 3, 6, or 9 h of halothane anesthesia, seven (24%) of 29 showed evidence of hepatic necrosis.²⁰ A rat model of halothane-induced hepatopathy showed that hepatic hypoxia was required to produce symptoms.²¹ To ensure adequate blood pressure, flow, and oxygen delivery during anesthesia, precautions should be taken when using halothane (or any other anesthetic!). In preventing the occurrence of postanesthetic hepatopathy, prevention of hepatic hypoxia during inhalation anesthesia is probably more important than choice of anesthetic.

Methoxyflurane decreases hepatic blood flow, and up to 50%

of an inhaled dose is metabolized by the liver.²² In addition, oxalate and free fluoride-ion metabolites of methoxyflurane are potential renal toxins. Of the volatile anesthetics, methoxyflurane is associated with the highest metabolite production of fluoride ion.

Isoflurane increases hepatic artery blood flow in humans, whereas halothane preserves hepatic arterial flow at 1 MAC but decreases it at 2 MAC.²³ Less than 1% of inhaled isoflurane is metabolized. It has not been associated with hepatic or renal toxicity.²⁴ Cardiovascular function during isoflurane anesthesia is less depressed than with halothane or methoxyflurane. The higher cardiac output associated with isoflurane anesthesia is likely to maintain better hepatic perfusion and oxygen delivery than is halothane. Thus, isoflurane appears to be a good choice for maintenance of anesthesia in patients with hepatic disease.

Biotransformation of sevoflurane (3% to 5%) is less than halothane but more than isoflurane or desflurane.²⁵ Production of the trifluoroacetic acid hapten is extremely low and unlikely to induce an immune response such as the well-documented halothane hepatopathy. Free fluoride-ion production after exposure to sevoflurane is comparable to that from desflurane.²⁵ Sevoflurane reduces portal vein flow and oxygen delivery more than isoflurane. Hepatic artery flow increases in pigs concurrently receiving nitrous oxide and sevoflurane. Other studies have shown no change in hepatic artery flow associated with clinically useful concentrations of sevoflurane. Animal models therefore demonstrate that sevoflurane maintains good hepatic blood flow and liver oxygenation when administered at concentrations less than 2 MAC.²⁵

The effects of desflurane on hepatic blood flow are similar to those of halothane (Table 40.1). Desflurane differs from isoflurane structurally only by substitution of a fluorine atom for a chlorine atom. The substitution of a fluorine atom for other halogens generally makes a molecule more stable in terms of biotransformation. Indeed, desflurane metabolism to free fluoride ion is less than that of isoflurane.²⁶ Because of its low metabolism, low blood solubility (enabling rapid induction and recovery from anesthesia), and cardiovascular stability (maintaining hepatic perfusion), desflurane would appear to be a good anesthetic for patients with hepatic disease.

Nitrous oxide has been used in patients with hepatic disease in an effort to decrease the amount of volatile anesthetic required for anesthesia. There are no reports of direct hepatic injury caused by exposure to nitrous oxide as used in clinical practice. There is evidence of hepatic injury (centrilobular necrosis) caused by nitrous oxide in the hypoxic rat model.²⁷ It is unknown whether this mechanism of hepatic injury in hypoxic rats is the same as for halothane.

Muscle Relaxants

Nondepolarizing muscle relaxants such as pancuronium and vecuronium are metabolized by the liver. Effects of these relaxants may be prolonged in patients with hepatic disease. Concurrent administration of aminoglycoside antibiotics with nondepolarizing muscle relaxants may also prolong neuromuscular blockade.²⁸ This is likely to be a problem in large animals such as horses, for which prolonged recumbency may adversely affect

recovery to standing. Atracurium is a nondepolarizing muscle relaxant whose metabolism is independent of hepatic function. Atracurium undergoes plasma degradation via a metabolic pathway termed *Hofmann elimination* that depends primarily on plasma pH and temperature.²⁹ For patients with hepatic disease requiring neuromuscular blockade, atracurium seems to be a good choice.

Succinylcholine is a depolarizing muscle relaxant that is degraded by plasma cholinesterase. Cholinesterases are produced by the liver. Organophosphate compounds have cholinesterase-inhibiting activity and may potentiate the action of succinylcholine.³⁰ The phenothiazine tranquilizers (e.g., acepromazine) may inhibit cholinesterase activity, so succinylcholine should be used cautiously in patients medicated with acepromazine. The use of both acepromazine and succinylcholine should be avoided in patients with hepatic disease.

Centrally acting muscle relaxants such as guaifenesin (glyceryl guaiacolate) or mephenesin are metabolized by the liver.^{31,32} Although the margin of safety for use of guaifenesin is wide, side effects following administration of large doses include moderate hypotension, decreased tidal volume, and concentration-dependent hemolysis. Toxic effects may be caused by the metabolite catechol, which causes seizures, opisthotonos, prolonged incoordination, and respiratory paralysis. Increased incidence in side effects or occurrence of toxic effects may be observed when guaifenesin is administered to animals with hepatic disease.

General Guidelines for Patients with Hepatic Disease

Hepatic disease affects several vital body functions, with significant impact on anesthetic considerations (Table 40.2). Most injectable anesthetics are metabolized by the liver, so elimination may be significantly slowed in animals that are hypothermic. Use of heated circulating water blankets and administration of warm intravenous or irrigation fluids is advised. The advent of force air-warming systems (e.g., Bair Hugger) has dramatically reduced intraoperative and postoperative hypothermia.

Glucose metabolism is frequently affected by hepatic disease. Homeostasis of glucose can be maintained with loss of up to 80% of functional liver mass. Nevertheless, patients with severe hepatic disease that are stressed by anesthesia and surgery may become hypoglycemic. Hypoglycemia is present in 35% of dogs with portocaval shunts.³³ For this reason, blood glucose concentration is routinely determined and glucose administered in combination with isotonic crystalloids when indicated. If not corrected, hypoglycemia may delay recovery from anesthesia.

Excessive weight of ascitic fluid may impede lung expansion and pulmonary function. Ascitic fluid should be removed prior to anesthesia. Rapid removal of a large quantity of fluid may cause a fluid shift from the vascular space to the abdominal cavity as the formation of ascites continues. This can cause serious hypovolemia and cardiovascular compromise. Hypoalbuminemia is often present in patients with liver disease. When the albumin concentration is less than 1.5 g/dL, the plasma oncotic pressure is decreased such that pulmonary edema may occur following in-

Table 40.2. General guidelines for patients with hepatic disease

Evaluate coagulation profile prior to surgery
Use rapidly eliminated agents when appropriate (e.g., inhalant anesthetics and propofol)
Monitor hydration status
Monitor blood glucose, plasma albumin, and total protein concentrations
Monitor and maintain arterial blood pressure greater than 60 mmHg
Maintain eucapnia using appropriate ventilatory support
Be prepared to treat seizures with diazepam
Be aware of potential thromboembolic complications

travenous fluid administration with crystalloids. Arterial blood pressure may be difficult to maintain when plasma oncotic pressure is significantly decreased. Replacement of albumin and plasma proteins is indicated in these cases. If matched plasma from a donor animal is not available, dextran 70 (up to 20 mL/kg) or Hetastarch (10 to 20 mL/kg) may be administered. Although dextran will aid in reestablishing plasma oncotic pressure, its duration of effect is not as great as that of plasma. Human albumin solution (2.5 to 5.0 mL/kg intravenously) has been used in dogs and cats, as well.

Seizures caused by hepatic encephalopathy may require treatment. Diazepam or phenobarbital is commonly used to control seizures, but both drugs are metabolized by the liver, and significantly altered pharmacokinetics may result in prolonged duration of action. Avoid the use of anesthetics that may induce seizure activity, such as enflurane, ketamine, tiletamine (Telazol), or methohexital. There may be increased cerebral sensitivity to γ -aminobutyric acid (GABA) in some patients with hepatic disease. This increased sensitivity to GABAergic inhibition within the central nervous system may enhance the depressant effects of the barbiturates and benzodiazepine tranquilizers.

When there is concern about an animal's ability to metabolize anesthetics because of hepatic disease, use of local anesthesia may be considered as an adjunct to general anesthesia or as a substitute when appropriate. Although animals that are not depressed usually require tranquilization for effective use of local anesthesia, those with hepatic disease are likely to be depressed and therefore may require less tranquilization or sedation. Local anesthetics of the ester class (e.g., procaine and tetracaine) are metabolized by plasma cholinesterases produced by the liver, whereas the amide class (lidocaine, mepivacaine, and bupivacaine) is directly metabolized by the liver. For this reason, the generalized effects of local anesthetics may be prolonged and the toxic effects more apparent in patients with severe hepatic disease. This is unlikely to be a major deterrent for their clinical use, however.

Because of the liver's role in production of coagulation factors, the coagulation profile (one-stage prothrombin time and activated partial thromboplastin time) should be evaluated before surgery in patients with hepatic disease. If coagulopathy exists, fresh-frozen plasma or whole blood should be available and administered. Additionally, some hepatic neoplasms are associated

with significant abdominal hemorrhage and thrombocytopenia. A complete blood count with an estimate of the platelet concentration should be performed as part of the diagnostic workup.

Little is known about the influence of specific anesthetic techniques on coagulation in animals. In dogs, platelet aggregation was significantly decreased after administration of acepromazine and atropine but returned to normal during subsequent halothane anesthesia and surgery.³⁴ Coagulation deficiencies such as thrombocytopenia, thrombocytopeny, increased prothrombin time, increased activated partial thromboplastin time, hypofibrinogenemia, increased fibrin degradation products, and decreased antithrombin have been observed in dogs with gastric dilation–volvulus.³⁵ In dogs undergoing colonic anastomosis, there was less intraoperative bleeding and more advanced healing (detected histologically) 1 and 7 days after surgery following administration of epidural bupivacaine and general anesthesia when compared with general anesthesia alone.³⁶ Much work remains to be done to identify anesthetic techniques having the least effect on normal coagulation and healing during the convalescent period.

Portosystemic Shunt

Dogs with this congenital vascular anomaly are usually gaunt and small for their breed and age. Anesthetic management of dogs with portocaval shunt should be based on presenting clinical signs and physical status (Table 40.3). Signs of hepatic encephalopathy and hypokalemia may be present. Hypokalemia in animals with portocaval shunt may be caused by gastrointestinal (vomiting and diarrhea) or urinary loss (diuresis). Hypokalemia ($[K^+] < 3.5$ mEq/L) should be corrected gradually prior to anesthesia. Intravenous potassium administration should not exceed the rate of $0.5 \text{ mEq} \cdot \text{kg}^{-1} \cdot \text{h}^{-1}$.

Chronic hepatic dysfunction may be associated with increased GABAergic sensitivity and permeability of the blood-brain barrier. The effect of anesthetics and anesthetic adjuncts may be greater than expected and unpredictable. Diazepam has been used as a preanesthetic medication in dogs with portocaval shunt. However, reduced dosage requirements for benzodiazepines in cases of hepatic disease have been reported.^{37,38} Further, cases of fatal hepatic toxicosis associated with benzodiazepine administration have been observed in cats. Antagonists of the benzodiazepine receptor, such as flumazenil, have ameliorated signs of encephalopathy in a woman and in animal models of portocaval shunt.^{37–39} The value of flumazenil in the perioperative management of dogs with portocaval shunt is controversial and remains to be determined.

Animals with portocaval shunt may have hepatic insufficiency. When termination of action is highly dependent on drug hepatic metabolism (e.g., ketamine, acepromazine, xylazine, and diazepam), the use of such drugs should be avoided. Drugs that are highly protein bound (e.g., barbiturates) will be more active in animals with hypoalbuminemia. Drugs such as methohexital and ketamine that may induce seizure activity are contraindicated in animals with hepatic encephalopathy. Of the inhaled anesthetics, methoxyflurane undergoes the greatest metabolism by the liver. Thus, elimination of methoxyflurane may be prolonged in ani-

Table 40.3. Problems associated with portocaval shunt

Problem	Significance
Weight loss	May affect drug dose or disposition
Hypoalbuminemia	May affect drug dose, disposition, or plasma oncotic pressure
Hepatic shunt	Loss of hepatic metabolism of drugs
Low bile salts	Increase in absorption of intestinal endotoxin
Portal hypertension	May require second surgery and central venous pressure monitoring

mals with portocaval shunt. The use of halothane may cause hepatopathy in animals with poor hepatic perfusion and oxygenation, and therefore should be avoided in patients with portocaval shunt. Isoflurane, sevoflurane, or desflurane are suitable anesthetics for patients with this condition. Mask induction and maintenance with an inhalant are reasonable for animals with portosystemic shunts displaying advanced signs of hepatic dysfunction. Opioids may be used as analgesic supplements prior to or following anesthesia for surgical correction of the shunt.

Arterial blood pressure should be monitored during portocaval shunt surgery. Hypoalbuminemia and hypothermia predispose patients to hypotension that may be exacerbated by isoflurane-induced peripheral vasodilation. Judicious use of plasma, dextran 70 (10 to 20 mL/kg given over 1 h) or hetastarch to aid in maintenance of plasma oncotic pressure may be indicated. At high concentrations of isoflurane, myocardial contractility and cardiac output are also decreased. Hypotensive patients with portocaval shunt may fail to respond to catecholamine infusions such as dobutamine or dopamine. Surgical retraction of the liver or compression of the caudal vena cava may further decrease venous return, cardiac output, and arterial blood pressure.

Intraoperative management of patients for correction of portocaval shunt is often uneventful until the shunt is ligated. In normal dogs, portal pressure is reported to be between 8 and 13 cm H₂O, whereas portal pressure in dogs with portocaval shunt is usually lower.⁴⁰ Following surgical correction of the shunt, portal venous pressure should not be more than 9 to 10 cm H₂O above baseline measurement, or a maximum of 20 to 23 cm H₂O. Intraoperative measurement of central venous pressure is useful for estimating portal resistance and for predicting the development of postoperative portal hypertension.⁴¹ A decrease in central venous pressure after ligation of a single portocaval shunt indicates decreased blood transit from the intestine to the vena cava. Central venous pressure should not decrease by more than 1 cm H₂O from baseline measurement at 3 min after ligation to avoid postoperative portal hypertension.⁴²

Animals with portocaval shunts or intestinal ischemia may have increased absorption of endotoxin. Medical management of these patients includes fluid administration (e.g., 0.9% or 0.45% sodium chloride combined with 2.5% dextrose), potassium supplementation, dietary management, and appropriate antibiotic therapy to reduce toxin production from enteric bacteria.⁴³

Conditions Associated with the Oral Cavity and Pharynx

Animals with trauma or space-occupying masses of the head and neck frequently require general anesthesia. These patients are often difficult to intubate to secure and maintain a patent airway. Fractures of the mandible, maxilla, or temporomandibular joint may not permit examination to determine the range of jaw motion. Masticatory myositis may prevent opening of the mouth even while the patient is anesthetized. General anesthesia without a secure airway may result in aspiration, which can be fatal. Anesthetic management of these conditions should be initiated by preparing for placement of a tracheostomy tube. In dogs, a combination of intramuscular (IM) acepromazine (0.05 mg/kg) and intravenous (IV) hydromorphone (0.2 mg/kg) will induce a neuroleptanalgesic state with sufficient muscle relaxation to enable examination of the mouth and jaw. If the animal's laryngeal function or its ability to open its mouth is questionable, IV fentanyl (0.005 mg/kg) should be substituted for hydromorphone because there is a small, but real, risk of vomiting associated with hydromorphone administration. Owing to opioid-induced bradycardia, premedication with an anticholinergic agent is recommended. In dogs weighing over 18 kg, a maximum dose of 4 mg of hydromorphone is suggested to prevent excessive respiratory depression. In cats, a low dose of ketamine (4 mg/kg IM) combined with acepromazine (0.05 mg/kg) usually enables examination of the oral cavity.

IM or subcutaneous (SC) administration of xylazine in dogs or cats may cause emesis (Table 41.1). Dogs and cats with oral or pharyngeal masses are at high risk for aspiration pneumonia, so the use of xylazine, medetomidine, morphine, and other drugs that commonly induce emesis should be avoided. Xylazine administration in large animals is not associated with emesis and may be used to sedate horses (0.5 to 1.0 mg/kg IV) or cattle (0.1 mg/kg IM) for oral examination.

Removal of Esophageal Foreign Bodies

General anesthesia may be required for removal of esophageal foreign bodies in a variety of species. In a horse that has a foreign object lodged in the esophagus (i.e., choke), passage of a nasogastric tube or endoscope is facilitated by sedation with xylazine (0.5 mg/kg) or detomidine (10 to 20 µg/kg). If the foreign body cannot be retrieved or dislodged, the horse is anesthetized. Relaxation of the striated muscular coat of the esophagus may aid in removal of the obstruction. Skeletal muscle relaxation is enhanced at deeper planes of anesthesia. Muscle relaxation may also be improved by induction of anesthesia with guaifenesin (5% solution in 5% dextrose combined with 0.3% thiopental given to effect) or by administration of a neuromuscular blocker. In horses and cats, the proximal two-thirds of the esophagus has a striated muscle layer, whereas in dogs, the entire esophagus contains striated muscle.¹ General anesthesia is required for endoscopic foreign-body removal in dogs and cats. In anesthetized dogs and horses, skeletal muscle relaxation of the esophagus may be improved with a short-acting muscle relaxant (e.g., atracurium, 0.2 mg/kg IV). Administration of atracurium must be accompanied by tracheal intubation and support of ventilation. In some species, esophageal stricture can be a sequelae to esophageal foreign bodies. These patients require general anesthesia in order to perform balloon dilation or bougienage.

Anesthesia for Dogs with Gastric Dilation-Volvulus

It has been estimated that there are between 40,000 and 60,000 cases of canine gastric dilation-volvulus per year in the United States.² The condition is associated with multiple system problems (Table 41.2) resulting in a high mortality rate (40% to 60%).² Stomach distention severely restricts ventilation and decreases cardiac function. Metabolic alkalosis may develop from gastric sequestration of hydrogen ions. Later in the course of the disease, metabolic acidosis may occur from decreased cardiac output and poor ventilation, resulting in tissue hypoxia and lactate production. Consequently, cardiac arrhythmias such as sinus tachycardia, atrial fibrillation, ventricular tachycardia, or ventricular premature contractions are frequently observed. Because the metabolic status is difficult to predict, it is suggested that serum electrolytes, blood pH, and plasma bicarbonate concentration be measured prior to anesthesia. In one study, hypokalemia was

Table 41.1. Gastrointestinal effects of drugs used during anesthesia.

Drug	Effect
Acepromazine	Antiemetic
Atropine	Decreased motility
Cholinesterase inhibitors	Increased motility
Detomidine	Decreased motility
Diazepam	Appetite stimulant
Halothane	Decreased mucosal blood flow
Morphine	Emetic and gastrointestinal stimulant
Xylazine	Decreased motility; emetic

present in 33% of the dogs with gastric dilation-volvulus.³ Electrolyte abnormalities, acid-base imbalance, and gastric distension should be corrected as soon as possible. The derangements in acid-base balance frequently precipitate shock if left untreated. Restoration of circulating plasma volume should be initiated using high doses of isotonic saline solution (90 mL/kg IV) or hypertonic saline solution (7%, 4 mL/kg IV). In dogs with experimentally induced gastric dilation-volvulus and shock, a combination of 7% hypertonic saline in 6% dextran 70 (5 mL/kg IV) was superior to isotonic saline (60 mL/kg IV) for resuscitation.⁴ It is suggested that fluids be administered through one or two large-bore IV catheters.

Cardiac arrhythmias should be identified and treated prior to induction of anesthesia. In many cases, cardiac arrhythmias may not require antiarrhythmic agents and may respond to fluid therapy and correction of acid-base and/or electrolyte abnormalities. If antiarrhythmic therapy is necessary, lidocaine (2 to 4 mg/kg slow IV bolus followed by 25 to 100 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) and procainamide (0.5 to 2.0 mg/kg IV, and then 20 to 40 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$) separately or in combination have been used for treating premature ventricular contractions or ventricular tachycardia. Quinidine (6 to 8 mg/kg IM, every 6 h) has also been recommended for treatment of arrhythmias in dogs with gastric dilation-volvulus. Postoperative treatment of cardiac arrhythmias may also be necessary. A continuous lidocaine infusion may be prepared by adding 25 mL of 2% lidocaine to each 500 mL of IV fluid administered at a rate of 50 to 100 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$.

Administration of oxygen via face mask should begin before induction of anesthesia. The use of large doses of arrhythmogenic anesthetic agents such as thiobarbiturates or halothane should be avoided. The use of α_2 -agonists should be avoided in these cases because they may cause aerophagia and depressed cardiac output.⁵ In addition, xylazine causes decreased gastroesophageal sphincter pressure and may allow increased gastric reflux.⁶ α_2 -Agonists decrease intestinal motility in dogs and may prolong recovery of normal gastrointestinal function following correction of gastric distension.⁷ Neuroleptanalgesic combinations such as diazepam (0.2 mg/kg IV) and hydromorphone (0.1 mg/kg IV) are good choices for induction of anesthesia in dogs with unstable cardiovascular function. Opioids may decrease intestinal motility, but this effect is usually of minor clinical significance.⁸ Propofol or diazepam-ketamine has also been suggested

Table 41.2. Problems associated with gastric dilation-volvulus.

Problem	Significance
Acidosis/alkalosis	Measure pH
Cardiac arrhythmias	Attempt correction prior to anesthesia
Gastric necrosis	May cause arrhythmias
Hypokalemia/hyperkalemia	Measure K ⁺
Impaired venous return	Correct by decompressing stomach
Respiratory impairment	Treat shock
Peritonitis	Correct by decompressing stomach
Shock	Ventilate
	Begin antibiotics; poor prognosis
	Correct underlying problems

as a good choice for induction of anesthesia. For maintenance of anesthesia, isoflurane or sevoflurane would be excellent inhalants. Nitrous oxide is contraindicated prior to gastric decompression because it will equilibrate with gas in the stomach, increasing the intragastric volume and pressure.

Succinylcholine initially causes contraction of skeletal muscle. The distended stomach is predisposed to rupture if succinylcholine is administered prior to relief of excessive gastric pressure. If a neuromuscular blocking agent is used in the anesthetic management of gastric dilation-volvulus, it should be a nondepolarizing drug such as pancuronium or atracurium.

Of the dogs that die of gastric dilation-volvulus, 50% die on the day of surgery.⁹ Death is usually associated with septic shock or peritonitis secondary to gastric necrosis or perforation.¹⁰ Reperfusion injury has also been implicated as a factor associated with the high mortality from this condition.¹¹ Iron-chelating drugs such as deferoxamine have been evaluated for their ability to decrease injury in anoxic tissues that are subsequently reperfused.

Anesthetic Management of Horses with Acute Abdominal Distress

Acute abdominal distress in horses is often characterized by severe pain. Pain elicits a variety of responses that include release of catecholamines and corticosteroids.¹² The stress response and sympathetic stimulation resulting from pain are detrimental to an animal's well-being. It is often difficult to perform diagnostic procedures or examine a horse in severe pain. Judicious use of analgesics in horses with acute abdominal distress is essential.

Because of their strong analgesic and sedative effects, the α_2 -agonists have been used extensively in horses with acute abdominal pain. Depending on the amount of xylazine, detomidine, or romifidine administered in the preoperative period, the induction dose of anesthetic may need to be decreased. Cardiovascular depression associated with α_2 -agonists will often persist longer than either sedation or analgesia. Even though the sedative effects of these drugs may have waned, the anesthetic requirement will be decreased. At a comparable dose, detomidine is more po-

tent than xylazine and has a longer analgesic and sedative action.^{13–15} High doses of detomidine (i.e., 0.02 mg/kg IV) decrease cardiac output by 50%.¹⁶ The duration of cardiovascular side effects may limit the use of detomidine and romifidine as premedicants for horses undergoing surgery to correct intestinal problems.

Xylazine is a suitable alternative to detomidine in compromised horses. However, the usual 1.1 mg/kg IV dose of xylazine is often decreased to prevent excessive cardiovascular depression. Xylazine prolongs gastrointestinal transit time in a variety of species.¹⁷ In horses, xylazine (0.55 mg/kg IV) has been shown to decrease the motility index of circular and longitudinal muscle layers for 30 min.¹⁸ In ponies, xylazine (1.1 mg/kg IV) increased intestinal vascular resistance, motility, and oxygen consumption.¹⁹ In a study of cecal and right ventral colon myoelectric activity in ponies, xylazine (0.5 mg/kg IV) and/or butorphanol (0.04 mg/kg IV) resulted in decreased coordinated spike bursts for 20 min or longer.²⁰ It should be appreciated that the results of these studies were derived from horses or ponies with healthy gastrointestinal function. Clinically, it appears that these effects are rarely a disadvantage to using xylazine for preanesthetic medication in horses with colic. Furthermore, a study comparing myoelectric activity in equine intestine following three anesthetic regimens found no prolonged effect associated with (a) xylazine and ketamine, (b) thiopental and halothane, or (c) thiopental in guaifenesin and halothane.²¹ The conclusion was that the particular regimen of general anesthesia is relatively unimportant in the development of motility disturbances in horses after anesthesia.

Excessive cardiovascular depression is avoided in compromised patients by decreasing the preanesthetic dose of xylazine (0.1 to 0.5 mg/kg IV) and the subsequent administration of diazepam (0.02 to 0.04 mg/kg IV) or guaifenesin (55 to 80 mg/kg IV) when inducing anesthesia with ketamine (1 to 2 mg/kg IV). Induction may be accomplished with ketamine as a bolus or in combination with guaifenesin (1 to 2 g ketamine/1 L 5% guaifenesin). An alternative induction regimen is to combine thiopental (2 to 4 mg/kg) with guaifenesin, given to effect. Induction of anesthesia when using thiopental and guaifenesin does not depend on preanesthetic heavy sedation and muscle relaxation to prevent rigidity or excitement as does induction with ketamine.

Anesthesia may be maintained with either halothane or isoflurane (1.5% to 2.5%) in oxygen. Halothane has been associated with a 62% decrease in intestinal blood flow in ponies anesthetized at 1 minimal alveolar concentration (MAC).²² However, clinically significant deleterious effects of halothane on recovery from colic surgery have not been demonstrated. Horses anesthetized with isoflurane have higher cardiac outputs than horses anesthetized with a similar MAC of halothane.²³ Isoflurane anesthesia in horses undergoing surgery for colic is associated with a higher heart rate and lower arterial CO₂ concentration as compared with halothane.²⁴ Horses anesthetized with isoflurane recover more rapidly than those anesthetized with halothane.^{24,25} Thus, there are several advantages to using isoflurane over halothane for horses undergoing surgery for colic.

Damaged intestinal tissue may release toxins into the systemic circulation, which can lead to cardiovascular dysfunction and de-

creased tissue perfusion. Release of eicosanoids (leukotrienes, prostacyclins, prostaglandins, and thromboxanes) has been associated with colonic volvulus in ponies.²⁶ Administration of flunixin meglumine may counteract the deleterious effects of toxins released during abdominal surgery. In addition, generation of free radicals in the equine intestine following anoxia and subsequent reoxygenation has been demonstrated *in vitro*.²⁷ Such studies may be the basis for the empirical intraoperative treatment of certain cases of equine colic with free-radical quenchers such as dimethylsulfoxide (DMSO).

Opioid agonists such as oxymorphone, morphine, and meperidine can be safely used in horses experiencing pain.²⁸ These drugs frequently induce undesirable excitement in horses that are pain free, unless preceded with a suitable sedative or tranquilizer (e.g., xylazine or acepromazine). Use of an opioid agonist-antagonist such as butorphanol may be advantageous because this drug provides analgesia but has a “ceiling” on respiratory depression.²⁹ However, numerous other pain medications also are suitable for use in horses, including nonsteroidal anti-inflammatory drugs, local anesthetic agents, and α_2 -adrenoceptor agonists.³⁰

In addition to pain control, support of the respiratory and cardiovascular systems is paramount in managing anesthesia for colic surgery. The bulk and weight of the gastrointestinal tract filled with ingesta and/or gas impair venous return to the heart and consequently decrease cardiac output. Diaphragmatic excursion and pulmonary function are impaired by a full stomach during anesthesia. These effects decrease tissue perfusion and oxygenation, creating metabolic acidosis and complicating the anesthetic management of horses. Evaluation of acid-base status will aid in determining adequacy of ventilation. Respiratory acidosis (pH < 7.2) can be avoided by use of controlled ventilation. Aggressive fluid therapy with lactated Ringer's solution will aid in correcting mild to moderate metabolic acidosis if normovolemia is reestablished.³¹ It is not uncommon for a horse to require 30 L or more of isotonic IV fluids during colic surgery.

Monitoring arterial blood pressure is recommended in all species to provide some indirect information concerning cardiac output and tissue perfusion. Low tissue perfusion has been implicated in the occurrence of postanesthetic myositis.³² Maintenance of a mean arterial blood pressure above 70 mm Hg may be achieved by fluid administration, by adjusting anesthetic depth, and by careful infusion of dobutamine (3 to 5 $\mu\text{g} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ IV) or another sympathomimetic drug. Improved cardiac output will result when IV fluids are administered to hemoconcentrated patients. A decreased packed cell volume will decrease blood viscosity and improve cardiac output. Hypertonic saline (7% at 4 mL/kg IV) has been recommended for use in hypovolemic horses to expand plasma volume rapidly.³³ One advantage of hypertonic saline administration over isotonic crystalloid solutions is that a small volume is required. Correction of an extracellular volume deficit via administration of a small volume of hypertonic saline is accomplished more rapidly than with the administration of a large volume of isotonic fluid. However, the beneficial effects of hypertonic saline administration are short-lived and should be preserved with subsequent isotonic crystalloid therapy during anesthesia.

Cardiac arrhythmias may occur during anesthesia for surgical correction of an intestinal disorder. Bradycardia caused by increased vagal tone elicited from intestinal manipulation has been observed. Anticholinergic agents are occasionally used in horses for treatment of vagally induced bradycardia. However, high doses of these drugs may decrease gastrointestinal motility for up to 12 h in horses.³⁴ Horses treated with anticholinergics are more likely to develop postanesthetic colic if they have been fed within 4 to 6 h of anesthesia.³⁵ Perhaps a more important concern during anesthesia is the effect of atropine administration on cardiac arrhythmogenicity. Administration of atropine to halothane-anesthetized horses was associated with an increased incidence of tachycardia after administration of epinephrine or dobutamine.^{36,37} However, horses given low doses of atropine in combination with detomidine, guaifenesin, diazepam, ketamine, and halothane anesthesia were not predisposed to adverse cardiovascular effects when dobutamine was administered for control of arterial blood pressure.³⁸

Displaced Abomasum

This is a frequent problem in adult dairy cattle and occasionally in other ruminants such as llamas. In adult cattle, a standing laparotomy is the standard surgical approach. Regional anesthesia for standing laparotomy may be accomplished by a number of techniques, including the distal paravertebral block, the proximal paravertebral block, and the line block. For small ruminants such as goats, sheep, or llamas, general anesthesia will provide a more immobilized patient on which to perform surgery.

Particular anesthetic concerns for animals with displaced abomasum include disturbances in acid-base balance and electrolyte abnormalities. Similar to the pathogenesis of gastric dilation-volvulus in dogs, displaced abomasum in ruminants may initially present with metabolic alkalosis caused by abomasal sequestration of hydrogen chloride. Hypokalemia is a common concurrent finding because potassium is excreted by the kidneys in an attempt to retain hydrogen ions in response to metabolic alkalosis. As the disease progresses, metabolic acidosis occurs because of poor tissue perfusion and lactate accumulation. Shock, followed by death, is expected in untreated animals. Dehydration, poor circulatory volume, and electrolyte abnormalities must be corrected. Serum chloride less than 79 mEq/L and heart rate greater than 100 beats/min are associated with a poor prognosis.³⁹

Disorders of the Pancreas

Acute pancreatitis in dogs and cats is frequently associated with vomiting, anorexia, and abdominal pain. However, the diagnosis of acute pancreatitis is often difficult to make antemortem. Classic laboratory findings associated with pancreatitis (increased amylase and lipase activity) may not be observed. Conversely, increased pancreatic enzyme activity is not specific for pancreatitis. Intestinal foreign bodies are frequently associated with increased lipase activity. Exploratory laparotomy in healthy dogs (without signs of pancreatitis), in which abdominal tissues were examined but not surgically altered, was associated

with a threefold increase in serum lipase activity.⁴⁰ Morphine administration may cause elevation of amylase and lipase activity by increasing smooth muscle contraction in the pancreatic duct (sphincter of Oddi).⁴¹ In addition, many dogs with pancreatitis have concurrent disease, such as diabetes mellitus, hyperadrenocorticism, renal failure, neoplasia, congestive heart failure, or autoimmune disorders.⁴² Acute pancreatitis has been induced by drugs, including corticosteroids, nonsteroidal anti-inflammatory agents, organophosphates, thiazide diuretics, sulfonamides, tetracycline, azothioprine, furosemide, and estrogen.⁴³ Thus, it is likely that animals with acute pancreatitis are often anesthetized for reasons unrelated to diagnosis or treatment of pancreatitis. However, in some situations, such as acute necrotizing pancreatitis or pancreatic phlegmon, surgical therapy may be indicated. Endoscopic, surgical, or laparoscopic techniques can be used to place enterostomy tubes for enteral nutrition. Iatrogenic pancreatitis may also occur after abdominal surgery. Humans occasionally develop acute pancreatitis after renal transplantation, gastrectomy, and biliary tract surgery.⁴⁴ The “incidental” finding of acute pancreatitis is not uncommon at the necropsy of many patients with an unknown cause of death.

Medical management of acute pancreatitis basically consists of maintaining adequate fluid therapy and nothing per os. The use of plasma and analgesics has also been advocated for management of pancreatitis. Establishing normal pancreatic circulation is paramount for tissue healing. Preanesthetic preparation of patients with pancreatitis is accomplished by withholding oral intake of food and water and administering IV fluids to correct hydration and/or electrolyte imbalances.

The choice of anesthetics for use in a patient with pancreatitis is often based on other complicating factors identified for the patient. Intravenously administered α_2 -adrenergic agents have a hyperglycemic effect owing to inhibition of insulin release by the beta cells in the islets of Langerhans of the pancreas. This effect has been observed with epinephrine and with the potent sedative-analgesics such as detomidine and xylazine.⁴⁵⁻⁴⁹ While α_2 -adrenergic agonist-induced hyperglycemia is avoided by pretreatment with α_2 -adrenergic antagonists, sedative and analgesic effects are similarly prevented.⁴⁵⁻⁵¹ It is unknown whether the α_2 -adrenergic effects on the pancreas are of clinical significance in patients with pancreatitis. However, a conservative approach to anesthetic management of these patients generally avoids use of these drugs. Opioid analgesics (hydromorphone, buprenorphine, or butorphanol) are a suitable alternative to provide sedation and analgesia prior to induction of anesthesia. Morphine causes spasm of the sphincter of Oddi at the termination of the common biliary and pancreatic duct in 1% to 3% of the human population and may be associated with complications in animals with pancreatitis.⁴¹ Other opioids cause less spasm of this sphincter and are useful when indicated for treatment of pain associated with pancreatitis. In humans, because of better pain relief with fewer side effects, epidural administration of morphine is preferred for treatment of pain associated with pancreatitis.⁵²

There is no clear best choice for induction of anesthesia for patients with pancreatitis. Halothane would not be the anesthetic of

choice in patients with concurrent liver disease or those with cardiac dysrhythmias. Maintenance of anesthesia with isoflurane or sevoflurane is preferred in such cases. During surgery, the anesthetist should attempt to provide vigilant monitoring of anesthetic depth, prevention of hypotension, and maintenance of adequate vascular volume.

Obesity

Obese patients often have underlying physiological problems in addition to the condition for which anesthesia is required. Evaluation of obese animals for presence of pancreatitis, diabetes mellitus, hepatic insufficiency, or cardiac disease should be included in the diagnostic workup. An obese animal's veins may be more difficult to locate and catheterize. Drug dose should be adjusted to a patient's lean weight to avoid overdosing with anesthetic drugs. Obese animals anesthetized with halothane will also have a longer recovery time than other patients because of significant sequestration of the anesthetic in fat. Isoflurane and sevoflurane are more desirable inhalation anesthetics for obese animals because of their minimal biotransformation and low tissue solubility.

Preoperative hypoxemia (Pickwickian syndrome) due to hypoventilation is a common feature of obesity in humans and is markedly worsened by anesthesia. Obesity decreases the ventilatory capacity of patients during anesthesia, owing to decreased chest wall compliance. Hypoventilation may occur because of limited diaphragmatic excursion from the increased weight of the abdominal contents. The increased mass of the pharyngeal tissues and tongue may lead to upper-airway obstruction after premedication with tranquilizers or during induction of anesthesia. Obese patients given sedatives or tranquilizers prior to anesthesia should be continuously observed for airway obstruction. Rapid control of the airway at induction and positive-pressure ventilation during anesthesia are recommended. During recovery from anesthesia, obese patients should be kept intubated until they will no longer tolerate the endotracheal tube. Obese animals must regain normal muscle function to maintain an adequate tidal volume and a patent airway after extubation.

Chapter 42

Endocrine Disease

Ralph C. Harvey and Michael Schaer

Introduction
Diabetes Mellitus
Diabetes Insipidus
Hypoglycemia from Insulinoma
Hyperparathyroidism
Hypoparathyroidism
Hypoadrenocorticism (Addison's Disease)
Hyperadrenocorticism (Cushing's Syndrome)
Pheochromocytoma
Hypothyroidism
Hyperthyroidism

Introduction

Endocrine disease is more often a factor influencing anesthetic management than a disease directly requiring anesthesia for medical or surgical intervention. Patients with endocrine disease–induced derangements of homeostasis require that anesthetic management be designed to take into account the appropriate physiological support, perioperative monitoring, and selection of medications to reduce the risks associated with sedation, anesthesia, and analgesia. Recognition of physiological derangements typical of specific endocrine diseases provides the framework for customizing anesthesia for individual patients. Endocrinopathies often increase the requirements for intervention, particularly for physiological support.

Diabetes Mellitus

Insulin is essential for normal cellular function. The effects of insulin on normal cellular function include (a) inhibition of glycogenolysis, (b) inhibition of gluconeogenesis, (c) inhibition of lipolysis, (d) stimulation of glucose uptake into cells, (e) stimulation of potassium transport into cells, and (f) suppression of ketogenesis.¹

Carbohydrate, protein, and fat metabolism are all affected with an insulin deficiency. Glucose uptake is decreased, especially in fat and muscle. Also, control of hepatic gluconeogenesis is lost, with the resultant hyperglycemia leading to osmotic diuresis. Muscle tissue undergoes catabolic metabolism for energy, and protein synthesis is inhibited, resulting in muscle wasting. Acetyl coenzyme A and ketone bodies are produced for energy. Lipolysis is inhibited with a resultant accumulation of ketone bodies causing osmotic diuresis and metabolic acidosis. Prolonged hyperglycemia and ketonemia can lead to (a) metabolic acidosis,

(b) dehydration, (c) circulatory collapse, (d) renal failure, and/or (e) coma and death.¹

Diabetes mellitus should be suspected in any patient with the following clinical signs: (a) a recent history of polyuria, polydipsia, weight loss, or rapid onset of cataracts; (b) dehydration, weakness, collapse, mental dullness, hepatomegaly and/or muscle wasting; and/or (c) increased rate and depth of respiration and breath with a sweet acetone odor. Diabetes mellitus occurs more frequently in female dogs and male cats. These clinical signs should alert the clinician to the possibility of diabetes mellitus.

The presence of glucose with or without ketones in the urine, along with resting blood glucose of greater than 250 mg/dL with hyperketonemia, is a common finding. Electrolyte and renal function tests may be altered (especially hypokalemia) and serum alkaline phosphatase may be increased due to hepatic fatty infiltration. Severe metabolic acidosis (a pH of less than 7.1) should be treated with sufficient sodium bicarbonate to return pH to 7.2.

A patient with diabetes mellitus should be stabilized and regulated prior to anesthesia. The anesthetic protocol is probably not as critical as the adjunct support during and after anesthesia and surgery. The key to the anesthetic management of a diabetic is to use preanesthetic and anesthetic agents that will result in the shortest anesthetic recovery time with the least amount of drug hangover. Drugs that can be antagonized (narcotics, α_2 -agonists, and benzodiazepine tranquilizers) or are readily eliminated from the patient (propofol, etomidate, and inhalant anesthetics) should be considered. The goal is to get the patient awake as soon as possible so that the patient can resume its normal feeding schedule.

The procedure should be scheduled early in the morning after the administration of the patient's normal dose of insulin or one-half of the usual dose.² Preoperative and serial intraoperative and postoperative blood glucose levels should be determined. Ideally, the blood glucose should be maintained between 150 and 250 mg/dL. During the procedure, 2.5% to 5% dextrose in a balanced electrolyte solution should be administered to prevent hypoglycemia.³ An intraoperative fluid rate of 11 to 15 mL · kg⁻¹ · h⁻¹ is usually adequate. Depending on the blood glucose values, measured hourly, the dextrose drip may need to be continued following the procedure. Avoid blood glucose extremes and lower any marked elevations of blood glucose to a rate not to exceed 75 to 100 mg/dL per hour. As soon as a postoperative patient starts eating, it is probably not necessary to continue the dextrose in the

intravenous fluids. Close monitoring of the patient should be continued, because the stress of anesthesia and surgery may cause a diabetic to decompensate. A return home and resumption of the normal regulation pattern is desired as soon as possible. The use of corticosteroids may also cause decompensation and should be avoided unless absolutely necessary.

Diabetes Insipidus

If anesthesia is needed before correction of electrolyte abnormalities, it becomes essential to continue with diuresis. Oral water deprivation can be very deleterious for cerebral function and blood pressure, so water should not be withdrawn from these patients. Generous intravenous fluid therapy is indicated to avoid hypertonic encephalopathy. Serum sodium concentration should be monitored, and appropriate fluids administered to prevent it from rising to more than 160 mEq/L. The fluid of choice is 5% dextrose in water as needed, or half-strength (0.45%) saline with 2.5% dextrose may be used if a more isotonic solute is desired. Metabolism of the dextrose provides free water and thereby reduces plasma sodium. Chronic hypernatremia should be corrected slowly, at rate not to exceed 12 mEq for first 24-h period, with correction achieved over 72 h. Rapid-onset hypernatremia (occurring within less than 24 h) can be carefully treated more rapidly.

Hypoglycemia from Insulinoma

Monitoring and supplementation of blood glucose are required in patients with an insulinoma. Acute hypoglycemia must be recognized and treated effectively with dextrose. If there is no response to intravenous dextrose, a glucagon infusion may be useful. In postoperative patients, there is a risk of acute pancreatitis after surgical removal of the insulinoma. These patients may be maintained non per os for 1 to 2 days after surgery to help reduce the risk of acute pancreatitis. Continued monitoring of blood glucose is necessary to recognize potential hyperglycemia and hypoglycemia in the perioperative period. These patients may become insulin dependent.

Hyperparathyroidism

Preoperative management requires decreasing the serum calcium before anesthesia and surgery. It is important to evaluate renal status and stabilize or treat accordingly. After parathyroid (or thyroid) removal, there is risk of acute hypoparathyroidism. These animals require repeated monitoring for hypocalcemia during the first 48 h after surgery and appropriate management.

Hypoparathyroidism

Hypoparathyroidism occurs less often than hyperparathyroidism and is often diagnosed in patients after surgery to remove either the thyroid or parathyroid glands. Close monitoring of blood calcium is indicated. Rarely, preparturient eclampsia is present in bitches requiring Caesarean section. Treat hypocalcemia with

calcium gluconate until signs abate and serum calcium is at safe level, greater than 7 mg/dL.

Hypoadrenocorticism (Addison's Disease)

Hypoadrenocorticism is a deficiency in aldosterone and/or glucocorticoids that results from adrenal cortex dysfunction. As with diabetics, patients with hypoadrenocorticism should be stabilized and regulated prior to anesthesia and surgery when possible.

Hypoadrenocorticism can be caused either by diseases, destruction of the adrenal glands, or by decreased corticotropin (adrenocorticotrophic hormone [ACTH]) secretion. Primary idiopathic hypoadrenocorticism is the most common cause of hypoadrenocorticism in dogs and may be immune mediated. Other diseases that may destroy the adrenal glands include systemic mycosis, metastatic tumors, hemorrhagic infarction, amyloidosis of the cortices, canine distemper, and glucocorticoid therapy for certain disorders that might cause a selective deficiency of cortisol caused by negative feedback inhibition of the hypothalamic-pituitary-adrenal axis.⁴

Decreased ACTH secretion can cause secondary hypoadrenocorticism. Adrenocorticotrophic hormone directly stimulates glucocorticoid secretion and is secreted by the anterior pituitary gland. Decreased ACTH secretion may develop with diseases or tumors of the pituitary gland or with decreased secretion of corticotropin-releasing factor (CRF) owing to hypothalamic lesions. Prolonged negative feedback from exogenous corticosteroid therapy can cause glucocorticoid deficiency while maintaining adequate mineralocorticoid secretion.

The clinical signs of hypoadrenocorticism will depend on the particular adrenal hormone (aldosterone or glucocorticoids) most affected by the disease. The primary function of aldosterone is to stimulate absorption of sodium in the distal renal tubules and promote potassium excretion. Aldosterone deficiency produces hyponatremia and hyperkalemia. Hyponatremia with concurrent water loss can produce lethargy, nausea, impaired cardiac output, hypovolemia, hypotension, and/or impaired renal perfusion. Hyperkalemia will produce muscle weakness, decreased cardiac conduction, and excitability and bradycardia.

Glucocorticoid deficiency can result in significant physiological abnormalities. Cortisol stimulates gluconeogenesis, increases blood glucose, enhances extravascular fluid movement to the intravascular compartment, stabilizes lysosomal membranes, and counteracts the effects of stress. Cortisol depletion impairs renal excretion of water and energy metabolism, decreases stress tolerance, and can cause anorexia, vomiting, and/or diarrhea. Cortisol depletion rarely produces electrolyte imbalances.⁴

Hypoadrenocorticism should be suspected in any dog with a history of anorexia, vomiting, diarrhea, and lethargy when clinical findings are muscle weakness, dehydration, and bradycardia. Electrolyte imbalance may be suggestive of hypoadrenocorticism. Serum sodium levels are often less than 135 mEq/L, and serum potassium levels may be greater than 5.5 mEq/L. The sodium-potassium ratio may be less than 25:1 (normal is 33:1).

Hypoadrenocorticism is confirmed by measuring serum corti-

sol. Determination of plasma cortisol levels is the most accurate method of diagnosing hypoadrenocorticism, and resting plasma cortisol is often less than 10 µg/mL. Plasma cortisol will not significantly increase in response to exogenous ACTH administration in hypoadrenocorticism patients. Prednisolone replacement therapy must be withheld for 1 to 2 days before testing, but dexamethasone can be used without causing interference with the radioimmunoassay for cortisol.⁴

Diagnostic testing that may be helpful in confirming the diagnosis of hypoadrenocorticism includes the complete blood count (CBC), blood urea nitrogen (BUN), and electrocardiogram (ECG). The CBC reflects dehydration, and decreased cortisol will sometimes cause eosinophilia and lymphocytosis. BUN may be elevated by prerenal uremia or renal failure. The ECG may show evidence of hyperkalemia. In severe hyperkalemic cardiotoxicity, therapy may be warranted with calcium gluconate, sodium bicarbonate, insulin, and dexamethasone.

The anesthetic protocol used in the patient with hypoadrenocorticism is not as critical as the medical management prior to anesthesia. A patient with hypoadrenocorticism must be stabilized. The treatment objectives are (a) to correct the dehydration and treat hypovolemic shock if present, (b) to return renal function to normal, (c) to correct electrolyte imbalances, and (d) to supply glucocorticoids.⁵ In an Addisonian crisis, priorities are the patient's pH, hypotension, ECG complexes and rhythm, and the correction of hyponatremia, hyperkalemia, and any hypoglycemia.

Addisonian patients have decreased stress tolerance. The key to their perioperative management is to provide adequate intravenous fluid volume replacement and to provide exogenous glucocorticoids. A balanced electrolyte solution should be administered intraoperatively at a rate of 15 to 22 mL · kg⁻¹ · h⁻¹. The rate may be adjusted depending on the patient's physiological status. The fluid rate may be decreased postoperatively to approximately 90 mL · kg⁻¹ · day⁻¹. Again, this rate can be adjusted depending on a patient's physiological status.

Glucocorticoids should be given concomitantly with initiation of the anesthetic regimen. Preoperatively, 2 to 4 mg/kg of dexamethasone can be given intravenously or subcutaneously. Intraoperatively, a rapid-acting glucocorticoid such as prednisolone sodium succinate (Solu-Delta-Cortef) at a dose of 11 to 22 mg/kg should be administered intravenously and repeated as necessary. Postoperatively, additional glucocorticoids are given as needed. Patients with hypoadrenocorticism should be closely monitored for signs of hypotension and shock.

Hyperadrenocorticism (Cushing's Syndrome)

Although a common endocrine disease, hyperadrenocorticism is less problematic for successful anesthetic care than is hypoadrenocorticism. Patients with an excess of adrenal hormones will be predisposed to infection and poor wound healing. Most cats with hypoadrenocorticism are also diabetic. There is increased risk of pulmonary thrombosis and of thrombosis at other sites during the perioperative period.

Blood pressure monitoring and support are important for patients with hypoadrenocorticism because they are prone to hypertension. Preanesthetic evaluation should include baseline arterial blood pressure measurement. Patients with underlying hypertension should have blood pressure supported, if necessary, to prevent anesthetic-associated hypotension. Chronic hypertension predisposes patients to failures of autoregulatory control of tissue perfusion at reduced blood pressures that would be better tolerated by normotensive patients.

Pulmonary alveolar calcification is occasionally recognized on thoracic radiography with hypoadrenocorticism. This might cause hypoxemia from impaired perfusion, but is usually an incidental finding. A more commonly encountered problem related to the respiratory depression is impaired intraoperative ventilation. Many patients with hypoadrenocorticism have a large pendulous abdomen, which can impair ventilation during anesthesia. Monitoring ventilation with end-tidal carbon dioxide, pulse oximetry, and/or arterial blood-gas analysis is warranted.

When hyperadrenocorticism has been successfully treated, patients should have some functional adrenocortical reserve and thereby still be able to withstand the stresses of anesthesia and surgery. Adrenocortical reserve is indicated by a post-ACTH stimulation value of 3 to 10 µg/dL. Otherwise, these patients should be managed as having an iatrogenic adrenocortical insufficiency requiring glucocorticoid supplementation. Newer methods for medical management of pituitary gland-dependent and adrenal gland-dependent hyperadrenocorticism hold promise for more effective treatment and superior retention of adequate adrenocortical function.

Pheochromocytoma

Patients with pheochromocytoma are usually considered to be at very high anesthetic risk. The best approach to anesthetizing a patient with a pheochromocytoma is the preoperative monitoring and management of arterial blood pressures and cardiac function. Cardiac arrhythmias, particularly tachyarrhythmias, require diligent ECG monitoring. Stabilization of patients can require prolonged medical management, most often using phenoxybenzamine, a long-acting α-adrenergic antagonist, prior to anesthesia and surgery to lower and control arterial blood pressure adequately. Extreme hemodynamic instability is commonly a problem in these patients, especially if prior stabilization is inadequate. Even with prior stabilization, close attention to blood pressure and cardiac monitoring are imperative.

Surges in blood pressure and tachyarrhythmias are treated as they occur. Propranolol or esmolol may be useful in controlling tachyarrhythmias, but it is important to provide effective α-adrenergic blockade before initiating β-adrenergic blockade. For any adrenal gland surgery, there is very significant potential for intraoperative blood loss. This is particularly true for tumors involving the right adrenal gland because of proximity to the posterior vena cava. Cross-matched blood should be available, along with colloidal fluids, for immediate volume resuscitation.

After removal of the affected adrenal gland, acute and dramatic drops in endogenous catecholamine levels may occur. This

may be manifested as sudden and profound hypotension and bradycardia, especially in the presence of α -adrenergic and β -adrenergic blockade. Intravenous inotropic (e.g., dobutamine) and pressor (e.g., ephedrine or phenylephrine) support should be immediately available to treat hypotension rapidly.

Hypothyroidism

Untreated and inadequately treated hypothyroid patients have reduced metabolic rates and may more slowly recover from sedation or anesthesia. Any anesthetic drug should be used in low doses and ideally should require minimal or no metabolism or can be readily antagonized. Opioids, low doses of tranquilizers, propofol, and inhalants are the preferred preanesthetic and anesthetic drugs.

Hypothyroid patients are often obese and may suffer from anemia. Obesity may cause ventilatory problems under anesthesia that are caused by the excess amounts of abdominal and intrathoracic fat. Assisted or controlled ventilation may be necessary in these patients to keep them adequately ventilated. Moderate anemia may occur in hypothyroid patients. If the anemia is significant, blood transfusion should be considered prior to anesthesia and surgery.⁶ In severe cases of hypothyroidism (myxedema hypothyroidism), hypothermia and bradycardia may complicate anesthesia. These should be corrected slowly. Support with corticosteroids, levothyroxine, and respiratory support may be necessary.

Hyperthyroidism

Patients with thyroid adenomas, adenomatous hyperplasia, or adenocarcinomas may exhibit evidence of hyperthyroidism. Several factors may place these patients at higher anesthetic risk.⁷ A thyroid tumor may place mechanical pressure on the trachea, causing a partial obstruction and interfering with respiration. The surgical site may be highly vascular, and this can lead to excessive bleeding.

Hyperthyroid patients may rarely develop a *thyroid storm* during the procedure as a result of excessive thyroid hormone production. This is precipitated by catecholamine release and is characterized by an increased heart rate, increased blood pressure, cardiac dysrhythmias, elevated body temperature, and shock. Hyperthyroid patients often have increased metabolic rates, making them more prone to developing hypoxemia. Oxygen and glucose demand and carbon dioxide production are increased. Hyperthyroid patients may be more prone to heart failure. They have an increased heart rate and myocardial oxygen consumption.

Because of their increased metabolic rate, hyperthyroid patients may rapidly metabolize anesthetic drugs. Adequate oxygenation must be provided because of the increased oxygen consumption and demands of the patient. Intubation may be difficult if the tumor is compressing the trachea. Preanesthetic and anesthetic agents that decrease catecholamine response and myocardial irritability are preferred. Low doses of acepromazine or an

α_2 -agonist can be used as a preanesthetic in hyperthyroid patients. Acepromazine decreases myocardial irritability, and it blocks α -adrenergic receptors and thus may help counteract hypertension. An opioid can be combined with acepromazine because opioids generally slow heart rate and decrease myocardial oxygen consumption.

Anesthesia may be induced with low-dose thiopental, propofol, etomidate, or an inhalant by mask using isoflurane or sevoflurane. Inhalant induction alone may be stressful in some patients, worsening the overall cardiovascular status. Cardiovascular and respiratory parameters should be monitored closely and ventilation controlled when necessary. A 2.5% to 5% dextrose drip can be administered to meet increased glucose demands.

Cats with thyrotoxic cardiomyopathy, and particularly those with hyperthyroidism and concurrent hypertrophic cardiomyopathy, should be managed so as to reduce heart rate and optimize ventricular filling.^{8,9} The use of dissociative anesthetics and anticholinergics is avoided to help insure that a lower heart rate is maintained. Sevoflurane (or even halothane) is preferred over isoflurane so as to reduce heart rate and myocardial work. The use of acepromazine is avoided to prevent the reduction in preload and ventricular filling. By maintaining preload, ventricular filling, and diastolic interval, both myocardial blood flow and ventricular function are improved. Preanesthetic medication with an opioid such as buprenorphine and a benzodiazepine such as midazolam is followed by inhalant induction with sevoflurane. Intravenous induction with etomidate, propofol, or thiopental is acceptable in less severe cases.

Airway Disease

Stephen A. Greene and Ralph C. Harvey

Introduction
Respiratory Depression in the Perianesthetic Period
Airway Trauma
Brachycephalic Airway Syndrome
Laryngeal Abnormalities
Mishaps Involving the Airway

Introduction

Airway obstruction may be associated with trauma, congenital anatomic abnormalities, aspiration of foreign material, or laryngospasm. Specific management of airway obstruction in the perianesthetic period is determined by the severity of the obstruction and the underlying factors associated with its cause.

Respiratory Depression in the Perianesthetic Period

When possible, the use of potent respiratory-depressant medications should be avoided in patients with respiratory disease. When sedative/analgesics with respiratory-depressant effects (e.g., opioids) are used for premedication, the patient's respiration should be closely monitored (e.g., pulse oximetry, end-tidal CO₂, and arterial blood gas analysis). Mixed agonist-antagonist opioids such as butorphanol minimize respiratory depression. Butorphanol is described as having a "ceiling effect" on respiratory depression and analgesia.¹ This terminology implies that the dose-response curve for butorphanol will plateau at some point, thus imparting no further respiratory depression/analgesia as the dose is increased. Naloxone can be used to antagonize respiratory depression associated with opioid analgesics but will also antagonize analgesia.² Analgesia may be preserved to some extent by titrating naloxone "to effect" when reversing opioid-induced respiratory depression. However, *rapid* intravenous administration of naloxone has been associated with development of cardiac dysrhythmias and even sudden death.^{3,4} Administration of a mixed-agonist-antagonist opioid such as butorphanol may effectively antagonize severe respiratory depression while maintaining some analgesic action.⁵ Incremental dosing of butorphanol (0.05 mg/kg at a time) for antagonism of full-agonist opioids is advised to prevent sudden arousal and dysphoria.

Regional analgesia is gaining in popularity for improving postoperative analgesia. This technique causes less respiratory depression than do parenteral opioids. Following thoracotomy, analgesia may be enhanced by intrapleural injection of bupiva-

caine (1.5 mg/kg).⁶ For control of pain associated with procedures involving the hind limbs (and possibly procedures more rostral), epidural analgesia is a useful adjunct to general anesthesia. Epidural analgesia prior to surgery will decrease general anesthetic requirement.⁷ Inhalation anesthetics are associated with dose-dependent respiratory depression. Therefore, use of epidural analgesia as an adjunct to inhalation anesthesia may decrease respiratory and cardiovascular depression. Epidural analgesia in dogs is often accomplished using morphine (0.1 mg/kg) in sterile water or isotonic saline solution in sufficient quantity to yield 1 mL per 5 kg of body weight.⁸

Airway Trauma

Trauma to the head and neck can cause progressive respiratory distress. Airway occlusion may result from collapse or obstruction of the nasal or oral passages accompanied by tissue swelling, hemorrhage, and aspiration of tissues, blood, or foreign materials. Head trauma and secondary cerebral edema can decrease ventilation via neurological mechanisms independent of physical obstructions. Additional respiratory depression must be avoided to prevent associated increases in intracranial pressure and neurological morbidity. In a retrospective study of 85 dogs undergoing cervical spinal decompressive surgery, respiratory arrest was a significant factor in three (42%) of seven that died of complications arising during surgery.⁹

The airway and laryngeal function should be examined during a light plane of general anesthesia or while the animal is sedated. Care must be taken to avoid excessive depression from anesthetics with resultant inhibition of respiration or laryngeal activity. A clinical investigation found that observation of laryngeal function during light anesthesia with propofol or thiopental was superior to anesthesia induced with the combination of diazepam and ketamine.¹⁰

Surgical procedures on the nasal airway, pharynx, larynx, or trachea can be followed by obstructive postoperative swelling. Delicate surgical technique combined with perioperative anti-inflammatory doses of corticosteroids minimize this potential. Administration of pediatric strength phenylephrine nose drops in each nostril will counteract nasal passage hyperemia, improving ventilation and often stimulating increased swallowing.

Animals with thick or copious secretions in the respiratory tract have increased risk for airway obstruction. Endotracheal intubation restricts the diameter of the trachea and increases the likelihood of airway obstruction from viscid secretions. Parti-

cular attention should be given to patients with small endotracheal tubes (e.g., internal diameter < 5 mm). Decreased compliance detected by difficult positive-pressure ventilation (by squeezing the rebreathing bag) in a patient with abnormal respiratory tract secretions should prompt the anesthetist to inspect the airway. Suction of secretions from the endotracheal tube may be required periodically during anesthesia. In some cases, the best solution may be to reintubate the trachea with a different endotracheal tube. Pharyngeal suction prior to anesthetic recovery from nasal, pharyngeal, or oral surgery decreases risk of aspiration of blood and debris. When regurgitated material or blood has accumulated in the pharynx, the risk of aspiration can be reduced further by gently withdrawing the endotracheal tube with the cuff partially inflated. After delivery to the pharynx, matter can be removed by suction.

Administration of oxygen should continue throughout recovery when there is risk of postoperative airway obstruction or significant respiratory depression. If obstruction develops, supplementary oxygenation increases the time available for institution of airway control. Rapid-sequence induction of anesthesia with an injectable anesthetic may be necessary to regain control of the upper airway via an endotracheal tube. After reestablishment of a secure airway, it may be possible to resolve the underlying problems and then successfully recover the patient from anesthesia. In brachycephalic animals, resection of an elongated soft palate may be necessary to prevent airway obstruction associated with tissue swelling that has developed during the procedure. In severe cases of obstruction, an emergency tracheostomy may be necessary.

Brachycephalic Airway Syndrome

Anatomical abnormalities of the upper airway in brachycephalic dogs can severely compromise their ability to ventilate adequately. The primary defects of stenotic nares, elongated soft palate, and hypoplastic trachea are exacerbated in extreme cases with eversion of laryngeal sacculles and redundant pharyngeal tissues. Dogs with arytenoid cartilage, laryngeal, or tracheal collapse present similar anesthetic challenges. Reduction of the cross-sectional area of the trachea greatly increases resistance to airflow and the work of breathing. In addition, vagal tone is frequently high in brachycephalic dogs. Vagal stimulation associated with pharyngeal manipulation (difficult intubation) or vagotonic drugs can contribute to significant bradycardia and further airway narrowing. Preanesthetic administration of anticholinergic agents is indicated in these cases. The anesthetist's goals are to avoid deep sedation, especially in animals that are not continuously monitored; to intubate the trachea by using a rapid intravenous induction technique when practical; and to maintain tracheal intubation until the dog demonstrates adequate recovery from anesthesia. Anesthesia induction should be preceded by having the dog breathe oxygen through a face mask. Respiratory support during anesthesia may be required, especially in overweight animals. Obesity further impairs ventilatory function by decreasing tidal volume and functional residual capacity of the lung.

Recovery from anesthesia is judged to be adequate when a dog

strongly objects to the presence of the endotracheal tube. Reversal of the effect of opioids by naloxone administration may aid in rapid return of a dog's ability to maintain its airway. However, painful or distressed animals may experience more respiratory difficulty following extubation, so the benefits of opioid reversal should be carefully weighed against the potential complications of the increased pain and stress that may accompany reversal. Because of the presence of redundant tissue in the pharynx, most brachycephalic breeds (e.g., bulldog and shar-pei) benefit from having the anesthetist hold the dog's tongue and/or extend its neck immediately after extubation of the trachea. A source of 100% oxygen, an endotracheal tube, a laryngoscope, and an intravenous anesthetic-induction drug such as propofol should be immediately available. Ventilatory function of brachycephalic dogs should be closely monitored for at least 1 h following recovery from anesthesia.

Laryngeal Abnormalities

Abnormal laryngeal anatomy due to congenital malformation or acquired disease may affect respiration, especially during sedation. Tracheal intubation may be hindered by masses protruding into the glottis or by strands of tissue that cross the glottis. Smaller-diameter endotracheal tubes may be placed to solve this problem in some instances. However, an excessively narrow endotracheal lumen may severely affect ventilation, leading to hypoxemia or hypoxia.

Laryngospasm during the perianesthetic period occurs most frequently in cats, swine, rabbits, and primates, but has also been observed in dogs and horses. Laryngospasm may occur after irritation of laryngeal tissues by secretions or blood. Spasm of the larynx may be caused by touching the larynx during a light plane of anesthesia. Topical application of a local anesthetic such as lidocaine is recommended prior to tracheal intubation in these species to minimize tactile stimulation-induced laryngospasm. Neuromuscular blocking agents such as atracurium may be useful for preventing laryngospasm during tracheal intubation, although their use in domestic veterinary species is seldom needed. Extubation of the trachea can also trigger laryngospasm in susceptible animals. In one case, a Vietnamese potbellied pig apparently developed laryngospasm 4 h after tracheal extubation in spite of an uneventful recovery from inhalation anesthesia. Treatment of laryngospasm that occurs during tracheal extubation (or later) includes reintubation using anesthetics and neuromuscular blocking agents, if necessary. Nasotracheal intubation is an effective means of reestablishing a patent airway in some species, such as horses. Oxygen should be administered and the patient should be evaluated for subsequent development of pulmonary edema over the next 1 to 4 h. Pulmonary edema may accompany laryngospasm with clinical signs of dyspnea and tachypnea and production of pink frothy material in the airway becoming apparent during recovery from anesthesia.¹¹ Dogs with upper-airway obstruction can develop life-threatening pulmonary edema.¹² Factors associated with generation of pulmonary edema following airway obstruction are listed in Table 43.1. The extreme negative pressure produced by an animal with airway

Table 43.1. Factors associated with development of pulmonary edema following acute airway obstruction

Severe negative intrathoracic pressure
Decreased interstitial hydrostatic pressure
Catecholamine release
Vasoconstriction
Increased vascular hydrostatic pressure
Hypoxia
Increased permeability of pulmonary vasculature
Net accumulation of interstitial fluid
Inadequate lymphatic removal of interstitial fluid

obstruction when attempting to inspire causes decreased interstitial hydrostatic pressure in the lung. Simultaneous release of catecholamines causing increased vascular hydrostatic pressure may cause a net accumulation of interstitial fluid. Hypoxia associated with an acutely obstructed airway may promote fluid movement into the interstitial spaces by increasing permeability of pulmonary vasculature. Pulmonary edema formation after airway obstruction is probably multifactorial, so treatment is symptomatic. Oxygen supplementation to maintain an SpO₂ greater than 90%, diuretics, and corticosteroids are used to treat pulmonary edema. Emergency tracheostomy may be required to establish a patent airway rapidly. Tracheal intubation and positive-pressure ventilation are routinely used in human patients with pulmonary edema, for whom the syndrome is rarely fatal.^{13,14}

Horses may develop airway obstruction during tracheal extubation after anesthesia. Potential causes include laryngospasm, paralysis of the arytenoid cartilages, and mechanical obstruction. Epiglottic retroversion has been described as a cause of upper-airway obstruction in horses.¹⁵ Syncope as a consequence of complete upper-airway obstruction caused by a subepiglottic cyst has also been reported.¹⁶ Laryngospasm is associated with cessation of airflow, whereas paralysis of the arytenoid cartilages is characterized by stridor and decreased airflow. Laryngospasm may result from laryngeal irritation during anesthesia and/or extubation. Paralysis of the arytenoid cartilages has been associated with poor function of the recurrent laryngeal nerve. In horses, the recurrent laryngeal nerve may be susceptible to damage by hyperextension of the neck for a prolonged period during anesthesia.¹⁷ Postanesthetic paralysis of the arytenoid cartilages has also been observed following 2- to 4-h procedures in which a horse's trachea was intubated with an excessively large (in retrospect) endotracheal tube. Mechanical obstruction of the airway may occur during recovery from anesthesia if a horse becomes cast or positioned such that the neck is improperly flexed. Pulmonary edema following transient mechanical airway obstruction in a horse has been reported.¹⁸ Horses anesthetized with the head lower than the body may be at risk for accumulation of fluid in laryngeal tissues. These horses may develop airway obstruction by an edematous glottis after tracheal extubation. Many anesthesiologists prefer to recover horses at risk for upper-airway obstruction with a nasotracheal tube in place until the horse is standing. Treatment of a horse with postanesthetic airway obstruction is

initiated by placement of a nasal or oral endotracheal tube. If one of these techniques is not successful, an emergency tracheostomy is indicated. Supportive treatment includes administration of oxygen, diuretics, corticosteroids, antibiotics, and analgesics.

Mishaps Involving the Airway

Unfortunately, mishaps or accidents involving management of the airway during anesthesia increase morbidity and mortality among animal patients. It is therefore imperative that anesthesiologists become familiar with the anesthetic machine, ventilator, and intubating equipment available to prevent such mishaps. Vigilance in preventing excessive pressure buildup within an anesthetic circuit is required. The function of the "pop-off" valve should be continuously monitored. Sudden or unexplained increases in circuit or airway pressure should be immediately investigated. Equipment failure should be ruled out while anesthesia is maintained using a different delivery system. An unusual cause of increased inspiratory plateau pressure has been attributed to a leak in the bellows of a mechanical ventilator that allowed the driving gas of the bellows to enter the breathing circuit.¹⁹ Increased airway pressure may also occur from development of tension pneumothorax.

Venipuncture has also been associated with airway obstruction caused by iatrogenic trauma to vital structures in the neck. Injury of the recurrent laryngeal nerve may cause temporary paralysis of the arytenoid cartilage in horses. Aspiration pneumonia secondary to choke caused by a periesophageal hematoma following jugular venipuncture has been reported in a llama.²⁰

Airway obstruction has occurred in intubated patients following administration of nitrous oxide, which may diffuse into the air-filled endotracheal tube cuff, causing increased cuff pressure and endotracheal tube collapse.²¹ Overexpansion of the endotracheal tube cuff when administering nitrous oxide may be prevented by filling the cuff with an appropriate nitrous oxide-oxygen mixture (i.e., gas aspirated from the breathing circuit) rather than with air. Nitrous oxide may also diffuse into small bubbles of air found in some endotracheal tubes as a manufacturing defect. Expansion of these air bubbles with nitrous oxide has caused airway obstruction in guarded endotracheal tubes (those with a spiral wire used to prevent kinking of the tube).²² Prior to use, endotracheal tubes should be examined for material defects such as presence of air bubbles that contraindicate administration of nitrous oxide.

Inadvertent displacement of the endotracheal tube may cause airway obstruction. Subtle changes in position of the endotracheal tube may occur during radiography or surgical positioning. Flexion of the neck of anesthetized dogs has resulted in caudal displacement, endobronchial placement, or total occlusion of the endotracheal tube.²³

General Considerations

Development of an appropriate anesthetic protocol for any ocular patient should include not only drug selection, but also a perioperative management plan to provide an optimal postoperative outcome. This requires knowledge of not only the patient's physical status and the ophthalmic procedure to be performed, but also familiarity with ocular physiology and current medications administered for ophthalmic purposes.

Ocular and periocular structures are often neglected during anesthesia induction. Positioning of hands and equipment relative to the eyes should be noted during induction, especially when dealing with severely compromised globes with the potential to rupture. Mask induction may not be an option if the mask rubs or presses on the eye, and a patient's struggling during induction with a face mask may increase intraocular pressure (IOP) or potentiate eye rupture. Similarly, nasotracheal intubation in awake foals requires heavy restraint and is accompanied by coughing and gagging, which may increase IOP and further compromise the globe. Providing analgesia is particularly important in ophthalmic patients with substantial discomfort from their primary ophthalmic disease. These patients may be more inclined to struggle when restrained, which may result in increased IOP and additional damage to the globe during induction.

Horses with a nonvisual eye should be approached from the vi-

sual side. If approach from the nonvisual side is necessary, it should be accompanied by words of reassurance and gentle hand contact, which should be maintained until induction is complete. Movement of equine patients to lateral recumbency after induction should include careful control of the head to prevent additional trauma to the eyes. It has been suggested that ventral positioning of the head relative to the body during transport causes venous stasis and increased IOP. These effects may be responsible for intraocular hemorrhage observed shortly after induction in horses with traumatized eyes.¹ Supporting the head to keep it level with the body is recommended to avoid such an occurrence.

Protection of the dependent, nonaffected eye should also be considered during positioning of patients. Corneal protection of the eye not operated on in unilateral procedures may be afforded by application of corneal lubrication with or without a temporary tarsorrhaphy. Positioning of the patient's head and application of any topical ophthalmic preparations should be coordinated between the anesthesiology personnel and ophthalmologist to ensure the best possible surgical outcome when both eyes are to be operated on. Collapse of the anterior chamber of the dependent eye, possibly resulting from increased aqueous outflow caused by physical pressure on the globe, has been reported in birds positioned in lateral recumbency. The anterior chamber was reestablished within a few minutes of repositioning.² Resting the periocular region of the dependent eye on a soft padded eye ring or "doughnut" may help protect the eye from corneal abrasion and external globe compression that may result in hypotony.

Laryngeal stimulation should be minimized and endotracheal intubation accomplished as smoothly as possible to avoid any possible increases in IOP.¹ Lidocaine applied topically to the larynx, or administered intravenously (1.0 mg/kg), may be helpful in suppressing the cough reflex.³ In people, the anesthesia-related practices most likely to increase IOP significantly (i.e., at least 10 to 20 mm Hg) are laryngoscopy and endotracheal intubation.⁴⁻⁶ Although the mechanism is not clear, it has been suggested that it is related to sympathetic cardiovascular responses to laryngeal stimulation. The occurrence of increases in IOP during endotracheal intubation has not been clearly established in veterinary patients.

Positioning for the ophthalmic procedure may render ocular patients less accessible for anesthetic monitoring, and maintaining their appropriate level of anesthesia may become very difficult. Eye reflexes, jaw tone, and oral mucous membranes will not be assessable, although the ophthalmologist may be able to provide information about eye position and movements. Once the

head has been surgically draped, the airway also becomes inaccessible. A guarded (i.e., wire reinforced) endotracheal tube is recommended to prevent unobservable kinking and occlusion of the airway during surgical positioning. Capnography may be useful for detection of an obstructed airway or inadvertent disconnection from the anesthetic delivery system. Similarly, pulse oximetry may help detect desaturation should the endotracheal tube become kinked or the delivery system disconnected. However, the pulse oximeter may have to be placed somewhere other than on the tongue, which would put it in close proximity to the surgical field, where movement by the ophthalmologist may interfere with its function.

Monitoring heart rate (HR) and arterial blood pressure (BP) becomes essential in ocular patients when other types of monitoring are limited and are particularly important when including neuromuscular blocking agents (NMBs) in the anesthetic protocol. Preventing movement during ophthalmic procedures and facilitation of eye positioning may be accomplished by using NMBs to paralyze patients, but the inability of patients to indicate inadequate anesthesia with movement makes monitoring all the more crucial. Increased BP or HR may indicate an inadequate plane of anesthesia or the need for additional analgesics. Conversely, precipitous decreases in HR or BP may indicate too deep a plane of anesthesia or initiation of the oculocardiac reflex (OCR). Increased respiration rate may also be indicative of inadequate anesthesia, but such a response may not be evident in mechanically ventilated or paralyzed patients.

Tear production decreases during general anesthesia in people, dogs, horses, and possibly other species.⁷⁻¹⁰ Tear production in dogs decreases from baseline values within 10 to 15 min after subcutaneous administration of atropine and continues to decline after induction of general anesthesia with halothane or methoxyflurane. Indeed, within 30 to 60 min of onset of general anesthesia, tear production in dogs can approach negligible amounts regardless of whether atropine was administered before surgery. In a comparison of preanesthetic and postanesthetic Schirmer tear test values in dogs, significant decreases in tear production were evident for up to 24 h after the anesthetic procedure. Anticholinergic administration before or during anesthesia further decreased the postanesthetic Schirmer tear test values.¹¹ Based on drug-retention studies in humans, it has been suggested that canine eyes be lubricated every 90 min during general anesthesia.⁷ A study comparing the effects of sedative and opioid combinations on tear production in dogs determined that acepromazine-oxymorphone, diazepam-butorphanol, and xylazine-butorphanol significantly decreased tear production (80%, 68%, and 33% of baseline, respectively).¹² Xylazine alone did not significantly decrease tear production. Butorphanol alone did significantly decrease tear production, but when xylazine and butorphanol were combined, the decrease in tear production was greater than that observed with butorphanol alone. This suggests that xylazine and butorphanol act synergistically to decrease tear production in dogs.

Transient lens opacification may occur in rodents, such as mice, rats, and hamsters, during prolonged sedation or anesthesia. The opacification is believed to be caused by lack of blink-

ing and subsequent evaporation of fluids from the shallow anterior chamber, which then resolves upon awakening.¹³

In horses undergoing general anesthesia, tear production is reduced much less dramatically than in dogs. Normal tear production was restored within 3 h in horses undergoing halothane anesthesia.⁹ Although this may suggest that ocular lubrication may not be necessary to prevent corneal drying in horses, it is recommended that ocular lubrication be instilled in the eyes of all patients undergoing anesthesia. A flash fire involving ophthalmic ointment during anesthesia with nitrous oxide and oxygen has been reported,¹⁴ but a later study concluded that ophthalmic ointments do not offer a significant fire hazard.¹⁵ If intraocular surgery is planned or globe rupture has occurred, application of topical ophthalmic medications or lubrication should be restricted to aqueous-based formulations. Petroleum-based ointments that gain access to intraocular structures may cause severe uveitis and further compromise vision and ocular comfort. Taping the palpebrae closed or a partial temporary tarsorrhaphy are additional techniques for protecting the globe and keeping it moist.¹

A smooth anesthetic recovery, including appropriate analgesia and prevention of self-trauma, is the primary postoperative management goal. For patients who have undergone intraocular surgery, periods of excitement, incoordination, coughing, gagging, or retching are particularly undesirable. Recovery should be in a quiet, dimly lit enclosure where external stimuli will be kept to a minimum. Patients can be kept comfortable and quiet by appropriate analgesia and sedation, although minimal physical restraint or words of reassurance while holding some small patients may be more effective. Elizabethan collars for small patients and padded helmets or protective eyecups for large patients may help protect their eyes, but may not be readily tolerated by some. Recovery cages or stalls should have extraneous structures, such as feed-bowl rings, removed to prevent eye trauma during recovery.

Physiological Considerations

Ocular Physiology

Selection of an anesthetic protocol for intraocular surgery should include consideration of the effects on IOP, pupil size, and globe position.¹

Intraocular Pressure

Success of an ophthalmic procedure may depend on control of IOP before, during, and after the procedure. The overall effect of most anesthetics is to decrease IOP.¹⁵ This reduction may be attributable to a combination of factors, including depression of diencephalic centers regulating IOP, increased aqueous outflow, decreased venous and arterial BPs, and relaxation of extraocular musculature.¹⁶ Many of the factors affecting IOP are listed in Table 44.1.

IOP is determined by aqueous humor dynamics, intraocular (choroidal) blood volume, central venous pressure, and extraocular muscle tone.¹⁶ Normal range of IOP has been reported for dogs (10 to 26 mm Hg), cats (12 to 32 mm Hg), and horses

Table 44.1. Factors altering intraocular pressure.

Altering Factors	Change in IOP	Comments
Blockade of aqueous outflow	↑	Caused by any position or maneuver that increases CVP
Acute increase in arterial pressure	↑	Causes only a transient increase in IOP
Hypoventilation, airway obstruction, hypercapnia, choroidal vessel dilatation	↑	
Hyperventilation, hypocapnia	↓	
Endotracheal intubation	↑	Topical or IV lidocaine may prevent coughing, gagging, straining
Eyeball pressure	↑	Caused by face mask, orbital tumors, surgical traction, eyeball position, retrobulbar injection
Anesthetic drugs		
Barbiturates	↓	May depress central control of IOP or promote aqueous outflow
Propofol	↓	May prevent intubation-associated increase in IOP; may suppress depolarizing NMB-induced increase in IOP
Etomidate	↑	May be predominantly due to etomidate-induced myoclonus
Ketamine	↑ or ↓	Contradictory; effect may depend on premedication
α ₂ -Agonists	↓	Induces bradycardia, may promote OCR; may induce vomiting; may suppress sympathetic input and aqueous production
Benzodiazepines	↓	May be in response to central relaxation of ocular muscles
Acepromazine	↓	Decreases arterial blood pressure, suppresses retching and vomiting
Opioids	↓	IOP may increase with opioid-induced vomiting or retching
Neuromuscular blockers		
Depolarizing		
Succinylcholine	↑	Transient increase in IOP
Nondepolarizing		
Pancuronium	↓	Decrease or no effect
Vecuronium		
Atracurium		
Other drugs		
Methazolamide	↓	Carbonic anhydrase inhibitor; decreases formation of aqueous humor
Hypertonic solutions (mannitol)	↓	Increases plasma osmotic pressure, decrease aqueous humor formation
Phenylephrine	↑ or ↓	Effect is dosage dependent
Epinephrine	↑ or ↓	Effect is dosage dependent

CVP, central venous pressure; IOP, intraocular pressure; IV, intravenous; NMB, neuromuscular blocking agent; and OCR, oculocardiac reflex. Modified from Thurmon et al.,³ p. 814.

(mean, 23.5 to 28.6 mm Hg).^{17–19} For intraocular surgery, a low normal IOP is desirable.⁵ Lens or vitreous prolapse, expulsive choroidal hemorrhage, and subsequent retinal detachment are possible sequelae to increased IOP during or after intraocular surgery or in patients with penetrating eye wounds.⁵

Normal IOP depends on the delicate balance between aqueous inflow (production) and aqueous outflow (filtration).^{1,16} Obstruction of outflow, which may dramatically increase IOP, may be induced by coughing, retching, vomiting, excessive restraint of the head and neck, or any maneuver or position that increases central venous pressure.⁵ Indeed, coughing may increase IOP by as much as 40 mm Hg.²⁰

Aqueous humor is produced primarily by the ciliary body. It flows from the posterior chamber anteriorly through the pupil into the anterior chamber. Most of the aqueous humor exits the anterior chamber via the filtration angle of the eye, following a pattern of flow referred to as *conventional outflow*.¹ In conven-

tional outflow, aqueous humor enters the venous vascular system via the scleral venous plexus (analogous to Schlemm's canal in humans), drains into the vortex veins, passes through the orbital vasculature, and ultimately enters the episcleral venous system. The small percentage of aqueous humor that exits the anterior chamber via diffusion through iris stroma and ciliary body musculature is referred to as *uveoscleral* or *unconventional outflow*. In unconventional outflow, aqueous humor flows caudally to enter the suprachoroidal space and ultimately, the scleral and choroidal vasculature.¹

Intraocular (choroidal) blood volume is determined by arterial inflow, venous outflow, and tone of the intraocular vasculature.⁶ Autoregulation of choroidal blood flow minimizes the effects of arterial BP on choroidal blood volume and IOP. Sudden increases in systolic arterial BP may cause a transient increase in choroidal blood volume and IOP, but a temporary increase in outflow will adjust IOP back to normal. Sudden increases in choroidal blood

volume may also displace the vitreous forward into the anterior chamber during intraocular surgery or in patients with penetrating eye wounds. Marked IOP reductions may occur when systolic arterial pressure decreases below 90 mm Hg and choroidal blood volume decreases.⁵

A more direct, definitive relationship exists between central venous pressure and IOP.¹⁶ Increases in central venous pressure can increase IOP and choroidal blood volume by diminishing aqueous-humor outflow into the venous system.⁵ To maintain normal central venous pressure and IOP in humans, a slightly head-up position is preferred for patients undergoing intraocular surgery.⁶

Choroidal blood volume and consequently IOP increase in response to increases in PaCO₂ and decreases in PaO₂.²¹ Hypercapnia and hypoxemia induce vasodilatation, which increases intraocular blood volume accompanied by an increase in IOP. Conversely, respiratory alkalosis and hyperbaric oxygen conditions induce vasoconstriction and decreased aqueous-humor formation through reduced carbonic anhydrase activity, which decrease choroidal blood volume and IOP.²¹ In anesthetized dogs, inspired concentrations of 5% CO₂ caused a mean increase in IOP of 35.2%. Concentrations of 10% to 15% CO₂ increased IOP even higher.²¹ There is no apparent correlation between increased PaCO₂ and IOP in anesthetized horses.²² Unlike other species, horses have a greater dependence on unconventional outflow of aqueous humor, which may result in a more constant IOP during hypercapnia.

Vitreous has been described as a hydrogel consisting of a loose fibrillar network of collagen that supports the lens anteriorly and the retina posteriorly.¹ Although the vitreous volume is fairly constant, it may be decreased by administration of hyperosmotic agents, such as mannitol or glycerin. As indicated previously, vitreous may be displaced by changes in intraocular blood volume, but also by extraocular and orbicularis oculi muscle contractions. Muscle contractions and vitreous displacement that occur during an intraocular surgery, or with a penetrating eye wound, may cause expulsion of intraocular contents. Closure of the palpebrae may increase IOP anywhere from 10 to 50 mm Hg, depending on whether the closure is normal or forceful.⁶

Pupil Size

In mammals, iris musculature that controls pupil size is smooth muscle and is controlled primarily by the autonomic nervous system.²³ Parasympathetic stimulation of the iris constrictor muscle results in miosis (pupil constriction), and sympathetic stimulation of the iris dilator muscle results in mydriasis (pupillary dilation). In contrast, avian species have striated pupillary muscles, which are unresponsive to topically applied parasympatholytic or sympathomimetic agents.²⁴

Pupils are inaccessible for anesthesia monitoring during ophthalmic surgery. Although the ophthalmologist may be able to provide information about pupil size during the procedure, pupil size as an indicator of anesthetic depth is not reliable.^{25,26} Pupil size is of greatest concern in cataract-removal surgery, which requires the pupil to be widely dilated and the eye immobilized. Most anesthetic or sedative agents, with the exception of keta-

mine, will cause miosis.¹ Opioids have variable effects on pupil size among species^{27,28} and may adversely affect the mydriasis required for cataract surgery.²⁹ An intramuscular combination of hydromorphone-acepromazine caused significant miosis in dogs at 10 and 25 min after injection.³⁰ Administration of opioid antagonists (i.e., naloxone) may reverse miosis when it occurs.³¹ Prostaglandins, histamines, and other mediators of inflammation may cause miosis by a direct effect on the iris constrictor muscle.^{26,32} Consequently, antiprostaglandins and antihistamines may be administered prior to intraocular surgery. Sympathomimetic, cholinergic, and anticholinergic drugs applied topically to the eye will affect pupil size. It has been suggested that mydriasis is more difficult to achieve after the onset of sedation or anesthesia,²⁹ whereas mydriasis achieved prior to anesthetic induction or sedation is usually unaffected by the miotic properties of anesthetic and sedative drugs.¹

Globe Position

Globe motion during general anesthesia is not unusual, and position of the globe may vary among species and stages of anesthesia. However, motion is undesirable during corneal and intraocular surgery. Excessive manual traction to maintain a stable globe position may cause expulsion of intraocular contents or initiation of the OCR. In addition, eye reflexes that may be maintained during anesthesia in some species may also interfere with procedures. Paralysis with NMBs or retrobulbar regional anesthesia during general anesthesia should eliminate ocular reflexes and enable positioning of the globe without excessive manual traction, reducing the potential for expulsion of globe contents or initiation of the OCR.

Cardiovascular Physiology

Ocular patients are often elderly, with all the attendant problems associated with aging, such as loss of physiological reserve, pre-existing disease, and chronic medication administration. The depth of anesthesia required for adequate depression of ocular reflexes and globe motion to facilitate intraocular surgery often results in pronounced hypotension and may represent additional risk for elderly patients.³ Prolonged hypotension may predispose large animal patients to postanesthetic myopathy.³³ Balanced anesthesia combined with adjunctive anesthetic techniques, such as regional anesthesia or neuromuscular blockade, may allow a decrease in depth of inhalation anesthesia and a closer approximation of normal cardiovascular function.³

Oculocardiac Reflex

The OCR is a trigeminovagal (cranial nerves V and X) reflex that may be induced by pressure or traction on the eyeball, ocular trauma or pain, or orbital hematoma. Initiation of the reflex manifests as cardiac arrhythmias, which may include bradycardia, nodal rhythms, ectopic beats, ventricular fibrillation, or asystole.¹⁶ The afferent pathway of the reflex follows ciliary nerves to the ciliary ganglion and then along the ophthalmic division of the trigeminal nerve. The afferent pathway terminates in the main trigeminal sensory nucleus in the floor of the fourth ventricle. The efferent pathway starts in the fibers of the vagal

cardiac depressor nerve, resulting in negative inotropic and conduction effects. Although OCR may occur most commonly during ocular surgery, it may also occur during nonocular surgery when pressure is placed on the eyeball.¹⁶ It has been suggested that the more acute the onset, and the more sustained the pressure or traction, the more likely OCR is to occur. In people, OCR occurs most frequently during strabismus surgery in children and may be related to the degree of traction necessary to expose the medial rectus muscle during surgery.¹⁶ Hypercapnia significantly increases the incidence of bradycardia in these patients.

Atropine administration to prevent or treat the OCR is controversial in humans.¹⁶ Cardiac dysrhythmias may occur after atropine administration, especially in the presence of halothane, and may persist longer than the OCR response. In children, intravenous (IV) atropine or glycopyrrolate were more effective in preventing OCR than was intramuscular premedication with atropine, with glycopyrrolate producing less of a tachycardic effect than atropine.³⁴

Bradycardia is the most common manifestation of OCR, although other dysrhythmias are possible, as already mentioned. Treatment of OCR should begin with discontinuing stimulation. The OCR ceases when stimulation ceases, so communication with the surgeon to discontinue procedural stimulation is vital if an OCR is suspected. Fortunately, it is possible for the OCR to fatigue with repeated, prolonged stimulation.¹⁶ If bradycardia persists, treatment with atropine (0.02 mg/kg IV), or injection of lidocaine into the eye muscles to prevent transmission along the afferent limb of the reflex, may be effective.³ Precautions against initiation of the OCR should include assuring an adequate depth of anesthesia, maintaining normocarbida, and gentleness of surgical manipulation.¹⁶

Ophthalmic Medications

Eyedrops are concentrated medications that may cause systemic side effects, especially when administered to very small patients. Systemic effects may be minimized by diluting topical medications and limiting their frequency of application.^{4,16}

Cholinergic Agents

Glaucoma may be treated with cholinergic agents that decrease IOP primarily by increasing aqueous outflow. Direct-acting cholinergic agents are similar in structure to acetylcholine and produce effects similar to acetylcholine when absorbed systemically. Indirect-acting cholinergic agents are anticholinesterases. These facilitate the buildup of acetylcholine by slowing its enzymatic hydrolysis. Pilocarpine is a topical, direct-acting cholinergic agent commonly used in the treatment of glaucoma and may produce bradycardia or atrioventricular block if absorbed systemically.¹ These dysrhythmias may be similar to, and difficult to distinguish from, those produced by the OCR.³⁵ As mentioned in the section on neuromuscular blocking agents, to prevent prolongation of depolarizing neuromuscular blockade, anticholinesterase administration should be discontinued 2 to 4 weeks prior to succinylcholine administration.³⁵

Adrenergic Agents

Adrenergic agonists and antagonists are both used to treat glaucoma. Although the exact mechanisms for decreasing IOP are not clear, it is believed that the agonists primarily increase aqueous-humor outflow, whereas the antagonists primarily decrease aqueous humor production.¹ Adrenergic agonists, such as epinephrine or dipivefrin, may predispose patients to catecholamine-induced cardiac dysrhythmias. Topical application of adrenergic agonists has been associated with increased HR and BP in people.³⁶

Phenylephrine is an adrenergic agonist that is used to produce mydriasis prior to cataract surgery or in patients with uveitis. Subconjunctival phenylephrine has been associated with hypertension and pulmonary edema in a horse during anesthetic recovery.³³ In dogs undergoing cataract surgery, topical treatment with phenylephrine has been associated with arterial hypertension.³⁷ Topical application of 10% phenylephrine increased arterial BP and reflex bradycardia in normal dogs.³⁸ It has been suggested that the susceptibility of patients to the adverse effects of topically applied phenylephrine during anesthesia depends on several factors, including individual variability, frequency of application, concentration of the solution, and the anesthetic regimen.³⁹ Acepromazine may be useful in counteracting the hypertension produced by phenylephrine.^{37,39}

Timolol, a nonselective β -adrenergic antagonist that is commonly used to treat glaucoma, has been associated with more adverse systemic effects in people than have any other topically applied glaucoma medications.⁴⁰ Systemic effects in people may include bradycardia, hypotension, congestive heart failure, and exacerbation of asthma and myasthenia gravis.¹⁶ Profound bradycardia has been observed in dogs after topical administration. Significant decreases in HR and BP have been observed in anesthetized dogs within 30 min of topical timolol administration.⁴¹ Decreased IOP in both the ipsilateral and the contralateral eyes further substantiated systemic absorption of the drug. Timolol administration is contraindicated in animals with heart block, cardiac failure, or obstructive pulmonary disease.⁴¹

Carbonic Anhydrase Inhibitors

These inhibitors, such as methazolamide, decrease IOP by decreasing aqueous-humor production.⁴² Carbonic anhydrase is found in other tissues besides the eyes, most notably the red blood cells and kidneys.^{42,43} Administration of systemic carbonic anhydrase inhibitors impacts ion exchange in the kidneys, resulting in the retention of chloride and the excretion of bicarbonate and potassium. Treated patients may have metabolic acidosis and electrolyte imbalances, most notably hypokalemia and hyperchloremia. Some carbonic anhydrase inhibitors cause profound potassium excretion, as evidenced by the presence of hypokalemia despite metabolic acidosis that would typically be accompanied by hyperkalemia.⁴³

Acidosis and electrolyte imbalances may disrupt cardiovascular and neurological function. Hyperventilation would typically occur during metabolic acidosis as a compensatory mechanism, but hypoventilation during anesthesia may exacerbate the metabolic acidosis by inducing respiratory acidosis.⁴⁴ Acidosis may increase the potential for cardiac dysrhythmias during anesthesia.

Ideally, metabolic acidosis and electrolyte imbalance would be corrected prior to anesthesia, and ventilatory support would be provided to prevent significant respiratory acidosis.

Osmotic Agents

Examples of osmotic agents for treatment of glaucoma include mannitol and glycerin. These agents are usually used to produce a rapid decrease in IOP in patients with acute or subacute glaucoma, and are usually administered immediately prior to surgery. Increased central venous pressure, increased serum osmolality, and pulmonary edema have been reported in dogs treated with mannitol.^{45,46} The increase in osmolality may last for several hours. Although clinical pulmonary edema was not evident, histological evidence of pulmonary edema has been reported for dogs that received mannitol during methoxyflurane anesthesia.⁴⁷ It was suggested that pulmonary edema was less likely in patients being mechanically ventilated when compared with patients breathing spontaneously. Osmotic agents are not recommended in patients with preexisting cardiac or pulmonary disease, renal dysfunction, or dehydration.¹

Corticosteroids

Prolonged topical eye or systemic administration of corticosteroids may depress adrenocortical function.^{48,49} The need for corticosteroid supplementation in these patients prior to the stress of surgery and anesthesia has not been clearly determined. If hypoadrenocorticism is present, corticosteroids may be administered prior to anesthesia and surgery.^{50,51} It should be remembered that the coadministration of corticosteroids and NSAIDs may exacerbate the toxicity of both classes of drugs.

Anesthetic Drugs

Inhalation Agents

Inhaled anesthetics reduce IOP proportional to the depth of anesthesia in human patients during controlled ventilation and normocapnia. Reductions of 14% to 50% have been noted.¹⁶ Methoxyflurane has historically been the inhalation anesthetic preferred by ophthalmologists. It was believed to provide greater extraocular muscle relaxation, as well as a hypotonic and centrally rotated eye.^{50,52} Additionally, the slower recovery from anesthesia was preferred for ocular patients. Methoxyflurane is no longer commonly used in veterinary patients. It has been replaced with halothane, isoflurane, and sevoflurane, which provide rapid induction and recovery. Rapid recovery, however, potentially increases the risk of iatrogenic trauma or intraocular bleeding. Appropriate preoperative or postoperative medication should be used to provide a slower, calmer recovery.

In human adults, halothane decreases IOP, but in a manner that is not dose dependent and has a ceiling effect.⁵³ Isoflurane effects on IOP are similar to those of halothane.⁵³ Halothane sensitizes the heart to catecholamines,⁵⁴ which may become problematic in ocular patients that receive topical adrenergic drugs. It is not unusual for ophthalmic surgeons to administer intraocular epinephrine to dilate the pupil and control intraocular bleeding during surgery. Epinephrine may be readily absorbed through oc-

ular vasculature and produce systemic effects, such as cardiac tachydysrhythmias or premature ventricular beats, which may be exacerbated by halothane. In dogs and cats, the dysrhythmogenic dose of epinephrine is much higher when used with isoflurane,⁵⁴ possibly making it the preferred inhalation agent when used with exogenously administered catecholamines. It has been suggested that extraocular muscle relaxation and position of the globe are superior with isoflurane, but the information is anecdotal.³³

Although there is little information on the ocular effects of sevoflurane in veterinary patients, it is presumed to have effects on the eye similar to those of halothane and isoflurane. In humans undergoing nonophthalmic surgery, IOP was decreased equally in those patients receiving sevoflurane when compared with those receiving propofol.⁵⁵ In patients undergoing elective ophthalmic surgery, IOP did not increase during sevoflurane and remifentanyl anesthesia in response to tracheal intubation or laryngeal mask airway insertion.⁵⁶

Nitrous oxide (N₂O) administration is contraindicated when intraocular gas or air injection is intended for a closed eye.^{35,57} Air is sometimes injected into the anterior chamber of the eye to prevent synechia formation after corneal laceration or staphyloma repair. N₂O may diffuse into the intraocular air bubble, causing it to expand faster than the air can diffuse out, thereby increasing IOP. Sulfur hexafluoride (SF₆) may be injected into the vitreous space in retinal reattachment surgery and may expand to undesirable dimensions in conjunction with N₂O administration, resulting in increased IOP. It is recommended that if intraocular gas injection is intended in a closed eye, that N₂O be discontinued at least 15 to 20 min prior to injection. For repeat anesthetic episodes, it is also recommended that N₂O not be administered for at least 5 days after intraocular air injections and for 10 days after SF₆ injection.^{35,57}

Injectable Anesthetic Agents and Adjuncts

Anticholinergic Agents

Administration of atropine or glycopyrrolate to canine ophthalmic patients is controversial.^{50,58,59} One potential benefit is preventing the OCR, but anticholinergic administration may be undesirable in the presence of preexisting tachycardia. Conversely, anticholinergic administration may be appropriate in patients with preexisting bradycardia, or with concurrent administration of injectable drugs that may induce bradycardia (i.e., opioids and α_2 -agonists). Cannulation of the parotid duct may be more difficult during parotid duct transposition surgery if anticholinergics are administered preoperatively.⁶⁰ The potential for colic in horses contraindicates the routine administration of anticholinergics.

Topically applied atropine produces cycloplegia, which decreases aqueous filtration, and mydriasis, which predisposes patients to filtration angle closure. Both of these effects will increase IOP in dogs and people with glaucoma, but the effects of systemically administered anticholinergics on pupil size and IOP are not clear. In people, systemically administered atropine or glycopyrrolate has no effect on IOP in normal patients, and atropine has no effect on IOP in people with glaucoma.^{59,61} Atropine administered with neostigmine to reverse nondepolarizing neuromuscular blockade does not seem to increase IOP.¹⁶

Glycopyrrolate administered parenterally had no effect on pupil size or IOP in normal dogs, but the effects of atropine under similar circumstances was not investigated.⁶¹ In a retrospective study of glaucomatous dogs, anticholinergic administration did not adversely affect IOP, but only 30% of the dogs in the study had received anticholinergic treatment.⁶¹ It has been suggested that glycopyrrolate may have a lesser effect on pupil size and IOP than does atropine. This effect may be due to poor cellular penetration of end organs by quaternary ammonium compounds, such as glycopyrrolate, when compared with the tertiary amines, such as atropine. Consequently, the use of glycopyrrolate may be preferred in glaucoma patients requiring anticholinergic treatment.⁵⁹

Barbiturates and Propofol

Thiopental and pentobarbital decrease IOP.^{5,6} The mechanism for reduction is believed to be depression of the areas of the central nervous system (diencephalon) influencing IOP, and facilitation of aqueous outflow.¹⁶ Thiopental decreases IOP in both normal and glaucomatous eyes.

Although chemically dissimilar, propofol has clinical properties similar to those of thiobarbiturates.⁶² Studies in humans indicate that propofol decreases IOP and may negate the increase in IOP associated with intubation or the administration of depolarizing NMBs.⁶² The effect of propofol on IOP in children is similar to that of thiopental during induction of general anesthesia.⁶³

Etomidate

Although etomidate decreases IOP, etomidate-associated myoclonus may actually increase IOP.^{3,16} It is recommended that etomidate not be used alone for induction, but rather in conjunction with a benzodiazepine muscle relaxant (i.e., diazepam or midazolam) in patients with penetrating eye wounds.

Dissociative Anesthetics

The effects of the dissociative anesthetics in ophthalmic patients are contradictory, both for human and veterinary patients. In people, early studies indicate that ketamine increases IOP, but ketamine does not affect IOP when administered after diazepam and meperidine. When administered intramuscularly, ketamine may even lower IOP in children.⁵

Ketamine induces extraocular muscle contractions, which may increase IOP in some species.^{50,64} In horses, but not in dogs, prior administration of xylazine attenuates the increase in IOP.^{64,65} In patients with the potential for globe rupture, such as a penetrating eye wound or deep corneal ulcer, the extraocular muscle contractions and increases in IOP are undesirable, suggesting that the use of ketamine should be avoided in patients when rupture of the globe is a concern.

Ketamine causes nystagmus, which may persist even when combined with xylazine, making ketamine unacceptable as the sole anesthetic for ophthalmic procedures.^{50,65} The palpebrae remain open, the pupils dilate, and the palpebrae and corneal reflexes persist after ketamine administration.^{25,66} Ocular reflexes also persist after administration of the anesthetic combination of

tiletamine, a dissociative anesthetic, and the benzodiazepine zolazepam. Ketamine does not appear to decrease tear production in cats,⁶⁷ but the palpebrae remain open, which allows corneal drying and necessitates application of an ocular lubricant. Recoveries from ketamine administration can be very prolonged and uncoordinated, predisposing patients to ocular trauma.⁵⁰

α_2 -Adrenergic Agonists

Intramuscularly administered xylazine causes dogs and cats to vomit. Vomiting is less likely when xylazine is administered IV, but the potential still exists.⁶⁸ Consequently, xylazine should be used cautiously in patients with penetrating eye wounds.

Xylazine produces mydriasis in some species, possibly by inhibiting central parasympathetic tone to the iris or through stimulation of α_2 -adrenoceptors located in the iris.⁶⁹ In cats, rabbits, and monkeys, it has been reported that xylazine decreases IOP by depressing sympathetic function and decreasing aqueous production.⁷⁰ In horses, two studies determined that IOP could be decreased by 23% with the administration of 0.3 mg/kg xylazine IV and by 27% with the administration of 1.0 mg/kg xylazine IV.^{71,72}

Systemically administered xylazine may cause acute reversible lens opacity in rats and mice.⁷³ Topical application of xylazine produces cataract formation in the treated eye, whereas the contralateral eye remains unaffected. The mechanism for this effect is unknown. As mentioned previously, xylazine does not reduce tear production in dogs, but the combination of xylazine and butorphanol apparently works synergistically to decrease tear production significantly.¹² Xylazine does not decrease tear production in horses.⁹

Medetomidine is a more selective α_2 -adrenergic agonist. Topical administration of medetomidine decreased IOP in cats and rabbits, while producing mydriasis, suggesting that there are α_2 receptors in the eye that are involved in the regulation of IOP.⁷⁴⁻⁷⁶ In contrast, IV administration of medetomidine resulted in miosis in normal dogs, without a decrease in IOP.⁷⁷

IOP was not affected by systemically administered medetomidine in dogs that had received tropicamide (an anticholinergic and cycloplegic agent) topically. The pupil size in these dogs increased after tropicamide administration and continued to increase slightly after medetomidine administration, although it was not determined whether the continued increase was exclusively caused by the medetomidine.⁷⁸ Lens opacification has not been reported after medetomidine administration. Medetomidine may be administered as a continuous-rate infusion (CRI) in ocular patients to provide profound sedation and moderate analgesia postoperatively. The effects of systemically administered α_2 -agonists on IOP should be taken into consideration when tonometry is anticipated.

Benzodiazepines

Both midazolam and diazepam decrease IOP in dogs and cats after IV administration.^{6,79,80} The IOP decrease may be related to the centrally acting muscle-relaxant properties of the benzodiazepines. One study suggests that diazepam may negate the increase in IOP that occurs after ketamine administration.⁵

Phenothiazines

Acepromazine is a sedative with antiemetic properties that may prevent vomiting and gagging in ophthalmic patients who have undergone intraocular surgery or have a ruptured eye. In horses, acepromazine has decreased IOP as much as 20%.⁷² The longer action of acepromazine may be useful in providing a slower, quieter anesthetic recovery, thereby reducing the potential for postoperative trauma.

Analgesia

Ocular and periocular structures are richly innervated and highly sensitive. Symptoms of ocular pain include blepharospasm, photophobia, ocular discharge, rubbing of the eyes, and avoidance behavior. A variety of topical and systemic drug therapies are currently available to address pain management adequately in ophthalmic patients.

Opioids

Opioid selection for ocular patients should include consideration of quality of analgesia and appropriate duration of action. Opioids may be administered as a periodic injection or as a CRI.

Morphine decreases IOP, and other opioids are assumed to have the potential for a similar effect.⁶ Emesis, and the associated increase in IOP, is a possible side effect of opioid administration. This may suggest that opioid administration should be delayed until the patient is anesthetized. Bradycardia, which may predispose patients to the OCR, occurs with some opioids and may necessitate administration of an anticholinergic. As mentioned previously, the effects of opioids on pupil size are variable among species.^{27,28} Morphine produces miosis in dogs, rabbits, and people, and mydriasis in cats, rats, mice, and monkeys.^{27,28}

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) can inhibit both isoforms of the cyclooxygenase enzyme: COX-1 and COX-2. Although there is significant overlap in COX isoform functions, COX-1 is important for normal physiological function of the gastrointestinal tract, renal system, platelets, and blood flow to specific tissues.⁷⁹ Cyclooxygenase 2 is produced in part by macrophages and inflammatory cells that have been stimulated by cytokines and other inflammatory mediators, and is considered to be associated with the production of inflammation and pain.⁸⁰ Most of the currently used NSAIDs in veterinary medicine inhibit both COX-1 and COX-2.^{80,81} Other possible anti-inflammatory actions of NSAIDs include suppression of polymorphonuclear cell locomotion and chemotaxis through inhibition of leukotriene synthesis, decreased expression of inflammatory cytokines and mast cell degranulation, free-radical scavenging, and local anti-inflammatory effects caused by the accumulation of NSAIDs as organic acids at the site of inflammation.^{79,82–84} The responsiveness of the feline cornea to chemical stimuli of polymodal nociceptors was diminished by NSAIDs, suggesting that corneal pain may be inhibited by NSAIDs.⁸⁵ This effect may be due not only to inhibition of cyclooxygenase activity, but also to a direct effect of NSAIDs on the excitability of polymodal nerve endings.

Both systemic and topical administration of NSAIDs are widely used in ocular patients, with flunixin being the most popular. NSAIDs effectively prevent intraoperative miosis, and control postoperative pain and inflammation after intraocular procedures, as well as controlling uveitis and alleviating pain from various other ocular conditions or disease processes.⁸⁶

NSAIDs have been associated with decreased platelet aggregation, gastrointestinal ulceration and bleeding, and renal and hepatic damage.⁸⁷ Topical NSAID administration is associated with irritation of the conjunctiva, corneal cytopathy, decreased aqueous outflow, and its systemic absorption through nasal mucosa.^{88,89} The use of NSAIDs in acutely inflamed canine eyes may increase IOP, possibly due to decreased aqueous outflow.⁸⁹ Corneal complications reported with topical use of NSAIDs in humans may be attributable to the solution's vehicle, solubilizer, or preservative, rather than the active drug itself.⁷⁹

Coordination of systemic and topical NSAID application is essential to prevent excessive administration and toxicity. The NSAIDs should be used cautiously in geriatric patients, who often have preexisting renal and gastrointestinal disease.

Intravenous Lidocaine

In a preliminary study of dogs undergoing intraocular surgery, it was determined that lidocaine administered IV as a loading dose (1.0 mg/kg) followed by CRI (0.025 mg/kg/min) may provide preemptive analgesia similar to morphine administered IV as a loading dose (0.15 mg/kg) followed by CRI (0.1 mg/kg/h).⁸⁷ The exact mechanism for the analgesic effects of IV lidocaine in these patients has not been established, although inhibition of A- δ fiber and C-fiber discharges from sensory neurons of the eye may be involved.

Local and Regional Anesthesia

Local or regional anesthesia may be adequate for less invasive procedures or may be included as part of a balanced general anesthetic regimen. Topical anesthesia for diagnostic and therapeutic procedures in veterinary ocular patients usually requires accompanying sedation to gain cooperation of the patient. Topical anesthesia and sedation may be the preferred technique in ruminants and horses in which a standing procedure is anticipated or in other patients in which general anesthesia would be accompanied by unacceptable risk.

Local anesthetics applied topically are readily absorbed through mucous membranes.¹ Systemic toxicosis is possible, though unlikely, but administration to small patients should be judicious.^{90,91} Topical anesthetics can be irritating and cause transient conjunctival hyperemia, as well as damage corneal epithelium, delay corneal wound healing, and mask signs of disease or discomfort.¹ It is recommended, therefore, that topical anesthetics be reserved for diagnostic rather than therapeutic purposes. Tear production and blink reflex will be reduced after topical anesthetic administration, necessitating the application of ocular lubricant to protect the cornea after completion of the procedure.¹

Topical administration of 1% morphine sulfate solution ap-

pears to provide local analgesia in dogs with corneal ulcers.⁹² The antinociceptive effect is possibly a result of interaction with μ opioid receptors, which have been identified in small numbers in normal canine corneas, and δ opioid receptors, which have been identified in the corneal epithelium and stroma of dogs. In contrast with the local anesthetics, this local analgesic effect is produced without delaying corneal wound healing or causing any discernible tissue damage.⁹²

Administration of local anesthetic to the surface of an open wound is referred to as a *splash block*. Splash blocks may be used for intraoperative and postoperative analgesia in ocular patients (i.e., after enucleation). Bupivacaine (0.5%) is commonly used for this technique because of its longer action. The maximum dose should not exceed 2.0 mg/kg to avoid potential toxicosis. Epinephrine may be added to the bupivacaine (1:200,000) to reduce bleeding and delay systemic absorption. In a recent study assessing the duration of effect of topical local anesthetic administration, it was determined that two applications of 1 drop of 0.5% proparacaine, with a 1-min interval between drops, resulted in 25 min of reduced corneal sensation in dogs.⁹³

Regional anesthetic techniques commonly used for ocular patients include auriculopalpebral nerve block, supraorbital nerve block, and retrobulbar injection. Techniques for these nerve blocks are described elsewhere in this text.⁹⁴

The auriculopalpebral nerve, which is a terminal branch of the facial nerve (cranial nerve VII), provides motor innervation to the orbicularis oculi muscle. Blockade of the auriculopalpebral nerve eliminates forceful blepharospasms, thereby facilitating ocular examination or minor surgical or diagnostic procedures.¹ In horses, auriculopalpebral block has no adverse effects on tear production or IOP.^{74,95}

The supraorbital nerve, which is a termination of the ophthalmic branch of the trigeminal nerve (cranial nerve V), provides sensory innervation to most of the superior palpebra. Blockade of this nerve is commonly performed in sedated horses for placement of a subpalpebral lavage tube, repair of a palpebral laceration, or other similar minor procedures.¹ Other sensory nerves that are less commonly blocked include the infratrochlear, zygomatic, and lacrimal nerves.

Retrobulbar or peribulbar injection can be performed as an adjunct to sedation or general anesthesia. Retrobulbar injection of local anesthetic will block the optic (cranial nerve II), oculomotor (III), trochlear (IV), ophthalmic and maxillary divisions of the trigeminal (V), and the abducens (VI) nerves. Blockade of these nerves causes desensitization of the globe and palpebrae, akinesia of the globe, transient vision loss, pupil dilation, and decreased IOP.¹ The Peterson eye block is a well-known example of a retrobulbar technique used in cattle for regional anesthesia. During general anesthesia, retrobulbar injection has also been performed in horses to eliminate ocular movement without the accompanying disadvantages of deeper planes of anesthesia.^{33,96} Potential complications of retrobulbar injection include retrobulbar hemorrhage, trauma to the optic nerve or globe, intrathecal injection of local anesthetic, and death.⁹⁰ Retrobulbar injection has been advocated to prevent the OCR, but performance of the technique itself has the potential to elicit the OCR.^{1,16} Large vol-

umes of local anesthetic or orbital hemorrhage may cause either proptosis of the globe or displacement of the vitreous if the globe has been penetrated.¹

Neuromuscular Blocking Agents

Paralysis of extraocular muscles relaxes the eye, allowing the globe to roll centrally and proptose slightly. These effects greatly facilitate positioning of the globe for ophthalmic surgery,^{97,98} eliminating the need for significant surgical manipulation to obtain proper globe positioning and decreasing the potential for initiating the OCR.⁵⁸

Depolarizing NMBs, such as succinylcholine, increase IOP just prior to paralysis in horses and people.^{5,6,99} This effect may be due to an increase in choroidal vascular dilatation, or initial contraction of extraocular and orbital musculature. The increase in IOP subsides after approximately 8 min.¹⁰⁰ Although the increase in IOP would indicate that the use of succinylcholine should be avoided in patients with severely compromised eyes that are at risk for rupture, administration in patients with intact globes would seem reasonable as long as enough time was allowed for the increase in IOP to subside prior to incision.

Nondepolarizing NMBs do not appear to increase IOP.³⁵ Studies have indicated that vecuronium and pancuronium decrease IOP, whereas atracurium has no effect on IOP in people and dogs.^{101–105}

As mentioned previously, indirect-acting cholinergic drugs are anticholinesterases that are used for treating glaucoma. Because anticholinesterases inhibit or inactivate the plasma pseudocholinesterases responsible for the metabolism of succinylcholine, they may cause prolonged paralysis.¹⁰⁶ It has been recommended that indirect-acting cholinergic drugs be discontinued 2 to 4 weeks prior to neuromuscular blockade with succinylcholine, although normal levels of plasma pseudocholinesterase activity may not be totally restored for 4 to 6 weeks.³⁵

The effects of depolarizing NMBs are not reversible, whereas those of the nondepolarizing NMBs are reversible with anticholinesterases, such as neostigmine and edrophonium. Anticholinesterases are not associated with increases in IOP.³ An anticholinergic (e.g., atropine or glycopyrrolate) is commonly administered prior to the anticholinesterase to prevent profound bradycardia in small animals and ruminants. Although the use of anticholinergics is usually avoided in horses, anticholinesterases may still be used for nondepolarizing NMB reversal, but should be administered very slowly while the HR is monitored. Alternatively, the use of nondepolarizing NMBs with a briefer action, such as atracurium, may be more desirable to avoid the need for reversal.³ Neuromuscular paralysis reversal should be complete to prevent hypoventilation, struggling during recovery, self-trauma, and increases in IOP.

As mentioned previously, birds have striated rather than smooth iris musculature and may require paralysis to produce mydriasis. Topically applied parasympatholytic or sympathomimetic agents are ineffective in birds.¹ Intracameral injection of *d*-tubocurarine has produced mydriasis in pigeons.¹⁰⁷ Apnea and salivation occurred in raptors after intracameral injection of

muscle relaxants.²⁴ Topically applied vecuronium was found to produce the most consistent and greatest pupillary dilation in three species of psittacines with the fewest systemic side effects when compared with *d*-tubocurarine and pancuronium.¹⁰⁸ However, the differences in systemic side effects among the three psittacine species indicate that vecuronium should be used cautiously when applied bilaterally.

The use of sequential nondepolarizing and depolarizing NMBs is controversial.³ In humans, a small amount of nondepolarizing NMB is administered first to block the initial muscle contractions of the depolarizing NMB. The depolarizing NMB is then administered to produce immobilization and allow intubation. Although this technique prevents coughing and gagging, and muscle fasciculations are not evident, IOP still increases during intubation.¹⁶

Increases in IOP may occur with increases in PaCO₂, necessitating mechanical ventilation, which may be facilitated by the administration of NMBs. It has been suggested, however, that hyperventilation may fail to decrease IOP because of the increases in intrathoracic and central venous pressure accompanying the use of mechanical ventilation.¹⁰⁵

Electroretinography and Anesthesia

Electroretinography (ERG) is used primarily as a diagnostic test for progressive retinal atrophy or other degenerative retinal disorders, and to assess retinal integrity in dogs for which ophthalmoscopic evaluation of the fundus is not possible prior to cataract surgery.¹⁰⁹ Complete ocular akinesia is preferred during the ERG, which requires general anesthesia, and possibly neuromuscular blockade. The ERG requires dark adaptation of the patient and is performed in the dark, which makes anesthetic monitoring a challenge. There has been no standard generated for the ERG in unanesthetized patients.¹⁰⁹ Halothane and isoflurane depress the ERG in dogs, but the results are considered useful as long as the ERG for the patient and the control animal are generated under identical anesthesia conditions.^{1,110,111} No single anesthetic protocol has been established for the performance of ERGs, although propofol induction with isoflurane maintenance has been used successfully in dogs.¹¹² Sedation and a cooperative patient may prove adequate for a semiquantitative ERG as is typically performed for preoperative screening of cataract patients.¹

- Care of Newborns
- Perioperative Pain Management

Introduction

The ideal anesthetic protocol for cesarean section would provide ample analgesia, muscle relaxation, and sedation or narcosis for optimal operating conditions and safety without unduly endangering either mother or fetus. By their very nature, anesthetics, analgesics, tranquilizers, and sedatives cross the blood-brain barrier. Because the physicochemical properties that allow drugs to cross the blood-brain barrier also enable their placental transfer, it is not possible to selectively anesthetize the mother. Agents that affect the maternal central nervous system will also produce fetal effects, which effects are generally characterized by depression and decreased viability. In many cases, cesarean section is an emergency procedure. Due to the emergent nature of surgical fetal extraction, the physical condition of the mother and fetus is less than optimal because veterinary assistance has been delayed. Thus, the veterinarian is faced with the dilemma of having to anesthetize the mother, who may already be compromised, without adversely affecting the fetus.

Selection of an anesthetic protocol for cesarean section should be based on safety of the mother and fetus, patient comfort, and veteri-

narian's familiarity with the anesthetic technique. Factors in decision making regarding anesthesia protocol include considerations of the physiological alterations induced by pregnancy and labor, the pharmacology of selected drugs and their direct and indirect effects on the fetus and neonate, the benefits and risks of the techniques chosen, and the risk of procedure-related complications associated with anesthetic management. Regardless of the technique used, a major goal associated with drug selection should be to minimize fetal depression. This may be achieved by surgical expediency, which decreases maternal recumbency time and fetal drug absorption. This goal is of major importance in the larger species. With prolonged uterine isolation prior to fetal delivery, placental perfusion decreases, resulting in fetal hypoxemia, acidosis, and distress.

Physiological Alterations Induced by Pregnancy

Metabolic demands of gestation and parturition are met by altered physiological function (Table 45.1). Most of the data describing physiological alterations of pregnancy have been obtained from data collected in humans and ewes. Although little work has been done in other species, the changes should be comparable, if not greater, in magnitude. Birth weight expressed as percentage of maternal weight for people, sheep, dogs, and cats is 5.7%, 11.4%, 16.1%, and 13.2%, respectively.¹ This suggests that the physiological burden and therefore physiological alterations may actually be greater in animals than in women.

Cardiovascular

During pregnancy, maternal blood volume increases by approximately 40%; plasma volume increases more than red cell mass, resulting in decreased hemoglobin concentration and packed cell volume.² Increased heart rate and stroke volume cause cardiac output to increase 30% to 50% above normal.^{3,4} Plasma estrogens decrease peripheral vascular resistance, resulting in an increase in cardiac output while systolic and diastolic blood pressures remain unchanged. During labor and the immediate postpartum period, cardiac output increases an additional 10% to 25% as a result of blood being extruded from the contracting uterus.⁵ Cardiac output during labor is also influenced by body position, pain, and apprehension.² During labor, systolic pressure increases by 10 to 30 mm Hg. Although central venous pressure does not change during pregnancy, because of increased venous capacity, it increases slightly (4 to 6 cm of water) during labor and has been reported to increase by 50 cm of water during

Table 45.1. Physiological alterations induced by pregnancy.

Variable	
Heart rate	↑
Cardiac output	↑
Blood volume	↑
Plasma volume	↑
Packed cell volume, hemoglobin, and plasma protein	↓
Arterial blood pressure	o
Central venous pressure	o, ↑ During labor
Minute volume of ventilation	↑
Oxygen consumption	↑
pH _a and PaO ₂	o
PaCO ₂	↓
Total lung and vital capacity	o
Functional residual capacity	↓
Gastric emptying time and intragastric pressure	↑
Gastric motility and pH of gastric secretions	↓
Gastric chloride ion and enzyme concentration	↑
SGOT, LDH, and BSP retention time	↑
Plasma cholinesterase	↓
Renal plasma flow and glomerular filtration rate	↑
Blood urea nitrogen and creatinine	↓
Sodium ion and water balance	o

o, no change. BSP, sulfobromophthalein sodium; LDH, lactate dehydrogenase; PaO₂, arterial oxygen partial pressure; PaCO₂, arterial carbon dioxide partial pressure; pH_a, arterial pH; SGOT, serum glutamic-oxaloacetic transaminase.

painful fetal extraction.⁶ The posterior vena cava and aorta can be compressed by the enlarged uterus and its contents during dorsal recumbency. This can cause decreased venous return and cardiac output with resultant decreased uterine and renal blood flow. Although this does not appear to be as serious a problem in dogs and cats, time spent restrained or positioned in dorsal recumbency should be kept to a minimum.^{7,8}

Because cardiac work is increased during pregnancy and parturition, cardiac reserve is decreased. Patients with previously well-compensated heart disease may suffer pulmonary congestion and heart failure caused by additional cardiac workload associated with gestation and the increased hemodynamic demand secondary to parturition-associated pain. In such patients, pain and anxiety control is a key component of successful management. However, care must be taken to avoid additional cardiac depression and decompensation induced by excessive doses of sedatives or anesthetics. The use of ecbolic agents during or after parturition can adversely affect cardiovascular function. Oxytocin in large or repeated doses induces peripheral vasodilation and hypotension, which can adversely affect both mother and fetus through decreased tissue perfusion. Ergot derivatives induce vasoconstriction and hypertension.⁹

Pulmonary

During pregnancy, increased serum progesterone concentration enhances respiratory center sensitivity to arterial partial pressure

(tension) of carbon dioxide (PaCO₂). As a result of increased ventilatory minute volume, PaCO₂ progressively decreases during gestation and is near 30 mm Hg at parturition. Because of long-term renal compensation, respiratory alkalosis does not affect arterial pH. Ventilation may be further increased during labor by pain, apprehension, and anxiety. Oxygen consumption increases by 20% owing to the developing fetus, placenta, uterine muscle, and mammary tissue. Arterial oxygen tension remains unchanged.²

Pregnancy also affects the mechanics of ventilation. Airway conductance is increased and total pulmonary resistance is decreased by progesterone-induced relaxation of bronchial smooth muscle. Lung compliance is unaffected. Functional residual capacity (FRC) is decreased by anterior displacement of the diaphragm and abdominal organs by the gravid uterus. In addition, during labor, FRC decreases further because of increased pulmonary blood volume subsequent to intermittent uterine contraction. Because of the decrease in FRC, airway closure at end exhalation develops in approximately one-third of human parturients during tidal ventilation.² Total lung capacity and vital capacity are unaltered. Because FRC is decreased, hypoventilation induces hypoxemia and hypercapnia more readily in pregnant than nonpregnant patients. Hypoxemia is exacerbated by increased oxygen consumption during labor. Oxygen administration prior to anesthetic induction increases oxygen reserve by facilitating pulmonary denitrogenation. Preoxygenation is advisable if a patient is tolerant.

Induction of anesthesia with inhalation agents is more rapid in pregnant than nonpregnant patients. Equilibration rate between inspired and alveolar anesthetic partial pressure is accelerated by increased alveolar ventilation and decreased FRC. Additionally, increased progesterone and endorphin levels in the central nervous system decrease anesthetic requirements. Minimum alveolar anesthetic concentration values are reduced in pregnant compared with nonpregnant ewes. Thus, anesthetic induction may be extremely rapid, requiring as little as one-fourth to one-fifth the time required for nonpregnant patients.¹⁰ Care must be taken to prevent volatile-agent overdose in pregnant patients.

Gastrointestinal

A number of functional changes in gastrointestinal tract physiology occur with gestation and parturition. Physical displacement of the stomach by the gravid uterus, decreased gastric motility, and increased serum progesterone delay gastric emptying during gestation and are manifest during the last trimester. Acid, chloride, and enzyme concentrations in gastric secretions are increased associated with altered hormone physiology during gestation. Lower esophageal sphincter tone is decreased, and intragastric pressure is increased. Pain and anxiety during labor have been shown to decrease gastric motility further.²

As a result of altered gastric function, the risk of regurgitation (both active and passive) and aspiration is greater in parturients. Because increased gastric acidity and decreased gastric muscular tone may be present, metoclopramide and an H₂ antagonist drug (cimetidine, ranitidine, or famotidine) may be administered as part of the preanesthetic protocol.¹¹ Frequently, patients pre-

sented for cesarean section have been fed or the time of the last feeding is unknown. Parturients should be regarded as having a full stomach, and anesthesia techniques should be selected that produce rapid airway management and control to prevent aspiration of foreign material. Incidence of vomiting is increased by hypotension, hypoxia, and toxic reactions to local anesthetics. Smooth induction of general anesthesia and prevention of hypotension during epidural anesthesia will decrease the incidence of vomiting. Because silent regurgitation can occur when intragastric pressure is high, a cuffed endotracheal tube is preferred for airway management. Passive regurgitation can be induced by positive-pressure ventilation with a face mask or by manipulation of abdominal viscera. Atropine administration may increase gastroesophageal sphincter tone, thereby helping to prevent regurgitation, but may also inhibit the actions of metoclopramide that increase gastric motility and emptying by sensitizing gastric smooth muscle to acetylcholine.^{6,11}

Liver and Kidney

Pregnancy induces minor alterations in hepatic function. Plasma protein concentration decreases slightly, but total plasma protein is increased because of the increase in blood volume. Bilirubin concentration is unaltered. Serum enzyme concentrations (serum alanine aminotransferase [SALT] and alkaline phosphatase) are slightly increased, and sulfobromophthalein sodium retention is increased. Plasma cholinesterase concentration decreases. Despite these alterations, overall liver function is generally well maintained.²

Decreased plasma cholinesterase may lead to prolonged action of succinylcholine in pregnant patients, particularly if they have been exposed recently to organophosphate parasiticides (e.g., anthelmintic, flea collars, or dips). Normal or slightly elevated blood urea nitrogen or creatinine levels may indicate renal pathology or compromise in parturient patients. It would appear wise in such patients to avoid the use of drugs with known nephrotoxic potential, such as methoxyflurane, aminoglycoside antibiotics, and nonsteroidal anti-inflammatory drugs.

Renal plasma flow and glomerular filtration rate are increased by approximately 60% in pregnant patients, so blood urea nitrogen and creatinine concentrations are lower than in nonpregnant patients.⁶ Sodium and water balance are unaffected.

Uterine Blood Flow

Maintaining stable uteroplacental circulation is important to fetal and maternal homeostasis and neonatal survival. Uterine blood flow is directly proportional to systemic perfusion pressure and inversely proportional to vascular resistance created in myometrial blood vessels. Placental perfusion is mainly dependent on uteroplacental perfusion pressure; however, placental vessels have rudimentary mechanisms for changing vascular resistance. Obstetric anesthesia may decrease uterine blood flow and thereby contribute to reduced fetal viability. In addition, uterine vascular resistance is indirectly increased by uterine contractions and hypertonia (oxytocic response). Placental hypotension is induced by hypovolemia, anesthetic-induced cardiovascular depression, or sympathetic blockade producing reduced uterine perfusion pres-

sure. Uterine vasoconstriction is induced by endogenous sympathetic discharge or by exogenous sympathomimetic drugs having α_1 -adrenergic effects (epinephrine, norepinephrine, methoxamine, phenylephrine, or metaraminol).^{2,12,13} Hypotension induced by adjunctive drugs and increased uterine tone induced by ecbolics should be avoided.

Summary

Parturients are at greater anesthetic risk than are healthy nonparturient patients because of pregnancy-associated physiological alterations. Cardiac reserve diminishes during pregnancy, and high-risk patients can suffer acute cardiac decompensation or failure. Pregnant patients are prone to hypoventilation, hypoxia, and hypercapnia because of altered pulmonary function. Inhalation and local anesthetic requirement is decreased, thus increasing the likelihood of a relative overdose and excessive depression. Finally, emesis or regurgitation and aspiration can occur if induction is not immediately followed by rapid airway control.

Pharmacological Alterations Induced by Pregnancy

Pregnancy-associated alterations in physiological function affect the uptake, distribution, and disposition of anesthetic agents and adjuncts. The concentration of free (nonionized, unbound) drug in maternal plasma depends on uptake from the drug administration site, protein binding, distribution to maternal tissues, placental transfer, biotransformation by maternal liver, excretion, and fetal distribution and metabolism. The effects of pregnancy on several anesthetic agents have been studied. The rate of barbiturate biotransformation appears to be decreased in pregnancy.¹⁴ Also, succinylcholine and procaine metabolism are decreased because of decreased plasma cholinesterase concentration; however, this effect is not clinically significant in most cases.¹⁴ Increases in renal blood flow and glomerular filtration associated with pregnancy should favor renal excretion of drugs. Inhalation anesthetic dose (minimum alveolar anesthetic concentration) is reduced for all agents.

The placenta is highly permeable to anesthetic drugs. The physiochemical properties that make a molecule a good anesthetic drug also enable rapid transfer across the uteroplacental interface. Anesthetic drugs administered to the mother cross the placenta and induce fetal effects proportionate to those observed in the mother. Placental transfer of drugs can occur by several mechanisms; by far, the most important is simple diffusion.

Diffusion across the placenta is determined by molecular weight, the degree to which the drug is bound to maternal plasma proteins, lipid solubility, and degree of ionization. Drugs with low molecular weight (MW < 500 daltons), a low degree of protein binding, high lipid solubility, and poor ionization diffuse rapidly across the placenta. Drugs with high MW (>1000 daltons) that are highly protein bound, have low lipid solubility, and are highly ionized cross the placenta slowly. Most anesthetics and anesthetic adjuncts diffuse quickly across the placental bar-

rier because of their low molecular weight, high lipid solubility, low degree of ionization, and low percentage of protein binding. The muscle relaxant drugs are an exception because they are highly ionized and of low lipid solubility. Although they can be recovered from fetal blood, they are generally regarded as having minimal placental transfer and negligible fetal effect.^{14,15} The placenta does not appear to metabolize anesthetics or anesthetic adjuncts.

Physiochemical properties and physiological/pharmacokinetic events that occur within the fetus and dam also affect placental drug transfer.¹⁴ The degree to which a drug is ionized is determined by its pK_a and pH of the patient's body fluids. Drugs that are weak acids will be less ionized as pH decreases.¹⁵ For example, thiopental is a weak acid with a pK_a of 7.6. In acidemic patients ($pH < 7.4$), a greater proportion of the administered dose is in the nonionized form. As the ionized form of the drug decreases, the dose fraction that is protein bound is reduced, thus effectively increasing the effect on a milligram basis. As a result, it is well recognized that acidemia decreases the required anesthetic dose of thiopental and other barbiturates. Weakly basic drugs such as opioids and local anesthetics are more highly ionized at pH values less than their pK_a .¹⁶ Thus, their effect on the mother and fetus is less on a milligram-dose basis.

Distribution of drug between mother and fetus is also influenced by their respective blood pH. Normally, the fetal pH is 0.1 pH unit less than that of the mother. Thus, weakly basic drugs such as opiates and local anesthetics are found in higher concentration in fetal tissues and plasma than in those of the mother because of ion trapping. The lower fetal pH decreases the concentration of nonionized drug, maintaining the maternal-fetal concentration gradient and increasing nonionized drug transfer across the placenta to the fetus.¹⁷

Fetal drug concentration is altered by fetal redistribution, metabolism, and protein binding. The drug concentration in the umbilical vein is greater than drug exposure to the fetal organs (brain, heart, and other vital organs). As much as 85% of umbilical venous blood initially passes through the fetal liver, where drug may be sequestered or metabolized. In addition, umbilical venous blood containing drug enters the inferior vena cava via the ductus venosus and mixes with drug-free blood returning from the lower extremities and pelvic viscera (Fig. 45.1). Therefore, the fetal circulation buffers vital fetal tissues from sudden high drug concentrations. Binding of drug to fetal proteins may reduce bioavailability.^{14,15} Fetal drug metabolism is not efficient because the fetal microsomal enzyme system is not as active as in later life. Drug concentration and effects in the fetus can be considerably greater and last longer than in the mother. Fetal drug toxicity can be enhanced by fetal or maternal metabolism to more toxic metabolites and by drug interaction.¹⁷

The administration of a fixed dose of drugs with rapidly decreasing plasma concentration (e.g., thiopental, propofol, or succinylcholine) briefly exposes the fetus and placenta to a high maternal blood drug concentration. This is in contrast to the sustained maternal blood levels of drugs administered by continuous infusion or inhalation, which result in continuous placental transfer of drug to the fetus.^{14,17}

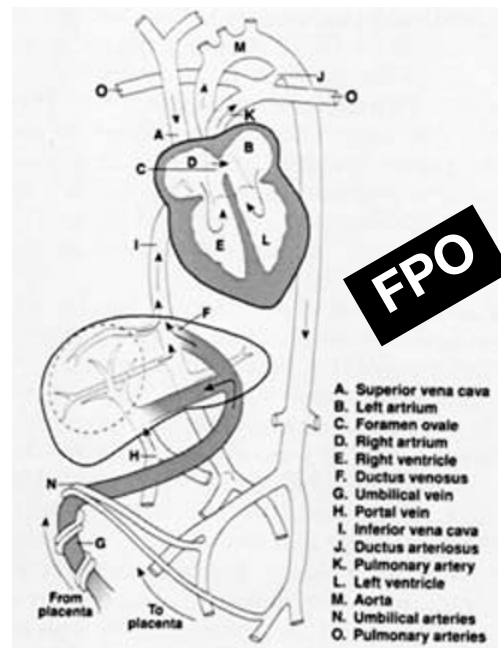

Fig. 45.1. The direction of blood flow in the fetal vascular system is indicated by *arrows*. The darkened vascular segments represent the umbilical blood and its path of flow into the liver and inferior vena cava via the ductus venosus. Blood flow through the foramen ovale and ductus arteriosus provides a direct path to the arterial system, bypassing the lungs. In neonates, the ductus arteriosus and foramen ovale closes shortly after birth. This functional closure results in blood flowing through the neonate's lungs, where it is arterialized as in the adult. The time required for anatomical closure of the foramen ovale in the foal may be as much as 12 months. Two months may be required for permanent closure of the foramen ovale.

Anesthetic Drugs and Cesarean Section

Anesthetic drugs should be carefully chosen and properly administered to avoid excessive maternal depression and to maximize neonatal vigor and viability. As noted above in the pharmacology section, the specific characteristics that make a drug an excellent anesthetic agent are also those that facilitate transplacental transfer and neonatal depression in short order. Therefore, it is prudent to consider that no agent should be used unless distinctly indicated. A brief overview of anesthetic drug classes in periparturient anesthesia follows.

Anticholinergic Agents

Anticholinergic drugs, such as atropine or glycopyrrolate, should be administered to most parturient patients to decrease salivation and inhibit excessive vagal tone that may occur when traction is applied to the uterus.^{18,19} Many parturients have recently eaten, increasing the likelihood of regurgitation, which is enhanced by hypoxia or hypotension. The influence of anticholinergics upon emesis is controversial.^{6,19} In women, atropine has not been shown to decrease the incidence of emesis at parturition.¹⁹

Glycopyrrolate increases gastric pH, thus decreasing severity of Mendelson's syndrome should regurgitation and aspiration of vomitus occur.²⁰ Additionally, because glycopyrrolate does not readily cross the placenta, it does not affect the fetus to the same extent as atropine. Therefore, it may be a more appropriate anticholinergic for use in these patients.

Tranquilizers and Sedatives

Because of their long duration of action, there are no indications for the routine use of these agents in parturient patients.^{6,16,17} They should be restricted to markedly apprehensive or excited parturients and only in doses sufficient to induce a calming effect. Acepromazine can induce significant maternal and fetal depression even at relatively low doses. Diazepam and midazolam can induce neonatal depression characterized by absence of vocalization and by lethargy, hypotonus, apnea, and hypothermia immediately following birth.²¹⁻²³ It has been suggested that these effects are dose related and can be minimized by administering low doses (<0.14 mg/kg intravenously [IV]) although no safe dose has been established in domestic animals.²³ Residual benzodiazepine-induced lethargy and muscle relaxation in either the mother or neonate can be antagonized with flumazenil, a specific benzodiazepine antagonist administered to effect.²⁴

Xylazine rapidly crosses the placenta and induces both maternal and fetal respiratory and circulatory depression. When used in conjunction with ketamine, significant and potentially life-threatening cardiopulmonary changes result in decreased tissue perfusion in healthy dogs.²⁵ The use of xylazine or xylazine-ketamine combinations probably should be avoided in small animal patients presented for cesarean section. On the other hand, xylazine-ketamine combinations have often been used in mares suffering from dystocia. Little information is available regarding use of detomidine or medetomidine in companion animal cesarean section anesthesia. Their structural and pharmacological similarities to xylazine suggest that similar precautions be observed with their use.

Opioids

These rapidly cross the placenta and can cause neonatal respiratory and neurobehavioral depression.^{17,26,27} In addition, fetal elimination may require 2 to 6 days. It appears equianalgesic doses of opioids induce equal degrees of depression. Therefore, the choice of an opioid is based on the duration of desired action. The most commonly used opioids are fentanyl, meperidine, oxymorphone, and hydromorphone, in order of increasing duration of action.¹⁷ Recently, agents having opiate agonist and antagonist activity have been used for obstetric analgesia. These agents include butorphanol and buprenorphine. They reportedly induce less respiratory depression than do pure opiate agonists. Butorphanol provides fairly predictable mild to moderate levels of sedation in some species in addition to its analgesic qualities.

One of the advantages of opioid agonists is that direct antagonists are available to reverse their action. Of the antagonist agents, naloxone (0.04 mg/kg IV) appears to be the most effective. It is a pure antagonist without agonist action. Nalorphine and levallorphan, two other antagonist agents, have opiate activ-

ity of their own and can increase respiratory depression induced by other nonopiate agents (e.g., barbiturates, phenothiazines, and inhalation agents). Because all opioid antagonists rapidly cross the placenta, maternal administration before delivery has been advocated to reverse opioid-induced neonatal depression. This technique deprives the mother of analgesia at the time when it is needed most. Therefore, these agents should be administered directly to neonates. Finally, because the action of naloxone is shorter than that of most opioid agonists, renarcotization may occur when naloxone is metabolized and excreted. Thus, both mother and neonates should be carefully monitored for recurring signs of narcosis after opioid reversal with naloxone.¹⁷ Should this occur, additional naloxone can be given.

Sedative-Hypnotics

Thiopental given IV produces rapid induction of basal narcosis for intubation and inhalation anesthesia. The pharmacological effects of thiopental on cardiovascular and respiratory function include increased heart rate, decreased arterial pressure, and changes in peripheral vascular resistance. Cerebral blood flow, oxygen consumption, perfusion pressure, and intracranial pressure decrease with thiopental administration. Apnea is common on induction. Recovery from thiopental is generally rapid because of redistribution and metabolism. Metabolism occurs primarily in the liver. Although thiopental rapidly crosses the placenta, it is also rapidly cleared from the neonatal circulation. Fetal metabolism may contribute to its rapid clearance in utero. Barbiturates can cause neonatal respiratory depression, sleepiness, and decreased activity. Suckling activity is decreased and has been reported to be depressed for 4 days in neonates.¹⁷ These effects are reduced when thiopental is administered in lower doses (<4 mg/kg).¹⁷

The administration of propofol IV produces rapid induction of basal narcosis for intubation and inhalation anesthesia. The pharmacological effects of propofol on cardiovascular and respiratory function are nearly identical to, but slightly greater than, those of thiopental: Arterial pressure and vascular resistance decrease. Cerebral blood flow, oxygen consumption, perfusion pressure, and intracranial pressure decrease as with thiopental. Apnea is common on induction. Recovery from propofol is prompt and smooth owing to rapid redistribution and metabolism. Metabolism occurs primarily in the liver, but extrahepatic metabolism also occurs. Because of its extensive distribution and rapid metabolism, recovery is very rapid in some species. Although propofol rapidly crosses the placenta, it is rapidly cleared from the neonatal circulation.

Several recent studies have compared the use of propofol in companion animal cesarean section anesthesia with more traditional general anesthesia techniques. In dogs, propofol followed by isoflurane anesthesia resulted in newborn survival rates comparable to epidural anesthesia and superior to general anesthesia induced with thiopental.²⁸ Cohort retrospective studies by Moon and coworkers^{22,23} indicated that administration of propofol IV followed by isoflurane increased puppy vigor, vocalization, and survival following surgery. Their findings were similar to those in the previously reported study by Funkquist et al.²⁸ Constant-

rate infusion of propofol as a sole anesthetic agent in pregnant ewes demonstrated maternal hemodynamics superior to those of isoflurane anesthesia.²⁹ The uterine blood-flow profile was similar in both techniques. Propofol-sevoflurane anesthesia in pregnant goats demonstrated that fetal physiology was maintained following propofol administration, but hemodynamic indices decreased after exposure to sevoflurane.³⁰ These studies support the inclusion of propofol in a balanced general anesthesia protocol for cesarean section. In dogs and cats, the induction dose of propofol is 4 to 8 mg/kg IV. Supplemental doses are 0.5 to 2.0 mg/kg IV. Longer-term constant-rate infusions of propofol to maintain anesthesia may result in some fetal depression, however. The induction dose in sheep and goats is 3 to 5 mg/kg IV.

Etomidate is a short-acting nonbarbiturate hypnotic. In dosages suitable for anesthetic induction, etomidate induces rapid anesthesia with no significant cardiovascular effects in dogs.^{31,32} Cerebral blood flow, oxygen consumption, perfusion pressure, and intracranial pressure decrease as with thiopental. Apnea is common on induction. Etomidate is rapidly redistributed and metabolized by hepatic microsomal enzymes and by plasma esterases. Fetal tissue perfusion is well maintained, as shown by more rapid initiation of neonatal spontaneous breathing and greater fetal vitality at delivery than with thiopental.³³ The induction dose of etomidate in non-premedicated dogs and cats is 1.0 to 3.0 mg/kg IV.³⁴ Based on its rapid elimination profile in cats, etomidate may be suitable for repeated administration IV in low doses in this species.³⁵ However, repeated administration of etomidate may also cause acute hemolysis, as has been reported in dogs.³⁶ Etomidate frequently causes pain on IV injection in non-premedicated patients. In addition, myoclonus or involuntary movements can occur upon injection, but can be prevented by premedication with benzodiazepines and/or opioids.

Saffan is a combination of two progesterone-like steroids (alphaxalone, 9 mg/mL, and alphadolone, 3 mg/mL). This agent can be administered intravenously or intramuscularly to cats. Anesthetic induction is smooth and rapid. Cardiovascular depression is proportionate to dose and similar to that of equivalent doses of thiopental or methohexital. Saffan induces less respiratory depression than barbiturates and is compatible with the commonly used preanesthetics, muscle relaxants, and inhalation anesthetics.³⁷ It has been shown to cross the placenta. Its use in dogs is not recommended because the solubilizing agent (cremaphore) causes severe histamine release. However, it has been used to induce anesthesia in dogs pretreated with antihistamines.³⁸ Alphaxan-CD has recently been introduced in Australia as a short-acting anesthetic for use in dogs and cats. In this formulation, alphaxalone is solubilized in a cyclodextran carrier void of histamine-releasing properties. It has proved to be an effective short-acting anesthetic with minimal cardiopulmonary depression and few adverse effects. Because of these properties, its use for anesthesia in cesarean section surgery appears promising.

Dissociatives

Ketamine has been used in general anesthesia for cesarean section. In women, doses of less than 1 mg/kg induced minimal neonatal depression.^{19,24} Alternatively, thiopental (2 to 3 mg/kg)

and ketamine (0.5 mg/kg) have been coadministered to induce anesthesia in parturient women. A more recent publication indicates that low doses of ketamine (3 to 5 mg/kg IV in dogs, 2 to 4 mg/kg IV in cats, and 2 mg/kg IV in horses) may be used for anesthetic induction.³⁹ Because effective induction doses for these agents are higher in companion animals than humans, neonatal depression is more likely to be associated with their use. A retrospective cohort study in dogs indicated that ketamine use leads to increased puppy risk associated with respiratory depression, apnea, decreased vocalization, and increased mortality at birth.^{22,23} For these reasons, ketamine should be used cautiously in this species. No data for comparative fetal viability are available in other species.

Little information is available regarding the use of tiletamine-zolazepam in cesarean section. Based on pharmacological profile, characteristics of this proprietary drug mixture are qualitatively similar to other dissociative-benzodiazepine tranquilizer mixtures. In vivo characteristics of these agents suggest that caution be used in companion animal cesarean section anesthesia, because of their rapid and extensive transplacental transfer and absence of specific antagonist agents.

Neuroleptanalgesia

The combination of opioid and tranquilizer class drugs can induce anesthesia effectively in depressed, exhausted parturients. As noted above, both opioids and tranquilizers extensively cross the uteroplacental interface and may cause significant fetal depression. These agents are usually used as an anesthetic supplement following fetal removal, although they have been successfully used for induction and maintenance prior to fetal extraction. If fetal depression is noted after administration of these agents, oral sublingual administration of naloxone (1 to 2 drops) rapidly reverses opioid effects in neonates. Continuous monitoring for neonatal renarcotization is warranted.³⁹

Inhalation Agents

Inhalation anesthetics may be used to induce anesthesia in calm or depressed dams. These agents readily cross the placenta with rapid fetal and maternal equilibration. Thus, the degree of neonatal depression is proportional to the depth of anesthesia induced in the mother. Deep levels of maternal anesthesia cause maternal hypotension, decreased uterine blood flow, and fetal acidosis. Isoflurane, sevoflurane, or desflurane are preferred because induction and recovery of mother and neonate are more rapid. Nitrous oxide can be used to potentiate their effect, thus decreasing the total amount of volatile agent administered. If nitrous oxide is administered at 60% or less, fetal depression is minimal and neonatal diffusion hypoxia does not occur upon delivery.¹⁷⁻¹⁹

Skeletal Muscle Relaxants

These cross the placenta to a very limited degree and have little effect on neonates when used in reasonable clinical doses; thus, these drugs are very useful in balanced anesthesia techniques for cesarean section to facilitate rapid airway management and provide surgical site relaxation.^{15,18,19} Because of its rapid onset of action and relatively brief duration, succinylcholine is a tradi-

tional choice when combined with an ultra–short-acting barbiturate or propofol for induction of anesthesia and airway control. Mivacurium has also been used because of its rapid onset of effect and relatively brief (15 to 20 min) duration of action. Atracurium and vecuronium provide an intermediate (20 to 35 min) duration of action.³⁹ Their characteristics make them attractive alternatives in longer procedures. The use of long-acting muscle relaxants, such as pancuronium (45 min), is generally avoided because of their length of action when compared with procedure time.¹⁷

Guaifenesin has been used to relax skeletal muscle in horses, cattle, and small ruminants. Although limited in reports, clinical impressions indicate that transplacental transfer is minimal based on vigor of the newborn after delivery.

Local Anesthetics

These are frequently used in combination with other agents or as the sole anesthetic agent for regional techniques. Esters of paraaminobenzoic acid (procaine or tetracaine) are metabolized by maternal and fetal pseudocholinesterase. Thus, there is little accumulation of these agents in the fetus. Amide derivatives (e.g., lidocaine, mepivacaine, bupivacaine, etidocaine, and ropivacaine) are metabolized by hepatic microsomal enzymes. After absorption from the injection site, blood levels decrease slowly but can reach significance in the fetus. Neonatal blood concentrations in excess of 3 µg/mL of lidocaine or mepivacaine can cause neonatal depression at delivery. These concentrations rarely occur after epidural administration but can occur with excessive volumes of drug used for local infiltration.¹⁷

Sympathetic blockade resulting in maternal hypotension and decreased uteroplacental perfusion may occur after epidural injection. This can be controlled by judicious administration of IV fluids to offset increased capacity of the vascular tree.¹⁷ In addition to IV fluids, vasopressors can be used to treat maternal hypotension caused by sympathetic blockade. Because ephedrine acts centrally and has minimal arterial vasoconstrictor properties while increasing venous tone and thereby preload, it can be used to treat maternal hypotension, thus restoring uterine blood flow. Mephentermine acts in a similar manner. Other agents with α -adrenergic activity increase maternal blood pressure by increasing systemic vascular resistance. This may cause uterine blood flow to decrease, and fetal deterioration often occurs. In addition, these agents can stimulate hypertonic uterine contractions, further decreasing uteroplacental perfusion.^{17,19}

Anesthetic Techniques for Cesarean Section

General Anesthesia

Cesarean section anesthesia can be accomplished either by regional or general anesthesia. Advantages of general anesthesia include speed and ease of induction, reliability, reproducibility, and control. General anesthesia provides optimum operating conditions with relaxed immobile patients. Tracheal intubation ensures control of the maternal airway, thereby preventing aspiration of vomitus or regurgitated rumen contents. In addition, it

provides a route for maternal oxygen administration, thereby improving fetal oxygenation. When general anesthesia is administered properly, maternal cardiopulmonary function is well maintained.^{19,39}

General anesthesia may be more appropriate than regional anesthesia in selected clinical situations. These include maternal hypovolemia, prolonged dystocia in which the mother is exhausted and the fetus is severely stressed, maternal cardiac disease or failure, morbid obesity, cases in which the mother is so aggressive or fractious as to preclude regional anesthesia, and brachycephalic dogs with upper airway obstruction. Finally, most veterinarians are more confident of their ability to induce general anesthesia safely than to use regional anesthesia techniques.

General anesthesia does have certain disadvantages. It will likely produce greater neonatal depression than will regional anesthesia. Inadequate anesthetic plane causes maternal catecholamine release, which may result in hypertension and decreased uteroplacental perfusion, leading to both maternal and fetal stress and deterioration of cardiopulmonary function.^{12,13,26} Loss of airway protective reflexes following anesthetic induction may produce aspiration and airway management challenges when the trachea is not properly intubated. Aspiration and inability to intubate the trachea successfully are the leading causes of maternal mortality associated with cesarean section in women.^{19,39} Fortunately, dogs, cats, and horses are relatively easy to intubate because of their anatomical features. However, ruminants and swine are relatively difficult to intubate, and this presents problems for most veterinarians in rural practice.

Dystocia in mares is an emergency in which duration has a profound effect on the survival of foals.⁴⁰ Foals are normally delivered within 20 to 30 min after chorioallantoic membrane rupture. Few foals survive when the duration is increased to 40 min, and none are likely to survive when the duration is 90 min or longer.^{41,42} In a recent article, the time from chorioallantoic rupture to delivery was significantly different in surviving foals (71.7 ± 34.3 min) when compared with nonsurviving foals (85.3 ± 37.4 min).⁴⁰ This makes dystocia in mares more of an emergency than it is for most species, where as little as 15 min can mean the difference between a live and dead foal. Importantly, the method of resolving a dystocia has an impact on the time from chorioallantoic rupture to birth. Four procedures can be attempted: assisted vaginal delivery (AVD), in which the mare is awake and manually assisted to some degree; controlled vaginal delivery (CVD), where the mare is anesthetized and the clinician is in control of delivering an intact foal; fetotomy, where the dead fetus is reduced to more than one part and removed vaginally in the awake or anesthetized mare; and cesarean section, where the fetus is removed through a uterine incision by celiotomy.⁴³ It has been suggested that CVD, followed rapidly by cesarean section if initial attempts are unsuccessful, is the best choice for dystocia resolution.⁴⁰

Physical examination, anesthetic induction, and delivery should be accomplished in the shortest period possible when there is the chance of delivering a live foal.⁴⁰ Time-consuming methods of anesthetic induction in mares should be abandoned in favor of methods that provide reliable sedation and smooth con-

trolled induction with favorable recoveries. Sedation can be achieved rapidly with xylazine (0.8 mg/kg IV) followed by induction with ketamine (2.2 mg/kg IV) and diazepam (Valium, 0.08 mg/kg IV). Anesthesia is then maintained with isoflurane or halothane in 100% oxygen.⁴⁰ While CVD is attempted, the ventral abdomen is clipped and prepped so that, if needed, cesarean section may be accomplished rapidly. In one report this approach to dystocia resulted in 94% of the CVD mares and 89% of the cesarean section mares surviving to discharge with a 42% delivery of live foals. Nearly 30% of foals survived to discharge.⁴⁰ In these scenarios, specific choice of anesthetic agent is probably less important than the time to induction and delivery of the foal.

Much of the previously published recommendations for anesthesia of term mares has been extrapolated from work done in other species and may not be relevant. Goals for delivering anesthesia are no different than for other species, but with a greater emphasis placed on rapid completion of the procedure. Laboring mares are typically agitated and distressed prior to anesthetic induction, and good sedation is therefore important to ensure a smooth and safe induction. Xylazine and detomidine will provide sufficient sedation and can be reversed in neonates after delivery. Detomidine may cause less increase in uterine tone than xylazine and has been suggested by some as the sedative of choice in mares.⁴⁴ When butorphanol is combined with xylazine or detomidine, reliable restraint and analgesia occur. The dose of xylazine or detomidine can be lowered when combined with butorphanol, minimizing potential side effects of the α_2 -agonists.

There is little work regarding use of tiletamine-zolazepam in mares presenting for dystocia, but based on pharmacological profile, it should be similar to other dissociative-benzodiazepine tranquilizer anesthetic combinations. It has been suggested that because of the potential for ion trapping, the use of benzodiazepines should be avoided in mares presenting for cesarean section,⁴⁵ but there is no evidence to support that this occurs excessively in foals. Ketamine is rapidly cleared from maternal and fetal circulation, causes minimal cardiovascular depression, and provides for a smooth induction, making it suitable for induction in pregnant mares. Thiopental is also rapidly cleared from fetal circulation and would be acceptable for inducing anesthesia, though induction may be rough when used alone. Recent work done in pony mares has found that maintenance of anesthesia with propofol or a combination of guaifenesin, ketamine, and detomidine (GKD) preserved cardiovascular function in both the mare and fetus.^{46,47} This suggests that GKD could be suitable for anesthetic induction of term mares. Guaifenesin is a centrally acting muscle relaxant that crosses in minimal amounts to the fetal circulation. In the field where equipment is not readily available for delivering inhalation anesthesia, a mixture of guaifenesin-ketamine-xylazine has been infused to effect for up to 1 h to maintain an adequate level of central nervous system depression.⁴⁸

Studies have been done comparing the effects of isoflurane and halothane in pregnant mares, and no marked differences between the two have been demonstrated.⁴⁹ Less soluble agents (such as isoflurane and sevoflurane) would have the advantage of being more rapidly cleared from foals after delivery as compared with the more soluble agent halothane.⁴⁵

Monitoring and support of an anesthetized pregnant mare are no different than for any anesthetized horse. Care should be taken to avoid maternal hypoxia in order to maintain fetal oxygenation until delivery. Mechanical ventilation should be considered to help offset the ventilation-perfusion mismatching that occurs. When using positive-pressure ventilation (PPV) to improve oxygenation of mares, arterial blood gases should be assessed shortly after initiating PPV to ensure that the desired increase in PaO₂ is actually occurring. PPV in a mare with severe abdominal distension has the potential to drastically decrease cardiac output to all tissues, including maternal circulation to the foal. Arterial blood pressure should be monitored directly and ideally kept above 70 mm Hg by adjusting anesthetic depth and rate of fluid delivery, and by administering inotropes and vasopressors, as needed.

Mares recovering from dystocia or cesarean section may have a difficult time regaining the strength needed to stand. Special attention should be given to the condition of the recovery stall, and the floor should be cleaned of all obstetric lubricant and dried. Mares should be placed on a well-padded surface in the recovery stall and may be rope assisted during recovery when necessary.

A spectrum of techniques for induction of general anesthesia for cesarean section in dogs and cats have been reported to be satisfactory (Table 45.2).⁵⁰ All reported techniques have common strategies for successful patient management which include the following points. Induction of anesthesia must be smooth and rapid. Excitement and struggling associated with excessive restraint and poor technique must be avoided. Intubation should be accomplished quickly and ventilation supported to ensure adequate oxygenation.

Maternal oxygen administration can significantly increase fetal oxygen content. Administration of oxygen to the mother is not associated with a significant decrease in uterine blood flow or fetal acidosis.¹⁷ Fetal red blood cells have a lower 2,3-diphosphoglycerate concentration than do adult red blood cells. Thus, fetal hemoglobin can carry more oxygen at low oxygen tensions than can adult hemoglobin. Physiologically, this is important because it ensures a higher level of hemoglobin saturation at the normally low oxygen partial pressures (PO₂ of umbilical vein, 30 mm Hg) to which the fetus is exposed.^{20,51} Inspired oxygen concentrations of 50% or more during general anesthesia result in more vigorous neonates because of improved oxygenation.¹⁷ Therefore, oxygen administration is indicated regardless of the anesthetic protocol.

Tidal and minute ventilation must be critically evaluated during the anesthetic period to avoid either hypoventilation or hyperventilation. The total effect of carbon dioxide on the fetus is not clear, but passive hyperventilation of the dam causes hypocapnia with decreased uterine artery blood flow. This decreased placental perfusion causes fetal hypoxia, hypercapnia, and acidosis. With adequate arterial oxygenation, a modest increase in PaCO₂ is well tolerated by the fetus.¹⁷ Adequacy of ventilation and oxygenation may be assessed by observing rate of respiration, excursion of the chest wall and/or reservoir bag, and color of mucous membranes; by implementation of pulse oximetry; and by determination of PaCO₂ and PaO₂.

Table 45.2. Selected anesthesia techniques for elective and emergency cesarean section anesthesia in common domestic species.

Species	Drug or Technique		
	Elective Cesarean Section	Emergency Cesarean Section	Comments
Dog	<ol style="list-style-type: none"> 1. Lumbosacral epidural 2. Anticholinergic Propofol, 4–8 mg/kg Isoflurane or sevoflurane Post-removal pain meds 3. GGE, guaifenesin glycerate ester; NSAIDs, nonsteroidal anti-inflammatory drugs.

Regional Anesthesia

This is a well-established technique for cesarean section.¹⁶ There is an increased sensitivity and distribution to local anesthetic agents during gestation and parturition. As a result, the dose of local anesthetic for epidural or spinal anesthesia can be reduced by approximately one-third in pregnant patients as compared with nonparturients. Regional anesthesia (epidural or subarachnoid) has the advantages of technique simplicity, minimal exposure of the fetus to drugs, less intraoperative bleeding and, because the mother remains awake, minimal risk of aspiration.⁵² In addition, muscle relaxation and analgesia are optimal. Caudal spinal anatomy in the lumbosacral region varies by species. The spinal cord terminates at the level of the sixth lumbar vertebra in dogs, reducing the risk of subarachnoid (true spinal) injection of the anesthetic agent. The spinal cord terminates variably between L7 and midsacrum in cats, making subarachnoid injection a greater possibility.⁵³ In swine and ruminants, the spinal cord terminates at the midsacrum, making subarachnoid injection a possibility at the lumbosacral junction.

Epidural anesthesia has been successfully used in dogs and cats for cesarean section anesthesia. Traditionally, a short-acting local anesthetic (2% lidocaine) is administered at a dose of 1 mL per 3.25 to 4.5 kg of body weight in the epidural space to provide surgical site anesthesia. In recent years, epidurally administered drugs, including lidocaine and bupivacaine in a 1:1 volumetric mixture, have provided extended duration of surgical anesthesia and pain management in the early recovery period. This may be supplemented with epidural opioids and α_2 -adrenergic agonists to extend the postoperative analgesic period.

Spinal techniques work well in sows, sheep, and goats. The technique is well established and not difficult. When using this technique, it is sometimes necessary to restrain a sow's head and forelimbs. If pigs are sedated and restrained in lateral recumbency with the head extended, the soft palate may occlude the airway and the patient may suffocate. This has been observed in

sows and gilts undergoing cesarean section with spinal anesthesia without additional sedatives or tranquilizers. Because cesarean section in swine is often viewed as a last-ditch effort by producers, it is often delayed until the sow's condition has deteriorated severely. Thus, a high percentage of sows presented for cesarean section are hypovolemic and hypotensive. Fluids can be readily administered to sows via indwelling catheters placed into the ear veins prior to anesthetic administration. This will restore circulating volume and offset hypotension induced by spinal techniques.

Spinal anesthesia often induces recumbency, which may not be desirable in large ruminants. If the veterinarian prefers, standing cesarean section in cattle may be performed using either a proximal or distal paralumbar block. In cows that are in poor condition, exhausted, or in shock, the distal technique is preferred because it does not induce a scoliosis-like position and the cow is more likely to remain standing throughout the procedure.

Disadvantages of epidural or subarachnoid anesthesia include hypotension secondary to sympathetic blockade. Hypotension induced by epidural anesthesia can be managed with IV fluid and catecholamine administration. Lactated Ringer's solution or 0.9% or 0.45% sodium chloride mixed with equal volumes of 5% dextrose solution can be administered at approximately 20 mL/kg over 15 to 20 min to maintain arterial blood pressure. When hypotension is severe, ephedrine may be administered (0.15 mg/kg IV). Hypotension and visceral manipulation during the procedure can cause nausea and vomiting.⁵⁴ Because the dam remains conscious, the forelimbs and head often move. This precludes the use of a spinal technique in highly excited or fractious patients and in mares, because they become hysterical when they are unable to stand.

Local Anesthesia

Local infiltration or field block may be used, but these techniques have several disadvantages when compared with regional tech-

niques. Infiltration requires larger amounts of anesthetic agent, which are absorbed and can create fetal depression. In addition, muscle relaxation and analgesia are not as profound or as uniform when compared with regional anesthesia. In many cases, field block is supplemented with heavy sedation or tranquilization to calm and stabilize a dam; these agents further contribute to maternal and fetal depression. For these reasons, field block is often abandoned for either general or epidural anesthesia.

Care of Newborns

Following delivery, the newborn's head is cleared of membranes and the oropharynx of fluid. The umbilical vessels should be milked toward the fetus to empty them of blood, clamped approximately 2 to 5 cm from the body wall, and severed from the placenta. Neonates can then be gently rubbed with a towel to dry them and stimulate breathing. It may also be helpful to swing neonates gently in a head-down position to help clear the respiratory tree of fluid. Vigorous motion should be avoided because amniotic fluid is readily absorbed in the lungs and contributes to distribution of pulmonary surfactant in the alveoli. The head and neck should be supported to avoid whiplash and prevent injury.

Flow-by oxygen administration in the vicinity of the muzzle is helpful to increase heart rate and oxygen delivery to tissues in distressed, exhausted neonates. Reversal of opioids by sublingual administration of 1 to 2 drops naloxone is warranted in cases where opioids were administered as part of the general anesthesia technique. An oral dose of 2.5% dextrose (0.1 to 0.5 mL) is helpful to improve energy substrates required for initial breathing effort in stressed neonates. Finally, maintaining warmth is vital because hypothermia can occur rapidly after birth.

A small IV catheter may be used to intubate and support oxygen delivery in neonates that will not initiate breathing, and their breathing can be artificially supported by using a syringe and three-way valve attached to an oxygen source. As a final measure, doxapram can be used to stimulate breathing in neonates. In pups, a dosage of 1 to 5 mg (approximately 1 to 5 drops from a 20- to 22-gauge needle) is topically administered to the oral mucosa or injected intramuscularly or subcutaneously. In kittens, the dosage is 1 to 2 mg (1 to 2 drops).⁵⁰ Airways must be clear before doxapram administration. External thoracic compressions may be warranted if heart rate is slow and does not respond to support measures. A rapid physical examination checking for genetic defects (cleft palate, chest deformity, or abdominal wall fusion) is also important to determine whether viability is present.

When general anesthesia is used in ruminants or horses, an alternate method of managing neonates may be used to good advantage. After uterine incision, the fetal head is delivered through the incision, the oropharynx is cleared of fluid, and the trachea is intubated with a cuffed tube. The fetus can then be delivered and the umbilicus severed. Because the uteroplacental and umbilical circulation is preserved until the airway is secured, hypoxia is prevented. Once the fetus is delivered, ventilation can be supported, if necessary, via a bag valve mask resuscitator.

After completion of surgery and recovery from anesthesia, the young can be introduced to their mother. If introduction is de-

layed, the neonates should be exposed briefly to the mother to provide colostrum and then kept in a warm environment until anesthesia recovery is complete to avoid accidental crushing. If regional anesthesia was used, they can be placed with their mother as soon as the surgery is complete.

Perioperative Pain Management

This represents a challenge in cesarean section patients because of concerns regarding transfer of anesthetic and analgesic drugs into milk and its impact on neonates. This area has been extensively studied in people and in food-producing species. Most of the current information is from humans and cattle; however, because of the similarity of the lactation process in all mammals, the information may be extrapolated to other species.

The phenothiazine tranquilizer chlorpromazine does not appear to transfer to milk at levels that cause fetal depression.⁵⁵ No corollary evidence is available for acepromazine, but similarity in molecular structure coupled with clinical experience supports a similar effect on newborns. The benzodiazepine class tranquilizer diazepam significantly crosses into milk and may cause lethargy, sedation, and weight loss in newborns.⁵⁶ Other class members, including clonazepam and alprazolam, induce drowsiness, hypotonia, and apnea in newborns after nursing episodes. The effect of lorazepam and midazolam are unknown; however, based on the effects attributed to other class members, they should be used with caution in lactating mothers. Xylazine transiently increases in milk and then decreases to nondetectable levels by 12 h after administration.⁵⁷ Detomidine (80 µg/kg) can be detected at a low level in milk after administration but is nondetectable by 23 h later.⁵⁸

Codeine, propoxyphene, and morphine are well tolerated by newborns when used in maternal pain management, even when repeat doses are administered over several days.⁵⁹ Meperidine (pethidine) has been reported to cause decreased suckling behavior and sedation when used in serial doses.^{59,60} Fentanyl (100 µg) and sufentanil (10 to 50 µg) are not detectable in breast milk after epidural administration in humans.⁶¹

Thiopental has been detected in colostrum and breast milk after a single bolus induction dose (5 mg/kg) in women.⁶² Long-acting barbiturates such as phenobarbital are contraindicated because of their extensive presence in milk.⁵⁵ Propofol is detectable in colostrum and milk after a single-dose administration.⁶³ However, little clinical effect is noted based on excellent newborn vitality immediately after delivery.^{22,23} The residual presence of inhalation anesthetic agents in milk is not known; however, clinical experience suggests that prolonged neonatal sedation following clinical recovery of dams is not common.

Local anesthetic drugs (e.g., lidocaine and bupivacaine) and first-generation bupivacaine metabolites are excreted in milk after their epidural administration in humans. Although these agents are detectable in milk, their influence on neonates is negligible based on maximum Apgar (activity, pulse, grimace, appearance, and respiration) scores at delivery.⁶⁴

Nonsteroidal anti-inflammatory drugs appear to reach only limited levels in milk after maternal administration. In humans,

acetaminophen and aspirin are considered compatible with breast feeding.⁵⁹ Studies evaluating carprofen in cattle indicated that milk levels were below detectable limits (<0.022 µg/mL) after a single-dose administration. After experimental induction of mastitis, carprofen was detected at low levels (0.16 µg/mL) for 12 h following single-bolus administration and decreased to undetectable levels (<0.022 µg/mL) by 24 h.⁶⁵ Following a single dose of ketoprofen (3.3 mg/kg) in cattle, nonquantifiable concentrations of ketoprofen were detected in milk for only 2 h.⁶⁶ Similar results have been reported in lactating goats.⁶⁷

With the possible exception of the nonsteroidal anti-inflammatory drugs and their potential for inhibiting newborn organ maturation, it appears that most commonly used analgesic drug classes may be safely administered during the lactation period without adverse effects on newborns.

Introduction

Proper care of trauma or critical patients requires advanced planning, an ordered protocol, and efficient use of time and resources. When a team approach is taken in the emergency room, with each member of the team given preassigned duties, rapid evaluation and treatment are possible. Airway, breathing, circulation, and neurological status should be immediately assessed upon a patient's arrival, and circulation, ventilation, and neurological function should be reassessed frequently during the initial treatment period. Respiratory rate and effort, heart rate and rhythm, blood pressure, pulse quality, capillary refill, central nervous system (CNS) function, and pain should be evaluated to determine the patient's status and prognosis.¹ Severely traumatized or critical patients are subject to a variety of complications that may manifest in the first few days following presentation. These complications may not be directly related to the initial insult, but reflect overall tissue destruction, immune suppression, and metabolic imbalances. These complications may be septic, nonseptic, or both in origin.^{2,3}

Critically ill patients should always be considered likely candidates for developing some form of *shock*, a state of generalized inadequate tissue perfusion. Hypotension usually accompanies shock, but during early compensation, shock can occur with normal blood pressure. Shock may result from blood loss, poor car-

diac function, sepsis, or interruption of tissue blood flow. The probability of recovery from shock is related to the magnitude of the oxygen debt that occurs. After an overwhelming injury or infection, the sequelae to oxygen debt may not be reversible. Inadequate resuscitation, another major insult (e.g., anesthesia and surgery), or several small insults during this time often result in death.

When anesthetizing critically ill patients, the primary goal is to optimize tissue perfusion and oxygen delivery to all vital organ systems while inducing unconsciousness, an appropriate degree of analgesia, and muscle relaxation. The ultimate goal of therapy should be optimal physiological function rather than restoration of measured hemodynamic parameters to normal. Values generally considered normal for healthy anesthetized patients are associated with higher rates of mortality in high-risk patients. In prospective studies of human trauma patients, survivability is associated with cardiac indexes 50% higher and blood volumes 110% to 120% higher than normal at the end of surgery.⁴ These values are necessary to meet the increased metabolic demand of fever and tissue repair in posttrauma and postoperative patients (Table 46.1).

Traumatized or critically ill patients are often near cardiopulmonary collapse or arrest. Causes of acute circulatory failure in these patients include severe myocardial ischemia, malignant dysrhythmias, hypoxemia associated with severe lung damage or airway obstruction, hemorrhagic shock, acid-base or electrolyte abnormalities, profound vagal tone such as is associated with the oculocardiac reflex, and electrocution. When cardiovascular collapse occurs during attempts to stabilize severely traumatized or critically ill patients, cardiopulmonary resuscitation should be instituted immediately.

Shock

Septic Shock

As a general rule, anesthesia should not be undertaken until a patient's vital organ functions have been assessed and stabilized. If the patient is in shock, the etiology should be determined and corrective measures initiated before anesthesia. Anaphylactic shock and neurogenic shock are characterized by relative hypovolemia and hypotension caused by acute increases in vascular capacitance. Hypovolemic shock and neurogenic shock are typically observed in acutely traumatized patients, whereas septic shock and the systemic inflammatory response syndrome (SIRS) develop after the initial insult. SIRS is a global activation of the

Table 46.1. Cardiovascular resuscitation goals for animals with systemic inflammatory response syndrome.

Variable	Goal
Mixed venous oxygen tension, PvO ₂ (mm Hg)	>40
Pulmonary artery pressure (mm Hg)	>25/10
Pulmonary wedge pressure (mm Hg)	218
Systemic vascular resistance (dyne × s/cm ⁻⁵ × m ²)	>1450
Pulmonary vascular resistance (dyne × s/cm ⁻⁵ × m ²)	45–250
Oxygen extraction (%)	22–30
Cardiac index (L/min × m ²)	>4.5
Oxygen delivery (mL/min × m ²)	>600
Oxygen consumption (mL/min × m ²)	>170

PvO₂, mixed venous oxygen tension.

immune system and release of many cytokines, resulting in a generalized increase in vascular permeability, neutrophil infiltration, and capillary microemboli. Early signs of SIRS and septic shock include brick-red mucous membranes, tachycardia, high cardiac output (in euvoletic patients), normal or low blood pressure, and low vascular resistance. Classifications of SIRS for dogs and cats based on the presence of various key clinical signs have been proposed and are listed in Table 46.2.⁵ Clinically, in cats, the signs of late-stage sepsis are more commonly recognized than are those of early hyperdynamic sepsis.⁶ Cats often differ from dogs in that a cat's signs of late shock include bradycardia, hypotension, and hypoglycemia.

In cats, lung function is often impaired early in SIRS because of rapid fluid accumulation. In dogs, the order of organ dysfunction is commonly gastrointestinal tract, followed by liver, kidney, and then lung. Patients suffering from noncardiogenic pulmonary edema may have this condition exacerbated by rapid crystalloid fluid administration. Persistent microcirculatory perfusion fail-

ure may lead to sludging of blood and increased immune cell and platelet aggregation. Along with the release of inflammatory mediators, these conditions result in poorly regulated coagulation and propagation of the inflammatory response. Toxic oxygen free radicals can cause further cellular damage, persistent edema, and increased oxygen diffusion distance between cells and capillaries. If oxygen delivery to tissues is chronically impaired, the systemic inflammatory state can lead to multiple organ dysfunction syndrome (MODS), traditionally defined as *irreversible shock*.

Successful management of animals with septic shock or SIRS depends on anticipation, not reaction.³ Appropriate antibiotic administration, aggressive cardiovascular support, and monitoring of the susceptible organs must be undertaken early. An algorithm depicting SIRS management is presented in Fig. 46.1.³ Therapeutic agents and doses used in the treatment of various metabolic derangements associated with SIRS are listed in Table 46.3.

Hemorrhagic Shock

Clinical signs of hemorrhagic shock most commonly encountered in acutely traumatized patients include pallor, cyanosis, disorientation, tachycardia, cold extremities, cardiac dysrhythmias, pump failure, tachypnea, hypotension, oliguria, disseminated intravascular coagulation, and progressive metabolic acidosis.¹ With acute blood loss, normal homeostatic reflexes vigorously defend blood pressure in an attempt to maintain vital organ function. As hemorrhage ensues, plasma renin levels elevate, the antidiuretic hormone level increases, and the sympathetic nervous system activates to produce tachycardia and arteriolar vasoconstriction. These mechanisms can maintain blood pressure until about 40% of normal blood volume is lost (more loss than is clinically acceptable).¹ Thus, an animal can be severely hypovolemic but normotensive. Once blood loss exceeds 40% of blood volume, compensatory organ mechanisms fail over time, and shock becomes irreversible. Prolonged poor tissue perfusion causes tissue ischemia, loss of cell membrane integrity, and cell death.¹ If the trauma involves crushing of tissues or severe burns, shock is accompanied by increased capillary permeability and rapid translocation of fluids. In addition, toxic factors from exogenous

From Purvis and Kirby.³

sources (e.g., microbial toxins) and endogenous sources (e.g., fat emboli, potassium-ion release, lysosomal enzymes, and myocardial depressant factor) are simultaneously released, causing further organ malfunction.⁷

The primary treatment of hemorrhagic shock is aggressive fluid therapy. Large-bore intravenous catheters should be placed in each cephalic vein and/or jugular veins, and warm, crystalloid solutions, blood, and/or hemoglobin-based oxygen-carrying solutions infused. If necessary, fluids can also be administered rapidly into the intraosseous space of the tibia or femur. When rapid infusion of large volumes of crystalloids decreases the concentration of serum total solids to below 3.5 to 4.0 g/dL, simultaneous colloid solution administration is advantageous in maintaining intravascular volume.⁸

Albumin is an excellent plasma expander, but is expensive and can induce immune responses. Hetastarch compares favorably to albumin and has an extremely low toxicity in people and animals.⁹ The dose of hetastarch is up to 20 mL/kg/day in dogs. In cats, a smaller volume and slower rate of administration are recommended. All colloids can affect coagulation, but rapid hemodilution with larger volumes of crystalloids can, as well. In dogs administered less than 30 mL/kg hetastarch, clotting time, clot retraction, platelet count, and whole clot lysis are not significantly affected.^{10,11} Hetastarch does, however, decrease all three components of the factor VIII-related complex. After a single

hetastarch dose, plasma expansion can last 24 to 48 h.⁹ Plasma administration decreases the continual decline of plasma protein level, but it is difficult to increase total protein significantly by plasma administration alone. The use of fresh-frozen plasma is best reserved for patients that are deficient in coagulation factors.

Hypertonic saline may be beneficial in the early treatment of hypovolemic and hemorrhagic shock.¹² Intravenous administration of small volumes (4 to 6 mL/kg) of 7.5% hypertonic saline has beneficial cardiovascular effects in hypovolemic dogs and cats.^{13–15} Increases in pressure and cardiac output appear to be mediated primarily by rapid increases in plasma volume.¹⁴ A second potential benefit of hypertonic saline administration is minimization of the risk of cerebral edema in patients with head trauma.^{16,17} Hypertonic saline (7.2% sodium chloride [formulations vary]; 4 mL/kg intravenously [IV]) may be administered over 15 min in acute hypovolemic episodes. The addition of a colloid to hypertonic saline appears to prolong its effects. It is important to remember that hypertonic saline shifts fluid from the extravascular space to the intravascular space. Total body water does not significantly increase unless additional crystalloid fluids are given soon after the hypertonic saline. Contraindications for hypertonic saline administration include hypernatremia, cardiogenic shock, renal failure, hyperosmolarity, uncontrolled hemorrhage, and thrombocytopenia (if in dextran). Hypertonic solutions may produce hyperchloremic nonrespiratory acidosis and hypokalemia.

Table 46.3. Therapeutic agents used to treat metabolic derangements associated with systemic inflammatory response syndrome.

Metabolic Derangement	Dose Regimen	Use and/or Frequency
Hypovolemia		
Hypertonic crystalloids		
7.5% NaCl solution (70 mL 23.4% NaCl in 180 mL 0.9% NaCl or 6% dextran 70)	4 mL/kg IV	Once
Colloids		
Plasma	Maximum: 20 mL/kg/24 h IV	As needed
Hetastarch 120	Maximum: 20 mL/kg/first 24 h, and then 10 mL/kg/24 h IV (slow infusion)	As needed
Dextran 70	Maximum: 20 mL/kg/first 24 h, and then 10 mL/kg/24 h IV (slow infusion)	As needed
3% Albumin (12 mL 25% human albumin in 488 mL lactated Ringer's solution)	20 mL/kg IV	Resuscitation
Isotonic crystalloids		
Lactated Ringer's solution	90–270 mL/kg IV 10–20 mL/kg/h IV	Resuscitation To meet ongoing needs
Altered clotting function		
Heparin (low dosage)	75–100 U/kg SC	Every 6–8 h
Heparin-activated plasma (incubate 5–10 U/kg heparin with 1 U fresh plasma for 30 min)	10 mL/kg IV	Every 3 h, based on clotting function
Metabolic dysfunction		
KCl	0.125–0.25 mEq/kg/h IV; do not exceed 0.5 mEq/kg/h	As needed
Glucose	50–500 mg/kg/h IV	As needed
NaHCO ₃	Base excess × 0.3 × body weight in kg = mEq needed to correct deficit, IV (slow infusion)	As needed (pH 7.1 or less)
Gastrointestinal tract dysfunction		
Cimetidine	5–10 mg/kg IV, IM, PO	Every 6–8 h
Ranitidine	2 mg/kg IV, IM, PO	Every 8–12 h
Omeprazole	0.7 mg/kg PO	Every 24 h
Misoprostol	3 µg/kg PO	Every 24 h
Sucralfate	250 mg (cats) PO 500 mg (dogs < 20 kg) PO 1 g (dogs > 20 kg) PO	Every 8–12 h Every 8–12 h Every 8–12 h
Kaolin-pectin	1–2 mL/kg PO	Every 6–8 h
Metoclopramide	0.2–0.5 mg/kg SC	Every 6–8 h
Renal dysfunction		
Mannitol	0.25–1 g/kg IV	Once (slow bolus)
Furosemide	1–2 mg/kg IV	If no effect, repeat in 2 h and increase dose by 1 mg/kg
Dopamine	1–3 µg/kg/min IV	As needed until urine production consistently > 2 mL/kg/h

IM, intramuscularly; IV, intravenously; PO, per os (orally); SC, subcutaneously; U, units.
From Hardie.⁵

Massive blood loss will eventually require transfusion of whole blood or packed red blood cells to replace oxygen-transport capacity. Hemoglobin-based oxygen-carrying solutions (e.g., Oxyglobin [bovine hemoglobin glutamer 200]) can serve to increase oxygen capacity; however, the effects are usually brief,

requiring additional blood-product transfusion. Trend monitoring of hematocrit (or hemoglobin concentration), total solids, central venous pressure, and urine output is helpful in guiding resuscitation. The use of whole blood should be reserved for patients that need cells and plasma. If the packed cell volume (PCV) is less

Table 46.4. Vasoconstrictor and mixed inotropic-vasoconstrictor drugs.

Drug (Trade Name)	Catecholamine Receptor Activation				Drug Dose and Infusion Schemes
	α_1	α_2	β_1	β_2	
Phenylephrine (Neo-Synephrine)	+++	+	– Little at high dose	–	Bolus: 0.15 mg/kg IV Infusion: 0.5–1.0 $\mu\text{g/kg/min}$
Methoxamine (Vasoxyl)	++	+	–	–	Bolus: 0.1–0.8 mg/kg IV (cardiac arrest) Bolus: 0.01–0.04 mg/kg IV (vasopressor)
Ephedrine	+	+	+	+	Bolus: 0.1–0.25 mg/kg IM; 0.03–0.07 mg/kg IV
Metaraminol (Aramine)	+	+	+	+	Bolus: 30–100 $\mu\text{g/kg}$ IM Infusion: 20–50 $\mu\text{g/kg/min}$
Mephenteramine (Wyamine)	+	+	+	+	Bolus: 0.2–0.6 mg/kg IM
Norepinephrine (Levophed)	+++	+++	+	Little	Infusion: 0.01–0.03 $\mu\text{g/kg/min}$ up to a maximum 0.1 $\mu\text{g/kg/min}$ to effect

IM, intramuscularly; IV, intravenously; NE, norepinephrine; +, positive effect; –, no effect.

^aMetaraminol replaces NE in storage vesicles in the nerve terminal. It has only one-tenth the potency of NE at α receptors and may eventually produce a hypotensive effect.

that 20% and the protein level is normal, transfuse cells. The rule of thumb is that 2.2 mL of blood/kg body weight increases the recipient's PCV by 1%; however, this depends somewhat on the hematocrit of the donor blood.

Oxyglobin is a hemoglobin-based oxygen-carrying solution that increases plasma and total hemoglobin concentration. Its elimination half-life is 30 to 40 h, but its effective action may be much shorter. Some blood tests that use colorimetric changes will be altered after the administration of Oxyglobin, because of the change in plasma color. The recommended dose in dogs is approximately 15 mL/kg IV (the label dose is up to 30 mL/kg) at a rate of 5 mL/kg/h (the label rate is 10 mL/kg/h). Patients should be carefully monitored during and after Oxyglobin administration because of its effects on vascular resistance and right atrial pressure. A more conservative dosing strategy considers trends in monitored total hemoglobin concentration (i.e., maintain 8 to 10 g/dL total hemoglobin). In cats, smaller volumes and slower administration should be used. To avoid volume overload when administering larger doses of Oxyglobin, it is recommended that central venous or right atrial pressure be monitored.

Spinal Shock

This is a common sequela to spinal cord injury or blunt trauma, which can disrupt sympathetic nervous system outflow. The patient's extremities will feel warm (peripheral vasodilation), and even though hypotension is present, heart rate is slow because of sympathetic denervation. These patients are relatively hypovolemic; that is, intravascular capacity greatly exceeds intravascular volume. Organ perfusion may or may not be adequate, and vascular resistance is drastically reduced. These patients are more susceptible to hypothermia because they cannot constrict peripheral vasculature. Fluids should be administered to increase vascular volume. If arterial pressure is low and the pulse cannot be pal-

pated, mixed inotropic-pressor-type drugs should be given to increase blood flow to vital organs. Intravenous ephedrine, mephentermine, or metaraminol are good choices in these patients (Table 46.4).¹⁸ Since resistance and flow are inversely related, the usefulness of pressors alone is limited. Use of vasopressors may compound compromised visceral perfusion and increase cardiac workload.⁶ If there is any question as to adequacy of contractility, pressors should not be used before inotropes. Not all inotropic or vasoconstrictor drugs produce equivalent hemodynamic effects. Hemodynamic responses to norepinephrine, epinephrine, and isoproterenol are illustrated in Fig. 46.2. These differences are medi-

Fig. 46.2. Differences in cardiovascular effects of intravenously administered norepinephrine (NE), epinephrine (EPI), and isoproterenol (ISO). Schematics represent relative effects on blood pressure (BP), femoral blood flow (FBF), renal blood flow (RBF), peripheral vascular resistance (PR), myocardial contractile force (MCF), heart rate (HR), and cardiac output (CO). Primary responses are noted as either α -, β_1 -, or β_2 -receptor mediated; and R, reflex mediated. Differences in cardiovascular effects of these catecholamines are caused by variation in α and β selectivity for each agonist and dose.

ated by variations in adrenergic receptor activation and dose. Indirect-acting agents such as ephedrine enhance release of endogenous norepinephrine from sympathetic neuronal terminals and also induce direct vasoconstrictive effects.

Cardiogenic Shock

This type of shock occurs when the ability of the heart to maintain cardiac output is insufficient to meet the body's demand. The circulatory compromise is caused entirely by cardiac dysfunction. Once overwhelming cardiac disease progresses and a patient can no longer compensate, signs of failure appear. If therapy does not improve systemic perfusion and the patient's ability to meet metabolic needs, the patient will die. The diagnosis and treatment of cardiogenic shock are beyond the scope of this chapter, but have been reviewed.¹⁹

Patient Monitoring and Pharmacological Support

Measurement of perfusion is challenging in veterinary patients. Lactate can be used as a surrogate measure for perfusion. In low-flow situations, tissue hypoxia results in increased anaerobic metabolism and subsequent increased lactate production. Studies suggest that trends in lactate concentration are more helpful in predicting outcome than is measuring cardiac output.^{20,21} The magnitude of the elevation is positively correlated with the magnitude of the underlying problem and negatively correlated with prognosis. The normal lactate concentration should be determined for each laboratory, but is generally less than 1.5 mM/L.

In traumatized or critically ill patients, either a continuous or intermittent electrocardiogram should be monitored with a rhythm printout obtained immediately prior to anesthesia or if abnormalities are noted. Antiarrhythmic drugs that may be useful during management of traumatized or critically ill patients include lidocaine, procainamide, and esmolol. Lidocaine can be used to treat ventricular arrhythmias (dogs: 1 to 4 mg/kg IV bolus, followed by 40 to 80 µg/kg/min IV infusion).²² Lidocaine should be used more cautiously in cats (0.25 to 1.0 mg/kg IV over 5 min).²² Refractory ventricular arrhythmias may require treatment with procainamide (1 to 10 mg/kg IV, followed by 20 to 50 µg/kg/min IV infusion).²² Since procainamide may cause profound hypotension, it should be administered in smaller doses, which are repeated when necessary. Esmolol (0.5 mg/kg slow IV, followed by 50 to 200 µg/kg/min IV infusion) is a β blocker with a very short half-life (a half-life of elimination of about 10 min) that may be used in the treatment of supraventricular tachycardias and ventricular arrhythmias. Esmolol significantly decreases contractility and should not be routinely used unless hemodynamic monitoring is available.^{23,24}

Several drugs commonly recommended for resuscitation and stabilization have been reevaluated since their introduction. Because of the potential complications of sodium bicarbonate, its use in resuscitation and intensive care units is continuously scrutinized. It has been used in advanced cardiac life support for 40 years, but its nonselective use has become controversial over the last 15 to 20 years.²⁵ In the treatment of arrest, it has gone from

being a first-line drug in the first American Heart Association's Standards for Cardiopulmonary Resuscitation and Advanced Cardiac Life Support to current recommendations that its use may be indicated in cases of protracted arrest or long resuscitative efforts with preexisting metabolic acidosis.²⁵ Reasons include lack of clinical studies of buffer therapy, knowledge that normal pH can be maintained by compression and hyperventilation, and the potential ill effects of bicarbonate therapy.²⁶

If sodium bicarbonate is used, it is reasonable that the time interval to its administration be based on the rate of metabolic acidosis development, rather than the duration of resuscitative efforts.²⁵ In dogs, serum-base deficits increase by 1.1 to 1.5 mEq/L for every minute of circulatory arrest; the arterial lactate concentration increases by 0.3 mmol/L/min (with epinephrine administration) and 0.6 mmol/L/min (without epinephrine administration) of arrest and cardiopulmonary resuscitation.²⁵

The role of bicarbonate therapy for metabolic acidosis caused by diminished oxygen delivery to tissues in critically ill or traumatized patients is also controversial.²⁷ Successful treatment of the underlying excessive intracellular production of hydrogen ions will often resolve the acidosis. It is not clear whether buffering the blood, extracellular fluid, and intracellular fluid actually slows the production of metabolic acid or simply facilitates its removal. Most current recommendations advise avoiding bicarbonate therapy for lactic acidosis unless acidosis is so severe that physiological functions are dangerously impaired. Little existing experimental data support the use of bicarbonate for the treatment of acidosis.²⁷ Additionally, bicarbonate administration is not without risk. Its potential adverse effects include negative inotropy, paradoxical cerebrospinal fluid acidosis, hypercarbia, alkalosis, vasodilation, hyperosmolarity, electrolyte disturbance (e.g., hypokalemia and hypocalcemia), shifting of the oxyhemoglobin-dissociation curve (i.e., decreased oxygen delivery because of increased affinity of hemoglobin for oxygen), and volume overload caused by sodium.²⁸ The standard formula used to calculate bicarbonate replacement is milliequivalents of bicarbonate = base deficit × 0.3 × body weight (kg). This formula is used for correcting metabolic acidosis in the extracellular fluid compartment. Total-body base-deficit correction may require a greater dose and intravascular correction a smaller dose. To avoid a vascular alkalosis, the dose should not be administered faster than it can be redistributed from the vascular space to the interstitial space. If administered too quickly, severe hypotension and death may result. A more conservative approach is to calculate the deficit, but administer only one-third of the dose at a time. Allow enough time for equilibration and recheck a blood gas. There are alternative alkalizing agents such as tromethamine (THAM) and Carbicarb (a mixture of sodium carbonate and sodium bicarbonate), but these alternative agents have not proven to be superior.

Dopamine has been used as a sympathomimetic and dopaminergic drug since the 1960s. The potential for protective effects of low-dose dopamine on renal and splanchnic perfusion has led to the widespread use of this drug in critically ill patients (Table 46.5). Although low-dose dopamine may increase urine production, it neither prevents nor improves acute renal failure. Even

Table 46.5. Positive inotropic drugs.

Drug (Trade Name)	Catecholamine Receptor Activation					Noncatecholamine Mechanism	Drug Dose and Infusion Schemes
	α_1	α_2	β_1	β_2	Dopamine

^aBlocks reuptake of norepinephrine.

^bPromotes release of norepinephrine from nerve terminal.

though low-dose dopamine does increase diuresis, it may actually increase the risk of acute renal failure in normovolemic and hypovolemic patients.²⁹ Similarly, there is no evidence that low-dose dopamine has beneficial effects on splanchnic function or decreased progression to MODS in sepsis.²⁹ Because of its effects on gastrointestinal motility, and respiratory, endocrine, and immunologic function, the use of low-dose dopamine is no longer routinely advised.²⁹ At higher doses, dopamine has been used as a pressor in septic patients, with the thought that β_1 activity, in addition to α_1 -adrenergic-mediated pressor effects, would improve contractility and minimize the effect of increasing afterload on cardiac output. Because of the aforementioned potential adverse effects, its use as a pressor is likewise being further questioned.²⁹

Additional controversy exists regarding the presence of dopaminergic receptors in the feline kidney. Putative DA₁-like receptors have been discovered in the cortex of the feline kidney.³⁰ DA₁ receptor pharmacology in the feline kidney appears to be similar to that of humans. There is a much smaller population of receptors in the feline renal cortex than in the renal cortex of rats, dogs, or people. It has been hypothesized that the smaller population of DA₁ receptors could account for the higher dose requirement to induce diuresis and natriuresis in cats when compared with other species.³⁰ However, as indicated for dogs, diuresis does not necessarily equate with improved renal function. Dopamine may be useful as an inotropic sympathomimetic agent in cats that have decreased cardiac output secondary to anesthetic drug administration.

Management of Selected Traumatized Patients

Head Trauma

The hallmark of severe closed head injury is loss of consciousness associated with increased intracranial pressure and brain ischemia. Severe lacerations of the head may be associated with severe blood loss and shock. If airway obstruction is evident, a tracheostomy may be necessary to ensure airway patency. Time is of the essence, because intracranial hemorrhage or hypertension can have devastating effects if undiagnosed or untreated for even a short period. In general, severe closed head injury resulting in stupor or coma has a poor prognosis.

Anesthetic agents that increase cerebral blood flow (e.g., halothane, nitrous oxide, and ketamine) are not recommended for use in these patients. Because barbiturates produce rapid induction, decrease cerebral metabolic requirement for oxygen (CMRO₂), and decrease cerebral blood flow, they may be reasonable agents for patients with severe head injury.³¹ Following acute brain injury, large doses of glucocorticosteroids (1 to 3 mg/kg dexamethasone) may be helpful in controlling cerebral edema, although this use is now quite controversial.³² Intubation and modest hyperventilation (arterial carbon dioxide partial pressure [PaCO₂] values of 28 to 32 mm Hg) may protect against dangerous increases in cerebral blood flow and pressure. Care should be exercised not to negatively impact arterial blood pressure and cardiac output with positive-pressure ventilation. If the PaCO₂ is allowed to decrease below 25 mm Hg, there is a danger

that the affected area of the brain may become ischemic because of excessive constriction of cerebral arterioles. The use of hyperosmotic solutions may help to minimize intracranial pressure caused by tissue edema. Mannitol is an ideal drug for preventing or treating increased intracranial pressure and cerebral edema associated with global ischemia or neoplasia. However, it is *not* recommended for immediate use in patients with suspected intracranial hemorrhage (head trauma). Hemorrhage or leaking of hyperosmotic solutions into perivascular neural tissue would increase interstitial fluid volume and intracranial pressure.

Cervical trauma may injure the innervation to respiratory muscles (phrenic and intercostal nerves) such that oxygen therapy, tracheal intubation, and mechanical ventilation may be necessary. Spinal injury may also cause autonomic dysfunction, resulting in gastric bloat, bradycardia, and electrolyte imbalances. Thermoregulation may also be seriously impaired.

Thoracic and Abdominal Trauma

Penetrating trauma of the thorax and abdomen is usually obvious. Blunt trauma presents a greater diagnostic challenge, because external examination may reveal no obvious abnormalities. A chest radiograph is essential following any type of thoracic trauma. Lung contusions, broken ribs, and flail chest are common. Pulmonary contusions may not become apparent until 12 to 24 h after injury. Radiographic findings might not correlate with functional deficits; therefore, arterial blood-gas analysis is essential for evaluating patient status. Severe hypoxemia often results from extensive lung contusions, and ventilatory support or oxygen therapy may be required. Low inspiratory pressures (<12 cm of water) should be used if intermittent positive-pressure ventilation (IPPV) is deemed necessary in patients that have a pneumothorax or bullae. Any accessible gas should be removed prior to anesthesia or if respiratory difficulty develops. Intermittent thoracocentesis may be adequate, but an indwelling chest drain should be considered if respiratory difficulty continues to develop. Pulmonary lesions tend to worsen within 24 to 36 h after injury.³³ Lung contusions will usually resolve in 2 to 5 days.¹ Medical management of pulmonary contusions includes oxygen, corticosteroid, analgesic, and antibiotic administration, and diuretic therapy when pulmonary edema is present. When contusions are severe, anesthesia, intubation, and low-pressure mechanical ventilation may be necessary.³³

In small animals, thoracic and abdominal injuries are commonly associated with blunt trauma rather than with penetrating objects. Common cardiac injuries include tamponade, contusion, and rupture. Patients with pericardial effusion and cardiac tamponade will manifest jugular vein distension, muffled heart sounds, and hypotension (Beck's triad) in addition to tachycardia and reduced pulse pressure. The administration of intravenous fluid and inotropic drugs (Table 46.5), and immediate pericardial drainage (pericardiocentesis), may be necessary to maintain an adequate cardiac output. It is best to avoid controlled IPPV in patients that have tamponade. An infusion of fentanyl (0.8 µg/kg/min IV) and midazolam (8 µg/kg/min IV) with orotracheal intubation and oxygen support, rather than an inhalant, may be used for anesthetic maintenance until the pericardium can be

opened and cardiac output improved. Patients with myocardial contusions will often develop ventricular dysrhythmias, which appear to be most common 24 to 72 h after trauma. Arrhythmias require correct diagnosis and appropriate therapy with antiarrhythmic agents prior to and during the surgical period. Myocardial rupture usually causes death at the scene of the accident.

In the urban environment, the incidence of abdominal injury has been reported at 13% of all dog and cat trauma cases treated.³⁴ Blunt abdominal trauma can damage several vital organs by rupturing spleen and/or liver, or kidney and urinary bladder, or perforating the bowel or large abdominal vessels. In cases with a history of severe abdominal trauma, common sequelae are hypovolemic shock caused by organ or vessel rupture and/or septic shock resulting from septicemia. Abdominal ultrasound and radiographs should be used to evaluate abdominal injuries. Abdominal vascular injuries can be assessed by diagnostic peritoneal lavage. Although not organ specific, this technique is helpful in diagnosing unstable patients with a history of severe abdominal injury. Abdominal compression may reduce hemorrhage, but can also reduce vital tissue perfusion. Urinary catheterization will help to evaluate urinary tract injury and renal function.

Thermal/Burn Trauma

Although treatment of severely burned patients is uncommon, several factors important to intensive care management should be kept in mind. As is true with any trauma patient, initial treatment involves attention to airway, breathing, and circulation. If a patient is apneic or in stridor, or if the face is burned or the history indicates inhalation of steam, smoke, or toxic fumes, the trachea should be intubated immediately after sedation and induction.¹ Inhalation of carbon monoxide can cause severe tissue hypoxia even though mucous membranes and arterial oxygen partial pressure (PaO₂) may be near normal. Blood oxygen content can be drastically reduced because carbon monoxide has 200 times more affinity for hemoglobin than does oxygen. Since the majority of oxygen is carried on hemoglobin, and not in solution in the plasma (as measured with arterial blood gas), oxygen delivery to the tissues may be severely impaired. After intubation, the animal should be placed in an oxygen cage or ventilated mechanically with oxygen. After the airway has been secured, the burn patient will require large volumes of fluid. Fluid loss because of increased capillary permeability, protein loss into the interstitial tissues, and evaporative losses can be extensive, especially within the first 12 to 24 h after injury.¹ It has been suggested that only crystalloid solutions be administered during this time, because colloid solutions would likely rapidly extravasate. Volume replacement should be closely monitored by measuring urine output and hemodynamic parameters regularly. Burn patients are hypermetabolic and will often have increased temperatures, increased catabolism, and increased oxygen requirements. Tachypnea and tachycardia are common, and parenteral nutrition is usually necessary to overcome metabolic losses.

Providing anesthesia for burned and crushed patients presents some unique problems, but selection of anesthetics is not critical if done on a rational patient-by-patient basis. To enhance preoperative and postoperative analgesia, the use of opioids (e.g., fen-

tanyl patches placed on an area of nonburned skin) should be considered with any technique. Transdermal or topical medications should not be applied to damaged epithelial surfaces, because the pharmacokinetics of the drug may be significantly altered. If there are no contraindications, ketamine may provide some degree of somatic analgesia. Ketamine may be given as a low-dose infusion (0.5 mg/kg IV, followed by 2 to 10 µg/kg/min IV) as an adjunct to opioid analgesia.

Burn patients may not respond normally to muscle relaxants.³⁵ For example, within 24 h of injury, succinylcholine administration is associated with a rapid increase in serum potassium concentration, which can cause cardiac arrest (see Chapter 15). In contrast, burn patients may demonstrate increased resistance to nondepolarizing muscle relaxants (e.g., pancuronium and atracurium).

The principles of treatment for patients with electrical burns are similar to those for patients with thermal burns. If the burn is located in the oral cavity, severe swelling of pharyngeal tissues may complicate efforts to intubate. The extent of burn is often misleading. Small cutaneous lesions may overlie extensive areas of devitalized tissue and muscle. Accordingly, these patients should be carefully observed for myoglobinemia and renal failure, as well as neurological deficits and pulmonary edema.¹

Anesthetic Management of Trauma and Critically Ill Patients

Most classes of anesthetic agents may be used in trauma and critically ill patients; however, the dosage requirement is usually reduced. Release of endogenous enkephalins, endorphins, and other amino peptides to reduce pain and stress may produce mild sedation and analgesia, reducing the dose requirement of anesthetic agents. Anesthetic management includes protection of the airway, provision for ventilatory support, and appropriate monitoring of the patient's condition. Premedicants may be advantageous to reduce anxiety and pain, and to offset anesthetic drug-induced adverse effects.

Premedication

During the preoperative period, vagal influences on cardiopulmonary function and excess secretions can be controlled by atropine or glycopyrrolate administration. Antimuscarinics are not routinely recommended for use in critically ill patients, though, because they often increase heart rate and myocardial oxygen consumption while decreasing the threshold for cardiac dysrhythmias.³⁶ Because the stomach may be full, measures to prevent regurgitation and aspiration before induction need to be considered. Aspiration of acidic gastric contents (pH < 2.5) will usually lead to pneumonitis and increased morbidity and mortality. When the risk of aspiration is high, several steps can be taken to minimize its occurrence and consequences, including glycopyrrolate administration to increase the pH of gastric contents, positioning of the animal to reduce gastric pressure, immediate intubation of the unconscious patient by using cricoid pressure and immediate inflation of the cuff, and the availability of suction to clear the pharynx of gastric reflux.^{32,37}

When stabilization is necessary prior to surgery, analgesics and/or sedatives can be given to help alleviate pain, fear, and apprehension. Some clinicians apply partial (cats and small dogs) or full (large dogs) fentanyl patches (Duragesic; 25-, 50-, 75-, or 100-µg/h release rate) that provide continual release for transcutaneous absorption of fentanyl over several days. In cats, partial exposure to a 25-µg/h release patch results in lower plasma fentanyl concentrations (1.14 ± 0.86 vs. 1.78 ± 0.92 ng/mL for a full 25-µg/h patch).³⁸ All patients should be observed for either inadequate analgesia and signs of overdose. To allow time for efficacious blood fentanyl concentrations to develop, 12 to 24 h are required in most patients. Anesthetic induction and maintenance dose requirements may be lessened in patients who have had fentanyl patches applied long enough for effective blood concentrations to be achieved; however, anesthetic management is not usually altered unless obvious sedation is present before anesthetic induction. If an analgesic is needed for immediate pain relief, either butorphanol (0.2 mg/kg IV) or a µ-agonist such as oxymorphone (0.05 mg/kg IV) may be given in small incremental doses. When further CNS depression is desirable, diazepam (0.2 mg/kg IV) or midazolam (0.2 mg/kg IV or intramuscularly [IM]) can be combined with the opioid. Benzodiazepines are not usually administered alone because they can induce unpredictable behavior in both dogs and cats. In depressed dogs, however, lower doses have been associated with rapid and profound CNS depression.³⁹ If neurological status needs to be serially assessed, a fentanyl constant-rate infusion (1 to 4 µg/kg IV loading dose, followed by 2 to 6 µg/kg/h IV) may be used. By 30 min after discontinuation of the constant-rate infusion, the sedative effects have usually abated. If shock, severe blood loss, and clotting are not of concern, acepromazine (0.01 to 0.05 mg/kg, up to 1 mg maximum) can be combined with butorphanol or oxymorphone to induce neuroleptanalgesia. If there is no contraindication to its use, medetomidine (1 to 3 µg/kg/h) can also be used for additional sedation and analgesia. In critically ill cats, both oxymorphone and buprenorphine have proven to be useful and relatively safe analgesics.

Induction

Barbiturates may decrease myocardial contractility, depress baroreceptor reflexes, enhance respiratory depressants, and are poor analgesics.⁴⁰ When given intravenously for anesthesia, they can cause venodilation and usually decrease venous return, cardiac output, and blood pressure. In the presence of moderate blood loss, however, thiopental has been shown to increase renal blood flow.⁴¹ The degree of myocardial depression induced is a function of dose and rate of injection, which together determine peak blood concentration following intravenous injection.⁴² Barbiturates are highly bound to proteins, and their pharmacokinetics can be influenced by a patient's acid-base status, albumin concentration, and concurrent drug administration.³⁶ Trauma patients are often acidotic and hypoproteinemic, so the induction dose requirement may be greatly decreased and should be anticipated by clinicians. Because barbiturates can be arrhythmogenic, they should be used cautiously in patients with preexisting arrhythmias. In severely hypovolemic patients or when severe

cardiac disease and/or preexisting arrhythmias are present, other agents or induction combinations may prove safer. If barbiturates are used, simultaneous administration of adjuvant drugs such as diazepam (0.2 mg/kg) or lidocaine (2.0 mg/kg) will decrease the barbiturate requirement and the incidence of arrhythmias.⁴³ Propofol induces similar hemodynamic depressive effects to those of thiopental. Accordingly, propofol is not recommended as a primary induction agent in trauma patients unless cardiovascular stability has been restored.

Unlike injectable agents, inhalation agents are readily excreted via the lung should an adverse response (other than cardiac or respiratory arrest) result. Inhalation agents are equally hypotensive compared with barbiturates and are safer than some injectable induction agents only because homeostatic mechanisms have longer to compensate for the depressant effects of the anesthetic during induction. The disadvantage of inhalant anesthetic induction is that higher concentrations must be used for intubation than would be required for maintenance. Halothane, enflurane, isoflurane, and sevoflurane all induce dose-dependent cardiopulmonary depression. Isoflurane and sevoflurane are the least depressant to cardiac output at equipotent (e.g., 1.5 minimum alveolar concentration [MAC]) concentrations. If the traumatized or critically ill dog or cat is alert or likely to struggle, has a full stomach, or has severe pulmonary dysfunction, induction with an inhalation agent alone is not recommended. Intravenous inductions in traumatized or critically ill patients may be preferred so that the airway may be controlled rapidly. Mask inductions are strictly contraindicated in patients that are vomiting or have been recently fed.

When planning anesthesia for trauma patients, there is a tendency to choose an anesthetic that is an adrenergic stimulant or is associated with minimal hypotensive effects. However, there are limited data to suggest the superiority of stimulant drugs for maintenance of anesthesia during severe hypovolemic shock or in patients with severe CNS injury.¹ For example, in hypovolemic pigs, ketamine's overall cardiovascular effects are similar to those of thiopental.⁴⁴

Ketamine is one of the few anesthetic agents with indirect cardiovascular stimulant properties. In healthy patients, it increases blood pressure, heart rate, and cardiac output secondary to increased sympathetic activity.⁴⁵ However, ketamine induces a direct myocardial depressant effect in patients whose sympathetic system is maximally stressed by hemorrhagic shock.⁴⁴ This is often the case in severely traumatized or critically ill patients. In patients with hypertrophic or restrictive cardiomyopathy (e.g., cats with idiopathic cardiomyopathy and normal left ventricular contractility), ketamine is contraindicated because it may induce tachycardia and decrease preload.³⁶ In patients with mitral regurgitation, ketamine is contraindicated because it may increase the regurgitant fraction through increased afterload. In contrast, in large-breed or giant-breed dogs suffering cardiogenic shock and myocardial failure as defined by poor contractility (dilated cardiomyopathy), ketamine may be a good choice for inducing anesthesia. When given alone, ketamine does not provide good muscle relaxation, and spontaneous movement is common. Because of their propensity to increase intracranial pressure, dis-

sociatives are not recommended for patients with severe closed head injury or open eye injury (e.g., corneal laceration).

Benzodiazepines enhance muscle relaxation and sedation when combined with ketamine, barbiturates, or opioids. Small intravenous doses of ketamine (5.5 mg/kg) combined with diazepam (0.27 mg/kg) titrated to effect can be administered to some high-risk patients if there are no contraindications to the use of ketamine. Lower intravenous doses of diazepam (0.2 mg/kg) and ketamine (2 to 3 mg/kg) may be given in rapid sequence to induce anesthesia in either traumatized or critically ill dogs or cats. If a patient is not sufficiently depressed after diazepam-ketamine administration, additional ketamine or delivery of low concentrations of sevoflurane or isoflurane by face mask will complete the induction. Isoflurane and sevoflurane are less arrhythmogenic and act faster than halothane and thus are the preferred agents in any trauma patient exhibiting arrhythmias or suspected of having myocardial injury.^{46,47}

Induction of anesthesia with opioids usually necessitates concomitant use of an adjunctive tranquilizer-sedative or inhalation agent. Because most opioid agonists can depress respiration and slow heart rate, intravenous administration should be preceded by preoxygenation, and an antimuscarinic should be available for rapid administration in the event that severe bradycardia is induced. In dogs, intravenously administered meperidine and morphine can be associated with a dose-dependent histamine release, which can cause severe hypotension. Cautious, slow administration is acceptable if blood pressure is monitored. In contrast, intravenous administration of oxymorphone, hydromorphone, or fentanyl has not been associated with histamine release and has proven relatively safe in critically ill patients. A μ opioid receptor agonist may be combined with a benzodiazepine for induction in critically ill patients. Oxymorphone or hydromorphone is commonly given intravenously in small increments (0.05 mg/kg) along with diazepam (0.2 mg/kg) until intubation is possible. Alternatively, intravenous midazolam (0.2 mg/kg) and fentanyl (5 to 10 μ g/kg) may be used. Because opioids and benzodiazepines given together do not cause myocardial depression or vasodilation, they make a good induction combination in patients in hypovolemic, cardiogenic, or septic shock, and in dehydrated patients. Nevertheless, because opioid inductions are slower than those achieved with barbiturates, nonbarbiturate hypnotics, or dissociatives, they are *not* recommended if rapid intubation of the airway is a necessity for patient survival.

For arrhythmic patients and patients with severe cardiac disease, etomidate is perhaps the safest drug for inducing anesthesia while maintaining cerebral and hemodynamic homeostasis. In doses of 0.5 to 2.0 mg/kg, etomidate produces minimal hemodynamic alterations and cardiac depression in animals.⁴⁸⁻⁵⁰ Adrenal cortical suppression may follow anesthesia induction, but this suppression is of limited concern when etomidate is administered as a single bolus to a hemodynamically unstable patient.¹ Etomidate is a rational selection for anesthesia induction in patients in compensated or decompensated (congestive) heart failure, whether caused by acquired chronic atrioventricular valvular disease or myocardial failure (dilated cardiomyopathy). To minimize side effects such as retching and myoclonus, etomidate in-

jection should follow the administration of a benzodiazepine and/or an opioid. With repeated use of etomidate in cats, hemolysis caused by the propylene glycol vehicle has been observed.

Anesthetic Maintenance

Along with proper monitoring, the first priority during maintenance of anesthesia is adequate oxygenation, which may require controlled ventilation of the lungs for normal gas exchange. Blood oxygen saturation can be easily monitored by pulse oximetry using a buccal mucosa, vulva or prepuce, tongue, toe, or ear site. Ventilation is monitored by using capnometry or capnography. Preservation of hemodynamic stability, which is also essential, is achieved by providing adequate intravascular volume, which can be monitored by placing central venous and arterial pressure catheters, by using inotropic agents if necessary (Table 46.5), and by maintaining proper anesthetic dose and ventilator settings.¹⁸

Opioids such as oxymorphone (0.1 mg/kg IV), hydromorphone (0.1 to 0.2 mg/kg IV), or fentanyl (0.005 mg/kg IV) combined with ketamine can be administered in small aliquots along with diazepam or midazolam to maintain brief periods of anesthesia. Administration of ketamine should be repeated at an approximate dosage of 1 to 2 mg/kg IV every 20 to 30 min or as necessary to maintain anesthesia. Administration of diazepam or midazolam can also be repeated (0.2 mg/kg IV) every 30 to 60 min or as necessary to relax muscles adequately. Recovery can be prolonged with repeated injections of benzodiazepines. Anesthesia should be limited to less than 2 h. Long recoveries may be problematic in cats because they metabolize benzodiazepines more slowly than do dogs. Flumazenil may be administered to antagonize benzodiazepines once the effects of the ketamine have worn off. Similarly, tiletamine plus zolazepam (Telazol) may be useful when given in low doses for minimal restraint. These injectable regimens are often supplemented with low concentrations of sevoflurane or isoflurane if anesthesia must be extended. For airway examinations or diagnostic procedures that are not painful, propofol may be used as an infusion (0.04 mg/kg/h IV) in patients in stable hemodynamic condition. Since propofol is relatively noncumulative in dogs, recoveries are similar to those from an induction dose. Recoveries are longer in cats than in dogs when infusion lasts longer than 30 min (probably because of decreased glucuronide conjugation). Cats are comparatively intolerant of phenols, which are linked to oxidative injury of feline hemoglobin. The safety of consecutive-day propofol administration (a propofol bolus and 0.2 to 0.3 mg/kg/min IV for 30 min) has been evaluated in cats.⁵¹ After 3 days, recovery times were prolonged, and there was a significant increase in Heinz bodies; by day 5, cats did not appear to feel well, were anorexic, and had diarrhea. Accordingly, propofol should not be administered continuously nor repeatedly at short intervals in cats.

When administered to hypovolemic animals, nitrous oxide does not appear to offer any hemodynamic advantage over halothane.⁵² Because trauma patients frequently have pulmonary contusions with increased venous admixture, nitrous oxide is not routinely recommended, and it is contraindicated if blunt tho-

racic trauma is suspected or either pneumothorax or hemothorax is present. Similarly, the use of nitrous oxide should be avoided in patients with a distended abdomen or diaphragmatic hernia that has caused respiratory compromise. Nitrous oxide is a known stimulant of cerebral metabolism and causes increased cerebral blood flow and intracranial pressure.⁵³ Therefore, it is not recommended for trauma patients with severe head or open eye injury.

Isoflurane and sevoflurane are equally hypotensive but do not sensitize the myocardium to the arrhythmogenic effects of catecholamines to the same extent as halothane.⁵⁴ Sevoflurane is less soluble than isoflurane and provides a potentially faster and smoother induction and recovery than isoflurane. When an inhalant anesthetic agent is used, myocardial depression and hypotension can be minimized by using as low a concentration as possible. In people, it is common to administer a muscle relaxant to help prevent patient movement when using low inhalant concentrations. Unfortunately, some human patients have recalled surgical events under these conditions.¹ Preanesthetic or intraoperative administration of an opioid or benzodiazepine tranquilizer with or without a muscle relaxant can help assure adequate CNS depression during low-dose inhalation anesthesia. In hypovolemic anesthetized patients, fentanyl, oxymorphone, butorphanol, or diazepam are preferred for reduction in inhalant requirement. Continuous-rate intravenous infusions of fentanyl, fentanyl-midazolam, ketamine, or lidocaine may be used to decrease the inhalant requirement. Acepromazine is not a good choice in these circumstances because it may increase vascular capacity, reducing blood pressure. In hypovolemic patients, compensatory vasoconstriction is often present preoperatively due to increased catecholamine activity. When anesthesia is induced, compensatory mechanisms may be blocked or fail, resulting in profound hypotension and reduced preload and cardiac output, especially if acepromazine has been administered. On the other hand, if adequate volume replacement has been achieved prior to acepromazine administration and inotropic support is available as needed, decreasing arterial resistance (α -adrenergic blockade) may improve perfusion (e.g., to kidneys and intestines).

Regional Anesthesia

Performing epidural or intrathecal blocks is contraindicated in patients that are septic or have a bleeding diathesis. Epidural or spinal blocks are contraindicated in hypovolemic patients because of the potential for profound sympathetic blockade induced by these techniques when using local anesthetics. Epidural administration of opioids (0.1 mg/kg of preservative-free morphine) or low doses of α_2 -adrenergic agonists (e.g., 1 to 3 μ g/kg medetomidine) may prove to be effective alternatives to local anesthetics in providing regional analgesia with minimal sympathetic blockade.^{55,56} In severely depressed patients, or in patients administered neuroleptanalgesia, superficial lacerations and wounds of the extremities can be managed with infiltration of local anesthetic or by performing peripheral nerve blocks. Local anesthetics may not be as effective when deposited in infected tissue because of ongoing inflammation and pH alterations.

Adjunctive regional therapy using a local anesthetic improves

analgesia while lowering the inhalation agent requirement. Intercostal nerve blocks (0.5 to 1.0 mL per site in dogs) with 2% lidocaine or 0.5% bupivacaine can be performed to control post-operative thoracotomy pain, as well as pain associated with fractured ribs. Interpleural administration of local anesthetics is also effective as an adjunct for thoracotomy and cranial abdominal pain associated with pancreatitis or with diaphragmatic hernia repair. With regional techniques, care should be taken to avoid exceeding the toxic local anesthetic dose for a given species. The maximum dose of bupivacaine is approximately 2 mg/kg in dogs and 1 mg/kg in cats. The maximum dose may be diluted, if necessary, for more complete coverage.

Intraoperative Support

Documentation of the medical history of each patient evaluated should include previous drug administration, because concomitant drug therapy must be considered when anesthetizing a patient. Adverse cardiovascular drug interactions are increasingly being reported. Examples of commonly administered cardiovascular drugs will be illustrated here, but a more complete discussion is available elsewhere.⁵⁷ Many cardiovascular drugs are metabolized in the liver through the several different isoforms of the cytochrome oxidase system. Drugs may either induce the isoforms, thereby decreasing the plasma concentrations of certain drugs, or inhibit the isoforms, thereby increasing the plasma concentrations of drugs. One of the first known interactions resulted from the decreased rate of hepatic metabolism of lidocaine when cimetidine was concurrently administered, leading to potential lidocaine toxicity. Cimetidine also increases plasma concentrations of quinidine, verapamil, and propranolol. Ranitidine inhibits fewer isoforms and is less likely to cause such interactions. Cimetidine also increases plasma concentrations of procainamide by inhibiting clearance by the kidneys. The likelihood of lidocaine toxicity increases when a β -adrenergic antagonist is administered with lidocaine. During the coadministration of agents that depress sinoatrial nodal function, lidocaine may cause sinoatrial arrest.⁵⁷ β -Adrenergic stimulants, such as dobutamine, decrease potassium concentrations and should be administered cautiously to patients receiving potassium-losing diuretics. Coadministration of captopril with hydralazine or procainamide may precipitate neutropenia because of impaired immune status. Nonsteroidal anti-inflammatory drugs may attenuate the antihypertensive effects of β blockers.⁵⁷ Many companion animals are administered herbal formulations that may interact with anesthetic, cardiovascular, tricyclic antidepressant, and monoamine oxidase-inhibitor drugs. The aforementioned interactions are representative of the many potential adverse interactions possible.

Perioperative Fluid Support

Several choices of fluids are available for use in traumatized patients undergoing anesthesia and surgery. With hemorrhage, there is contraction of extracellular volume as the intravascular compartment deficit is replaced with interstitial fluid. Administration of a physiological salt solution such as lactated Ringer's restores this depletion and also expands intravascular volume to help maintain cardiac output. In general, patients should be adminis-

tered 20 to 40 mL/kg intravenously prior to anesthetic induction. An exception is when patients are severely anemic or hypoproteinemic, have poor myocardial contractility, or have advanced valvular heart disease. Patients in hypovolemic shock can be given up to 1 blood volume (60 to 90 mL/kg) of isotonic electrolyte solution in the first hour. Many more animals have experienced problems after anesthetic drug injection, when compensatory mechanisms failed and underlying hypovolemia was unmasked, than have developed problems when crystalloid fluids were administered unnecessarily at these rates.³⁶ During anesthesia, hypotension caused by volume depletion often responds to replacement of one-quarter of the blood volume in 15 min as an intravenous fluid challenge. Replacement solutions should be isotonic, but not all isotonic solutions are optimal. Although 5% dextrose in water and lactated Ringer's with 2.5% dextrose are isotonic, once glucose is metabolized the remaining fluid is hypotonic and contains either all (5% dextrose) or half (2.5% dextrose) free water, which rapidly leaves the vascular compartment and may contribute to microvascular edema.¹⁷ In general, even optimal isotonic physiological salt solutions remain in the intravascular space for only 30 to 60 min before redistributing throughout the entire extracellular space.⁵⁸

Plasma expanders such as colloid solutions maintain intravascular volume for 2 to 5 h, but may have associated complications (Table 46.3). Dextran solutions can cause bleeding disorders and allergic reactions, and must be stored at stable temperatures (25°C) to prevent precipitate formation.^{59,60} Protein solutions can impair pulmonary function if they extravasate into damaged lung.⁶¹ Hydroxyethyl starch (6% solution in 0.9% sodium chloride) is a glucose polymer that has proven useful as a volume expander when the dose is limited to less than 20 mL/kg in dogs and 12 to 15 mL/kg in cats.⁶² Because colloid solutions can be hypertonic, they must be administered slowly to avoid rapid fluid shifts and volume overload.¹⁶

When extreme blood loss occurs, red cells must eventually be infused. Fresh whole blood (less than 6 h old) is preferable. After 1 day of storage, only 12% of the original platelets remain in human whole blood. Similar reductions may occur in stored blood of domestic animals. Regardless of its age, whole blood is preferred over packed red blood cells.¹ Fresh-frozen plasma should be reserved for specific coagulation disorders.⁶³ In acute trauma, the large majority of clotting disorders are secondary to large-volume fluid replacement that causes dilutional thrombocytopenia. If possible, surgery and anesthesia should be delayed until the PCV can be increased to above 20% and platelet abnormalities addressed. When ongoing losses and replacement occur simultaneously, the best method of assessing adequate blood volume replacement is to assess urine output (1 to 2 mL \cdot kg⁻¹ \cdot h⁻¹ is optimal), serial hematocrits, and total protein. Some questions remain with regard to optimum fluid management of severely traumatized patients in the perioperative period, including (a) the best methods of using non-erythrocyte-containing fluids in trauma resuscitation, (b) feasibility of systemic oxygen delivery (DO₂) and consumption-oriented resuscitation in high-risk surgical patients, and (c) the effects of fluid therapy on cerebral hemodynamics.⁶⁴

With regard to nonblood fluid resuscitation, if membrane permeability is normal, fluids containing colloids (albumin, dextran, and hydroxyethyl starch) expand plasma volume (PV) rather than interstitial fluid volume (IFV) or intracellular volume (ICV). Each gram of intravascular colloid can draw and hold approximately 20 mL of water (e.g., 16 to 17 mL of water per gram of hydroxyethyl starch) in the vascular space. To estimate the effects of fluid infusion on PV, the following formula can be used: $PV = \text{volume infused} \times (PV/V_d)$, where V_d = distribution volume. In mature animals, total body water accounts for 60% of the total body weight. The ICV is 40%, the extracellular volume (ECV) is 20%, the IFV is 16%, and the PV is 4% of total body weight. If an acute blood loss of 500 mL is to be replaced using the preceding formula and 5% dextrose, which contains no sodium, the remaining water after glucose metabolism, distributes throughout the total body water. For a 70-kg dog where plasma volume of 500 mL is to be replaced, the volume of 5% dextrose infused is 500 mL = volume infused \times (3 L/42 L), or approximately 7 L. In contrast, 500 mL of blood loss can be replaced with lactated Ringer's solution (LRS), for which the V_d is equal to the ECV or only 20% of the body weight (3 L/14 L) with just 2.3 L of LRS. If hyperosmotic fluids such as hypertonic saline (HS) are used, blood volume increases primarily by endogenous fluid PV expansion. These fluids come from the IFV initially and are transient in their duration of effect on PV. The immediate effect of 7.5% HS is to increase plasma volume by 2 to 4 mL for each milliliter infused. Thus, 500 mL of PV may be replaced with only 150 to 200 mL of HS. However, following equilibration, 7.5% saline increases PV by only approximately 1.0 mL for each milliliter infused. Small volumes of hyperosmotic solutions transiently restore hemodynamic function during shock, but because improved PV and flow decrease rather rapidly following resuscitation with hypertonic fluids, ongoing attention to maintenance of intravascular volume is necessary.⁶⁴ To prolong the initial improvement seen with hyperosmotic solutions beyond 30 to 60 min, continued infusion with a hypertonic solution, blood (if PCV is below 20%), or conventional fluids, or the addition of colloids, should be considered. One suggested protocol for volume resuscitation combines bolusing a synthetic colloid solution (1 to 5 mL/kg) with a replacement crystalloid solution (15 mL/kg). The dose of colloid solution should not exceed 20 mL/kg in dogs and 12 to 15 mL/kg in cats within the first 24 h. Rapid fluid loading is often associated with dilutional thrombocytopenia, hypoglycemia, and/or hypokalemia, and fluids should be supplemented to maintain serum levels within normal ranges.⁵

Studies in dogs have documented that HS may have a negative inotropic effect, whereas hyperosmotic dextrose produces a positive inotropic action.⁶⁵ Rapid (<30 s) administration of 2 to 4 mL of HS is also associated with an acute transient period of hypotension.⁶⁵ Infusion over a 3- to 4-min period will diminish this initial response. HS likely exerts its beneficial effect in treating hemorrhagic or endotoxic shock by rapidly increasing preload, whereas hyperosmotic dextrose solutions exert their beneficial effects by transiently increasing both preload and contractility.⁶⁵

In high-risk traumatized patients who survive, it has been doc-

umented that average blood flow and DO_2 are greater than in those patients that did not survive.⁶⁶ Survival is correlated with a DO_2 that is at least 600 mL $O_2 \cdot \text{min}^{-1} \cdot \text{m}^{-2}$ (Table 46.1). When DO_2 is maintained at this level, complications are also reduced. To implement DO_2 goal-oriented fluid resuscitation, cardiac output, hemoglobin content, and oxygen-hemoglobin saturation must be continually monitored. In many traumatized patients, improvement of overall systemic DO_2 may be less critical than the immediate restoration of adequate oxygen delivery to selected vital organ systems.

With respect to the effects of fluid therapy on cerebral hemodynamics, it appears that, in some subsets of traumatized patients (severe head injury), initial fluid therapy with 7.5% saline in 6% dextran improves patient survival (32%) when compared with those treated with conventional LRS (16%).⁶⁴ Concerns over adverse neurological sequelae with hypertonic solutions have not proven valid, with the exception of hyperosmotic resuscitation in canine experimental models of uncontrolled hemorrhage where hyperosmotic solutions actually increase bleeding tendency.⁶⁷

Commonly, trauma cases will present with nonrespiratory acidosis caused by shock and generalized stress. Ventilation of the lungs to induce a mild respiratory alkalosis will help normalize blood pH for the short term. With time, improved tissue perfusion and renal and hepatic function should resolve the problem. Treatment of metabolic acidosis with bicarbonate or other buffers should be carefully considered. More important measures in treating metabolic acidosis are fluid resuscitation, adequate ventilation, and rewarming. It is possible for patients with normal liver function to develop metabolic alkalosis 6 to 24 h after large-volume replacement with LRS.

Inotropic Support

Drugs commonly used to enhance myocardial contractility and increase cardiac output are listed in Tables 46.4 and 46.5.¹⁸ Ephedrine has proven an effective alternative to dopamine or dobutamine when administered during inhalation anesthesia to enhance cardiac output.⁶⁸ A 0.1-mg/kg intravenous dose of ephedrine transiently increases arterial pressure, cardiac index, stroke volume, arterial oxygen content (CaO_2), and oxygen delivery in dogs anesthetized with isoflurane (1.5 MAC). A intravenous dose of 0.25 mg/kg causes a greater and prolonged increase in arterial pressure while actually decreasing heart rate.⁶⁸ This presumably results from a reflex bradycardia associated with an acute increase in arterial pressure. The higher dose of ephedrine also increases hemoglobin concentration and CaO_2 , resulting in a 20% to 35% increase in oxygen delivery for at least 1 h. Increased hemoglobin concentration likely results from contraction of the spleen and increased circulating red blood cells. Splenic contraction results from either ephedrine's direct α -agonist effects or enhanced norepinephrine release. Because ephedrine can be administered as a convenient intravenous bolus with an onset of less than a minute, it is a useful for inotropic support of anesthetized patients. Dopamine and dobutamine have short half-lives and require constant infusion (Table 46.5). Close monitoring for development of arrhythmias is necessary, and, with dopamine, to avoid intense α receptor-mediated vasocon-

striction. In refractive cases, inotropic doses of dopamine and dobutamine may be supplemented with the coadministration of ephedrine to reduce vascular compliance and improve preload and stroke volume.⁶⁹

In septic shock, vasopressin has been used for unresponsive hypotension. During anesthesia, vasopressin has also been used to support blood pressure. It is a peptide hormone stored in the posterior pituitary and synthesized in the supraoptic and periventricular nuclei of the hypothalamus. The release of vasopressin can result from an increased plasma osmolarity, decreased blood volume or pressure, nausea, pain, endotoxemia, cytokines, and other stimuli. Either low secretion or excessive secretion leading to depletion causes a deficiency in vasopressin. Vasopressin may be effective in situations where severe refractory hypotension no longer responds to adrenergic agonists. Intravenous infusion of 0.25 to 1.0 mU/kg/min increases blood pressure and urine flow in many patients. Vasopressor therapy has been reviewed elsewhere.⁷⁰

Temperature, Oxygen, and Renal Support

Hypothermia should be treated vigorously because it is associated with reduced kidney function, poor platelet function, impaired glucose utilization, shivering and increased oxygen consumption by nonvital tissues, and decreased metabolism of anesthetics.¹ Bradycardias that do not respond to anticholinergics and spontaneous fibrillation may occur in hypothermic patients. Warming fluids and blood before administration helps maintain body temperature, reduces blood viscosity, and improves tissue blood flow. Warm-water blankets and heat lamps may help prevent further heat loss, but may not effectively re-warm patients because of inadequate body-surface-area contact and poor skin blood flow. Forced-air blankets will increase body temperature, but slowly. Maintenance of body temperature and rewarming may be easier when animals are anesthetized, because of high skin blood flow following inhibition of vasomotor control by anesthetics. Intense vasoconstriction after recovery from anesthesia may slow surface-rewarming efforts.

To prevent acute oliguric renal failure in severely traumatized patients, every effort should be made to maintain normal renal function. Unfortunately, there is no way to predict the degree of hypoperfusion that will result in renal failure in a given patient. Myoglobinemia must be treated by vigorous diuresis after muscle damage or electrocution. Once fluid volume and blood pressure have been normalized, furosemide (1 mg/kg) and dopamine (2 to 5 µg/kg/min) have been used together to increase renal blood flow and water and solute excretion, but renal therapy strategy remains somewhat controversial. Maintaining a functional renal system is essential for a favorable outcome following massive tissue damage.¹

Questions regarding perioperative renal function and renal physiology in critically ill patients remain.⁷¹ It is common for severely traumatized, critically ill patients to produce inadequate urine output. These patients are often given a “renal dose” of dopamine in an attempt to improve urine production and prevent oliguria. Dopaminergic receptors (DA₁ and DA₂) increase glomerular filtration rate (GFR) and inhibit proximal tubular re-

absorption of sodium. This combination of effects increases sodium excretion in euvoletic patients, but this action is diminished with prolonged infusion. Furthermore, in critically ill patients, dopamine’s natriuretic action is not always apparent, because antinatriuretic factors (antidiuretic hormone and aldosterone) may be elevated to induce sodium conservation. With lower-than-normal levels of GFR, low doses of dopamine become less effective. This lack of response may be caused by exhaustion of the renal reserve system, where low renal blood flow may have already caused a shift of blood flow to the inner cortex in an adaptive response to loss of nephron renal function. Hence, dopamine’s actions produce little additional urine. Despite these problems, dopamine can increase urine output in oliguric patients and in patients that are adequately hydrated. Several studies have also shown that dopamine improves urine output in patients that have not responded to fluid expansion or furosemide alone. By increasing renal flow, dopamine may improve delivery of furosemide to its site of action in the nephron.⁷¹

It is unclear whether dopamine is advantageous in the treatment of oliguric renal failure. Dopamine appears to be no better than saline in protecting renal function. In fact, dopamine-induced natriuresis may cause intravascular volume depletion, making the kidney even more susceptible to ongoing ischemic injury. Questions remain as to the clinical implication of increasing renal perfusion when there is decreased systemic blood volume. The routine administration of dopamine in severely traumatized patients should be carefully considered in the perioperative period.⁷¹

Urine flow, regardless of the quantity, indicates there is blood flow to the kidney, because, without it, urine production would cease. Numerous studies have shown, however, that there is no correlation between the urine volume produced and histological evidence of acute tubular necrosis, GFR, creatinine clearance, blood urea nitrogen levels, and creatinine levels in burn patients, trauma patients, or shock states.^{71,72} The control of blood flow to the kidney, the fraction filtered, and the volume returned to the systemic circulation are all regulated by a variety of mechanisms in an attempt to preserve filtration function during compromised circulation. These compensatory mechanisms have limits, and excessive vasoconstriction may eventually decrease filtration. This shift from compensation to decompensation may be prevented or exacerbated by pharmacological manipulations. The cortical-to-medullary redistribution of renal blood flow is designed to protect vulnerable medullary oxygen supply and demand balance at the expense of urine formation. Reduced GFR may reduce medullary tubular workload and oxygen consumption. Oliguria may be viewed in some circumstances (e.g., anesthesia) as a sign of normal protective compensatory mechanisms at work. Thus, an acute reduction in urine output could be either the result of acute renal failure or the consequence of normal compensatory mechanisms induced to prevent oliguria.⁷¹

Traditionally, inadequate urine production or oliguria has been defined as a urine output of less than 0.5 mL · kg⁻¹ · h⁻¹. Oliguria may, however, reflect a variety of factors independent of inadequate glomerular filtration. Thus, normal hourly urine output does not rule out impending renal failure any more than

lower-than-normal hourly urine output predicts renal failure. Reduced urine output during the anesthetic period in euvolemic patients is usually of little consequence to long-term renal function. It is more likely to be the result of compensatory renal mechanisms than a consequence of acute tubular damage or necrosis.⁷¹

Recovery

In postoperative patients, bowel and bladder function, pulmonary function, and skin integrity should be addressed. Patients that cannot turn themselves should be turned every 2 to 4 h. Bandages should be kept clean and dry; dried blood and soap should be removed. Eyes should be lubricated. Oxygen should be supplemented as needed. The environment should be quiet. Patients that are hospitalized for extended periods have special needs for appropriate social interaction.

Introduction

In the practice of veterinary anesthesia, neonatal and geriatric animals are a significant proportion of the patient population. Attention to the unique physiology and particular requirements of individuals within either of these age groups will contribute to the provision of safe, effective anesthesia and analgesia.

Physiology of Neonatal and Pediatric Animals

Neonatal and pediatric veterinary patients may be presented for either elective or emergency anesthesia. Much of our knowledge of the delivery of anesthesia to neonatal animals is based on our experience with young to middle-aged animals or is extrapolated from information obtained from human neonates.

Although the process of maturation and aging varies greatly between individual animals, species, and breeds, the neonatal and pediatric phases of life can be roughly defined. In dogs and cats, the neonatal period extends for the first 6 weeks of life and the pediatric period for the first 12 weeks.^{1–3} Foals and calves are generally considered to be physiologically mature by 4 to 6 weeks of age.⁴

Compared with young and middle-aged adults, neonatal and pediatric patients have a limited organ reserve, a decreased ability to respond to a physiological challenge or change, and increased “sensitivity” to anesthetic drugs that is manifest as exaggerated or prolonged effects after the administration of drug dosages that are appropriate for young adults. This results in an increased risk of perianesthetic complications in neonates, necessitating judicious administration of anesthetics and vigilant monitoring.

The unique physiology of neonates results in differences in pharmacokinetics and pharmacodynamics that contribute to altered sensitivity to drugs. These differences include the following:

1. Hypoalbuminemia, which results in a greater free, active portion of protein-bound drugs. This may have a profound impact on the activity of highly protein-bound drugs like barbiturates, ketamine, etomidate, and the nonsteroidal anti-inflammatory drugs (NSAIDs).
2. Increased permeability of the neonatal blood-brain barrier, which enables a larger percentage of drug to reach the brain.
3. An increased percentage of body-water content, which alters the volume of distribution. In foals, extracellular fluid volume is 43% of body weight, compared with 22% body weight in adult horses.⁵ The larger extracellular fluid volume results in a greater apparent volume of distribution of drugs that are highly ionized in plasma or relatively polar (e.g., NSAIDs).
4. A circulating fluid volume that is fixed and relatively centralized, making the neonatal patient more susceptible to hypovolemia. This reduced circulating volume also allows for greater delivery of anesthetic agents to the highly perfused tissues, including the brain.
5. Low body-fat percentage, resulting in a smaller adipose tissue compartment for drug redistribution.⁶ In foals, for example, total body fat is 2% to 3%, compared with 5% in adult horses.⁷
6. Immature hepatic metabolism for the first 3 to 4 weeks (perhaps up to 12 weeks) of life.^{8–10} Drug metabolism may be prolonged, extending the duration of effect of drugs or their active metabolites.
7. Immature glomerular filtration rate (GFR). In small animals, GFR does not mature until 2 to 3 weeks of age. Tubular secretion does not mature until 4 to 8 weeks of age.^{8,11,12} As a result of this immaturity in renal function, the effects of drugs dependent on renal excretion for termination of activity are prolonged. For example, the half-life of diazepam is increased in neonates due to decreased renal excretion.⁹ Although the kidneys mature more rapidly in foals and calves (the GFR is mature by 2 to 4 days of life and tubular secretion by 2 weeks of life),^{4,8} immature renal function may be prolonged in unhealthy animals.
8. A high metabolic rate with a concomitant higher rate of oxygen consumption. This necessitates a need for a rate of alveolar ventilation that is much greater than that of adults. Because of this increase in alveolar ventilation, anesthetic induction with inhalant anesthetics may occur more rapidly.

In addition to physiological differences that result in alterations in the pharmacokinetics and pharmacodynamics of anesthetics, neonatal physiology alone can contribute to increased anesthetic risk (Table 47.1). These physiological differences include:

Table 47.1. Physiological characteristics of neonates.

Cardiovascular system
Low myocardial contractile mass
Low ventricular compliance
High cardiac index
Low cardiac reserve
Cardiac output rate dependent
Poor vasomotor control
Respiratory system
High oxygen consumption
High minute volume
Nervous system
Immature sympathetic nervous system
Poor vasomotor control
Renal and hepatic systems
Immature hepatic microsomal enzyme system
Immature renal function
Body composition
Limited thermoregulation
Low body fat and muscle mass
Low protein binding of drugs
High body-water content
Large extracellular fluid compartment

1. Compared with the adult heart, the neonatal heart has less contractile tissue per gram of myocardial tissue, and ventricular compliance is limited.¹³ Stroke volume and cardiac reserve are limited in pediatric patients, and cardiac output is dependent on heart rate. Furthermore, the resting cardiac index is much higher in neonates than adults and is very close to maximal cardiac output, making the cardiac reserve minimal. An adult can increase cardiac output by 300%, whereas the neonate can only increase output by 30%.¹⁴

2. The sympathetic nervous system is not fully developed in neonates, and sympathetic stimulation results in only minimal increases in rate and contractility, further impairing the ability to increase cardiac output.¹² Sympathetic immaturity also manifests itself in poor vasomotor control and an incomplete or inadequate hypotension-induced baroreflex response.

3. Fetal circulation may persist in some patients. For example, normal healthy foals have a right-to-left shunt for the first 3 days, and the duration of the shunt is often extended in unhealthy foals.¹⁵

4. In the first 1 to 3 days (foals and calves) or 1 to 2 weeks of life (puppies and kittens), neonatal kidneys may be less efficient than adult kidneys at eliminating fluid loads and regulating electrolytes, so judicious use of appropriate intravenous fluids is necessary.^{6,8} Rapid or excessive fluid administration may result in pulmonary edema.

5. Pulmonary reserve is minimal, increasing the possibility of hypoxia during apnea or airway obstruction. The neonatal rib cage is compliant, resulting in less efficient ventilation and greater work of breathing. This predisposes young patients to hypoxia and ventilatory fatigue, especially in the event of airway

obstruction (e.g., endotracheal tube plugged with mucus) or respiratory disease.

6. Minute ventilation is high in neonates, raising the alveolar ventilation to a functional residual capacity ratio above that of adults. Closing volume is high in the neonate and occurs within the lower range of the tidal volume.

7. In small animals, the hematocrit decreases by more than a third in the first 28 days of life;^{16,17} thus, even minor hemorrhage can greatly affect oxygen delivery to tissues.

8. Neonates are more susceptible to hypothermia because of their immature thermoregulatory system, high body surface to mass ratio, and limited ability to vasoconstrict to conserve heat.

Physiology of Geriatric Animals

The effect of age per se on perioperative morbidity and mortality is related to the decreased physiological reserve of the various organ systems that occur with aging. Aging is a progressive physiological process that results in unavoidable alterations in organ system function. Within organ systems, reductions in functional reserve manifest as a decreased capacity for adaptation, a predisposition to the failure of homeostasis, and a reduced ability to respond to external stress. The effects of disease, stress, lack of exercise, genetics, malnutrition, and environment may hasten changes associated with aging. The time course of the aging process varies between organ systems within the same individual and between individuals. Assessment of the influence of aging on anatomical and physiological function in animals is further complicated by the marked variations in life span and life expectancy within and between species. There is little correlation between chronological and physiological age. For the purposes of this discussion, geriatric animals are considered to be those that have attained 75% of their expected life span.¹⁸

Pathophysiological changes associated with aging in organ systems influence anesthetic management (Table 47.2). Cardiovascular changes are multifactorial, reflecting not only age-related degeneration but also age-related disease. In the absence of a particular cardiovascular disease, the major anatomical changes in aging hearts are primarily an increase in the severity of myocardial fibrosis, valvular fibrocalcification, and ventricular wall thickening. Variable degrees of myocardial fiber atrophy result in decreased pump function and cardiac output. The heart rate may be affected if the pacemaker cells are involved. Fibrosis of the endocardium and valves leads to decreased compliance. Valvular incompetence may accompany valvular fibrocalcification. The vascular tree gradually loses elasticity, resulting in a decrease in distensibility, increased resistance to left ventricular output, and progressive hypertrophy of the ventricle. As ventricular hypertrophy and decreased chamber elasticity progress, the aging heart is more dependent on atrial contraction for diastolic ventricular filling. Thus, the atrial kick and normal sinus rhythm become more important in the maintenance of appropriate cardiac output.^{19,20}

In geriatric animals, the maximal chronotropic response during physiological stress decreases. In addition, despite higher endogenous levels of norepinephrine, the response to stress is decreased. This appears to be due to receptor attrition and reduced affinity for

Table 47.2. Changes in the anatomy and function of major organ systems in geriatric animals.

Cardiovascular system
Decreased arterial compliance
Decreased myocardial compliance
Decreased maximal heart rate
Decreased maximal cardiac output
Blunted β -receptor responsiveness
Pulmonary system
Reduced gas-exchange efficiency
Reduced vital capacity
Increased work of breathing
Decreased thoracic compliance
Decreased lung elasticity
Increased degree of airway closure
Nervous system
Increased sympathetic nervous system activity
Downregulation of β receptors
Decreased parasympathetic nervous system activity
Reduced central neurotransmitter activity
Increased sympathetic nervous system outflow
Renal and hepatic systems
Decreased drug clearance
Decreased glomerular filtration rate
Difficulty handling water-and-salt loads
Decreased urine concentrating ability and decreased ability to conserve sodium
Decreased perfusion and system blood flow
Decreased tissue mass
Body composition
Decreased skeletal muscle mass
Increased lipid fraction

agonist molecules. Whereas young adults increase cardiac output primarily through increased heart rate, geriatric animals increase cardiac output by increasing stroke volume in association with an increase in end-diastolic volume. Thus, geriatric animals depend more on preload than do younger animals and are not as tolerant of volume depletion in the perianesthetic period. This said, fit individuals maintain high levels of cardiac output and oxygen consumption, and reductions in cardiac index occur in direct proportion to reductions in skeletal muscle mass and metabolic rate associated with reductions in lean-tissue mass.^{19–21}

Pulmonary changes associated with aging include a decrease in ventilatory volumes and a reduction in the efficiency of gas exchange. Vital capacity, total lung capacity, and maximum breathing capacity decrease as the intercostal and diaphragmatic muscle masses reduce and the thorax becomes more rigid and less compliant. Functional alveoli and elasticity progressively decrease. As pulmonary elasticity decreases as result of decreases in lung elastin, the ratio of residual volume and of functional residual capacity to total lung capacity increase. Closing volume is increased, resulting in air trapping and an increase in ventilation-perfusion mismatch. As a result, PaO₂ decreases with age.²²

In the central nervous system, aging is associated with a reduction in brain size that occurs with the loss of neurons. Cerebro-

spinal fluid volume increases to maintain normal intracranial pressure. Despite this loss in brain tissue, functional and anatomical redundancy within the nervous system provides for the maintenance of functioning at levels that approximate those observed at somatic maturity. With the loss of brain tissue, cerebral blood flow decreases, but cerebral autoregulation of blood flow is well maintained. In addition to the loss of functional neurons in aging individuals, generalized depletions of dopamine, norepinephrine, tyrosine, and serotonin occur. Receptor affinity for neurotransmitters may be reduced. Compared with the neuronal plasticity observed in the young, this process is slower and less complete in geriatric individuals. As a result of these functional and anatomical changes in the central nervous system, geriatric individuals have a decreased requirement for anesthetic agents. The minimum alveolar concentration for inhalant anesthetics decreases linearly with age, and the requirement for local anesthetics, opioids, barbiturates, benzodiazepines, and other intravenous drugs is likely similarly reduced.^{19,23,24}

With aging, there is a primary loss of cortical kidney mass and functional nephron units. Total renal blood flow decreases with age, with the majority of the loss occurring in the renal cortex. In humans, one-half of the glomeruli present in the young adult atrophy or are nonfunctional by the age of 80. Glomerular filtration rate decreases, partly in response to a reduction in renal plasma flow. Geriatric individuals are less responsive to antidiuretic hormone and have an impaired ability to conserve sodium or concentrate urine. A reduction in renal blood flow makes the geriatric animal more susceptible to renal failure in the face of renal ischemia. Since geriatric patients cannot maximally retain sodium or water under conditions of volume depletion, the ability to correct fluid, electrolyte, and acid-base disturbances or to tolerate hemodynamic insults is reduced. Because geriatric patients have difficulty excreting a salt-and-water load, vigorous fluid and electrolyte therapy may result in excessive intravascular and extravascular volume, with the possible sequelae of congestive heart failure and peripheral edema. Those anesthetic drugs eliminated primarily by renal excretion have a greater elimination half-time in geriatric animals, necessitating a reduction in doses when these drugs are administered.^{25,26}

Hepatic clearance of drugs decreases with age as the mass of the liver decreases. In geriatric people, the liver mass, and consequently hepatic blood flow, may be decreased by 40% to 50%. Microsomal and nonmicrosomal enzyme function appears to be well maintained, although the reduction in hepatic mass significantly impairs overall hepatic function. Consequently, the metabolism of lipid-soluble drugs, particularly anesthetics, is decreased. Combined with decreased glomerular filtration and renal excretory capacity, the reduction in hepatic clearance of drugs results in an increase in the half-life and duration of effect of drugs that depend on these routes of elimination.^{19,25–27}

Aging results in changes in body composition that include a decrease in skeletal muscle, an increase in body fat as a percentage of total body weight, and a loss of intracellular water. A loss in total body water occurs as a result of decreased intracellular water and a reduction in plasma volume, although fit geriatric individuals maintain plasma volume well. Intravenous injection of

anesthetic drugs into a contracted volume of distribution results in an increased plasma concentration that may be responsible for the observation that geriatric animals are more sensitive to anesthetics. Increased adipose tissue is associated with an increase in the fraction of a single dose of a lipid-soluble drug redistributed to adipose tissue, further delaying elimination from the body.

Reductions in serum albumin concentrations in association with aging can lead to reduced protein binding of drugs. In addition, structural changes in the serum protein that occur with aging may decrease binding to the available protein. Theoretically, the administration of highly protein-bound drugs to animals with reduced serum proteins may lead to an exaggerated clinical effect.²⁸

A decrease in basal resting metabolic rate with age results in a reduction in the production of body heat. Consequently, geriatric individuals are less able to maintain core body temperature. This is particularly important in anesthetized animals placed in cold environments. Anesthetized geriatric animals tend to be more hypothermic than younger animals in the operative and postoperative periods, and rewarming occurs at a slower rate. Because shivering during recovery increases oxygen consumption by 200% to 300%, perianesthetic hypothermia alone may place severe demands on the cardiopulmonary system. If these demands are not met, arterial hypoxemia may ensue.¹⁹

Anesthesia

Preparation for Anesthesia

A thorough physical examination, including careful auscultation of the heart, is an essential component of preanesthetic assessment. In geriatric people, exercise tolerance is one of the most important predictors of perioperative outcome, and this is likely an important predictor of outcome in the anesthesia of geriatric animals. Significant, preexisting abnormalities should be corrected prior to the induction of anesthesia. Left untreated, these abnormalities are likely to be exacerbated by anesthesia. Neonatal, pediatric, or geriatric animals with limited physiological reserves are less able to respond to altered homeostasis. Hydration status should be assessed and fluid requirements carefully calculated. Fluid deficits should be corrected prior to anesthesia.

In neonates, standard preanesthetic blood work should include a minimum of hematocrit, total and fractionated protein, and blood glucose. Other blood work should be performed as indicated. In geriatrics, the preanesthetic assessment should include a complete blood count, serum chemistry profile, electrocardiogram, and urinalysis.

Neonates that are still suckling should not be held off food prior to anesthesia. Pediatric animals that are eating solid food should be denied food for only 3 to 4 h prior to anesthesia and should not be denied water at any time.

Premedication and Pain Management

Because of the immaturity of the neonatal nervous system, it has been a commonly held thesis that neonates are incapable of experiencing pain. However, we now know that neonatal humans and animals do indeed experience pain.^{29,30} In addition, evidence suggests that pain experienced at an extremely young age may

lead to dynamic changes in the nociceptive pathway, resulting in chronic pain conditions later in life.³¹ Like many pathologies, pain is easier to prevent than to treat. Regardless of age, every patient anesthetized for a painful procedure should receive appropriate analgesic therapy. As with other drugs, dosages of the analgesic drugs should be conservative, and patients should be closely monitored for signs of adverse side effects. Opioids are potent analgesics whose effects are reversible, making them an excellent choice for analgesia in neonates with immature metabolism or geriatrics with reduced hepatic function. The addition of local anesthetic techniques to anesthetic protocols for neonatal or geriatric animals is particularly appropriate. The inclusion of such techniques provides for additional analgesia and an associated reduction in the requirement for general anesthetics that may have more profound side effects. NSAIDs may be an option in older pediatric patients, but this class of drugs should be reserved for patients with mature, competent renal function.

The routine use of anticholinergics is not necessary, but, because neonates depend on adequate heart rate for maintenance of cardiac output, anticholinergics may be used to treat sinus bradycardia. Anticholinergics should also be considered in breeds with high vagal tone (e.g., brachycephalic breeds) and for surgical procedures that are likely to stimulate a vagal reflex (e.g., many ocular procedures). Geriatric animals may be less able to compensate for a slow heart rate than younger adult animals.

Sedation may not be necessary in quiet or debilitated patients. However, sedatives alleviate stress in anxious patients and decrease the dosage of drugs needed for induction and maintenance of anesthesia. The side effects of sedatives should be weighed against the side effects of having to use a larger dose of anesthetic drug. The opioids often provide adequate sedation and have the added advantage of providing analgesia. μ -Agonist opioids such as morphine, hydromorphone, and oxymorphone provide the most profound analgesia but also may cause greater cardiovascular and respiratory depression.³² Partial agonists (buprenorphine) and agonist-antagonists (butorphanol) provide only mild to moderate analgesia but also cause minimal cardiovascular and respiratory depression. Selection of an appropriate opioid is best made based on the particular analgesic requirements and the health status of the patient and the intended procedure.

Benzodiazepines are also useful sedatives/anxiolytics in neonatal or geriatric animals. Although they do not provide analgesia, they are reversible and produce little to no cardiovascular and respiratory depression. Benzodiazepines do not provide consistent or deep sedation and may need to be combined with other sedatives in very active or anxious neonatal or geriatric animals. The judicious use of low doses of α_2 -adrenergic agonists may also be considered for use in neonatal or geriatric animals. However, drugs in this class produce profound cardiovascular side effects (bradycardia, atrioventricular conduction block, and increased peripheral vascular resistance), and their use in either neonatal or geriatric animals should be confined to those cases where the benefit of their use outweighs the negative side effects associated with their administration. Low dosages of xylazine have been shown to be safe and effective in foals as young as 10 days of age.³³ Acepromazine may also be used for sedation of

neonates or geriatrics, but the cardiovascular effects, including hypotension, may be poorly tolerated in both geriatric and neonatal animals. The vasodilation caused by acepromazine can also contribute to the development of hypothermia. Acepromazine is not reversible and alone does not provide analgesia.

Induction

Anesthesia can be induced by using a variety of injectable anesthetic drugs or by mask delivery of inhaled anesthetics, when necessary. Etomidate or propofol may be excellent choices in neonates and geriatrics. Both agents are rapidly eliminated from the body by a variety of routes so that termination of activity does not depend on the functioning of a single organ system.³⁴ Propofol does produce respiratory and cardiovascular depression and should be titrated to achieve the desired depth of anesthesia. The administration of oxygen by face mask for approximately 5 min prior to the induction of anesthesia with propofol will reduce the risk of complications associated with propofol-induced apnea in either neonatal or geriatric animals. Preinduction sedation of animals, particularly with a sedative/analgesic drug, will reduce the dose of etomidate or propofol needed for induction. Ketamine, in combination with a benzodiazepine, is also a choice for the induction of anesthesia in either neonates or geriatric animals. Ketamine causes only mild respiratory depression and may actually improve cardiovascular function through stimulation of the sympathetic nervous system.³⁵ Although of benefit to geriatric animals, this response may be less in neonates because of their immature sympathetic nervous system. Ketamine requires either hepatic metabolism or renal clearance for termination of activity; thus, the effects of ketamine may be prolonged in patients with either immature or failing hepatic and renal systems.³⁵ Barbiturates may be used in low dosages for the induction of anesthesia in neonatal, pediatric, or geriatric animals, keeping in mind that drugs of this class are highly protein bound, and their termination of activity depends on both redistribution and hepatic metabolism. The response to barbiturates can be both pronounced and prolonged in either neonates or geriatrics with reduced plasma protein concentrations and/or immature or failing hepatic or renal function.

Inhaled anesthetics may be used for induction, as well as maintenance of anesthesia. This method is recommended only in sedated or debilitated patients because the prolonged excitement phase that occurs during induction can be more physiologically detrimental than a judicious dose of an injectable anesthetic. Environmental pollution and personnel exposure are also concerns during mask inductions with inhaled anesthetics. Induction in foals and calves with an inhaled anesthetic following nasotracheal intubation often results in rapid, excitement-free anesthesia simply because bypassing the nasal passages eliminates the ability to smell anesthetic gas.^{36,37} Because anesthesia can be induced with an inhaled anesthetic very rapidly in depressed neonatal and geriatric animals, excessive anesthetic depth may be reached very rapidly. Careful monitoring is a must.

Maintenance

Inhaled anesthetics that are minimally metabolized and easily cleared in animals with either immature or reduced hepatic or

renal function should be used for maintenance of anesthesia. However, it should be remembered that inhaled anesthetics cause dose-dependent hypotension, hypoventilation, impaired cardiac contractility, and hypothermia. Because of these side effects, inhaled anesthetics must be very carefully titrated, and vigilant monitoring should be employed to avoid excessive anesthetic depth. The concurrent administration of analgesics and sedatives will reduce the inhaled anesthetic requirement while decreasing the magnitude of their unwanted side effects.

Support

Along with a carefully chosen anesthetic protocol and conservative drug dosing, meticulous physiological support and vigilant monitoring are imperative during the anesthesia of neonatal, pediatric, or geriatric animals. Compared with adults, fluid requirements are greater in neonates (60 to 180 mL/kg/day)³⁸ because of their higher body-surface area, immature renal function (decreased ability to concentrate urine), higher percentage of body water, and higher respiratory rates leading to greater fluid losses.⁹ Conversely, overhydration should be avoided, because renal clearance may be limited and excessive dilution of serum protein can occur more readily in animals with preexisting hypoalbuminemia. Neonates have minimal stores of hepatic glycogen and are prone to hypoglycemia, so the use of dextrose-containing fluids should be considered.

In geriatric patients that have difficulty excreting a salt-and-water load, aggressive fluid and electrolyte therapy may result in excessive intravascular and extravascular volume, with the possible sequelae of congestive heart failure and peripheral edema. Thus, fluid therapy in the perianesthetic period of geriatric animals should be targeted at correcting specific deficits and maintaining adequate perfusion and oxygen delivery without delivering excessive electrolyte loads or fluid volumes.

Both neonatal and geriatric animals are highly susceptible to hypothermia, so every effort should be made to maintain normal body temperature. Hypothermia increases the incidence of adverse myocardial outcomes in high-risk patients, increases the incidence of surgical wound infection, adversely affects antibody- and cell-mediated immune defenses, changes the kinetics and action of various anesthetic and paralyzing agents, increases thermal discomfort, and is associated with delayed postanesthetic recovery.³⁹ The attempt of the body to rewarm itself is not benign, because shivering may cause a tremendous increase in oxygen consumption (200% to 300%), and this increased oxygen demand may not be met by an increase in oxygen delivery, particularly if anesthetic-induced hypoventilation occurs.

Diligent monitoring is crucial during the entire anesthetic period and well into recovery. Some commonly monitored indices are different in neonates than in adults, and anesthetists should be familiar with the normal physiological indices for each species and age group of individuals that are being anesthetized. Generally, neonatal and pediatric animals have a higher heart rate but lower blood pressure than adults. The normal heart rate in conscious neonatal dogs and cats is approximately 200 beats per minute, and the respiratory rate is approximately 15 to 35 breaths per minute. Mean arterial blood pressure in 1-month-old puppies

is only 49 mm Hg.⁴⁰ The average heart rate in foals 1 to 2 days of age ranges from 70 to 90⁴¹ beats per minute, and the normal respiratory rate is 30 to 40 breaths per minute.⁴²

Summary of Protocols

Suggested protocols for neonatal animals include an opioid premedicant with an additional sedative or tranquilizer, if required. Anesthesia can be induced with the intravenous administration of propofol or ketamine-benzodiazepine combinations. In severely compromised animals, anesthesia may be induced with an inhaled anesthetic delivered by face mask.^{43,44} For neonatal horses and cattle, suggested protocols include sedation with low-dose xylazine plus butorphanol followed either by intravenous administration of propofol or valium-ketamine or by nasal intubation and subsequent induction with an inhalant anesthetic.^{4,37} For all species, anesthesia is maintained with an inhalant and local blockade employed when possible to augment analgesia.

No one ideal anesthetic protocol exists for all geriatric patients. An understanding of the pathophysiological changes and the alterations in pharmacodynamics and pharmacokinetics that arise in conjunction with aging is necessary when choosing an anesthetic protocol for any geriatric animal. Particular attention to decreased dosage requirements and the titration of anesthetics to achieve the central nervous system depression necessary for a specific surgical procedure is advocated (Table 47.3). Whenever possible, local and regional anesthetic techniques should be employed to reduce the dosage of concomitantly administered inhaled or injectable anesthetics. Appropriate anesthetic manage-

ment of geriatric animals is centered around thorough evaluation and assessment; preoperative correction of identified abnormalities; vigilant, aggressive perianesthetic monitoring; careful titration of anesthetic drugs; and appropriate perianesthetic support.

Chapter 48

Dental Patients

Rachael E. Carpenter and Sandra Manfra Marretta

Introduction

General Preparation and Monitoring

Pain Management

Local and Regional Blocks

Take-Home Pain Medications

Introduction

Although sedation and local blocks alone have been advocated by some authors for dental procedures,¹ most procedures are best accomplished under inhalant anesthesia. Quite recently, several individuals have advocated anesthesia-free teeth cleaning. Proponents feel that more clients will pursue teeth cleaning if anesthesia is not used, because of the decreased cost and alleviated fears of anesthetic death or complications.² Many of the people performing and teaching these procedures are nonveterinarians, and a recent decision in a case brought before the Veterinary Medical Board in California has ruled that the procedure amounts to “the practice of veterinary medicine without a license.”³ The American College of Veterinary Dentistry has stated that thorough oral exams and dental radiographs are not possible in an unanesthetized patient and are needed to uncover any hidden dental disease that may be present.⁴

General Preparation and Monitoring

As with any anesthetic procedure, appropriate premedications and induction agents should be selected based on the requirements of the individual. An intravenous catheter should be placed to enable administration of fluids and for emergency access, if needed. All dental patients should be intubated with a cuffed endotracheal tube immediately after induction to prevent aspiration of water or cleaning solutions during dental procedures. Gauze sponges may be inserted in the pharyngeal area to further prevent aspiration. Packing the pharyngeal area too tightly can impede venous return and result in swelling of the tongue.⁵ If pharyngeal packing is used, a systematic method of ensuring that gauze is removed after the procedure prior to recovery from anesthesia is necessary. Dentistry in cats has been associated with tracheal rupture, likely from overinflation of the cuff contributing to tracheal trauma when the patient is turned from side to side to enable access to both sides of the mouth.⁶ In all instances and species, it is best to disconnect the breathing circuit from the endotracheal tube (after turning off the oxygen flow to minimize waste gas exposure) before repositioning the patient.

Following induction, heart and respiratory rates are assessed, and pulse oximetry, capnography, and blood pressure monitoring should be considered. Because vasodilation during inhalant anesthesia can exacerbate heat loss, hypothermia is a real threat to patients' overall well-being. Anesthetics further reduce the body's ability to respond to hypothermia. If a patient's attempt to regain body temperature is accompanied by severe shivering, increases in both myocardial work and systemic hypoxia are likely and undesirable. This may be especially important in geriatric animals with significant loss in functional cardiopulmonary reserve. Generally, it is safer to maintain a core body temperature during anesthesia than to try to regain body heat after anesthesia and surgery.

Pain Management

A balanced anesthetic plan for dental patients should include preemptive, intraoperative, and postoperative analgesics (Table 48.1). Pain associated with the procedure should be estimated prior to induction of anesthesia.⁷ Depending on the degree and magnitude of oral surgery performed, most pain will occur in the first 24 to 74 h postoperatively.⁸ Some residual discomfort might last longer. Individual patients should be frequently reassessed and treated, as needed. Behaviors indicative of pain (willingness to eat and drink, grooming behaviors, and activity level) may be best observed by the owners in the home environment. Analgesics commonly used in managing pain are the local anesthetics, opioids, α_2 -agonists and nonsteroidal anti-inflammatory drugs (NSAIDs). Opioids and α_2 -agonists can be used in the immediate preoperative and postoperative periods while the patient is in the hospital. Injectable or oral NSAIDs and longer-acting opioid preparations may be used during prolonged convalescence and for take-home medications.

Local and Regional Blocks

Local and regional anesthetic techniques are commonly used in the analgesic management of dental patients. Infraorbital, maxillary, mental, and mandibular inferior alveolar nerve blocks may be used before extractions. Caution should be used when blocking the inferior alveolar branch of the mandibular nerve, because inadvertent blocking of the lingual nerve may result in desensitization of the tongue and potential self-mutilation upon recovery. The lingual nerve is best avoided by keeping the needle close to the bone of the ventral mandible when performing the intraoral approach to the inferior alveolar branch of the mandibular nerve.⁵

Table 48.1. Common dental techniques and anesthetic/analgesic requirements

Dental Technique	Sedation/Anesthesia Requirement	Analgesic Requirement
Dental radiographs	Heavy sedation or general anesthesia	None
Gingivectomy/gingival biopsy	Heavy sedation or general anesthesia	Topical, infiltration or local blocks, and systemic analgesics for mild to moderate pain
Dental prophylaxis	General anesthesia	None
Minor extractions (minimal elevation required), deep subgingival scaling, and/or root planning and curettage	General anesthesia	Infiltration technique, local blocks, and systemic analgesics for mild pain
Surgical extractions (major elevation and bone removal required)	General anesthesia	Regional nerve blocks (e.g., infraorbital nerve block), and systemic analgesics for moderate to severe pain
Root canal therapy	General anesthesia	Regional nerve blocks, and systemic analgesics for moderate pain
Mandibulectomy/maxillectomy	General anesthesia	Regional nerve blocks, and systemic analgesics for severe pain
Jaw fracture	General anesthesia	Regional nerve blocks, systemic analgesics for moderate to severe pain (depending on type of fracture)

For analgesia of the maxillary teeth, care should also be taken to avoid insertion of the needle into the infraorbital canal when performing infraorbital blocks in cats and brachycephalic breed dogs. The canal is extremely short in these animals, and insertion of the needle into it may cause ocular damage. As an alternative, infiltration anesthesia can be used where local anesthetic is injected directly into the periodontal ligament and surrounding tissues. It is most effective when performed in areas with thin cortical bone (maxillary teeth and mandibular incisors) and when a small number of teeth need to be desensitized.^{5,9}

When using either lidocaine or bupivacaine, it is important to calculate the total dose of local anesthetic that can be safely used to avoid toxicity (Table 48.2). Generally, toxic doses of lidocaine are 10 mg/kg in dogs and 6 mg/kg in cats. The toxic doses of bupivacaine are lower and are approximately 3 mg/kg in dogs and 2 mg/kg in cats. Recent reports have examined the usefulness of opioids in extending the analgesia from local anesthetic in regional anesthetic techniques in humans. Both 0.075 mg/kg (0.035 mg/lb) morphine and 0.003 mg/kg (0.0015 mg/lb) buprenorphine have been shown to double the analgesic duration in humans when combined with either lidocaine or bupivacaine.^{10,11} Mu-opioid receptors have been located in human dental pulp, suggesting that local administration of opioids may be beneficial for dental procedures.¹² One study in humans found that pain scores were lowered for up to 24 h when morphine was added to the local anesthetics compared with patients that received local anesthetics alone.¹³ Little data are available regarding the use of opioids with local analgesics for dental blocks in veterinary patients, but it may prove to be a useful local application of this class of analgesics.

Take-Home Pain Medications

One challenging aspect of pain management for veterinary dental patients involves medication that can be sent home for managing lingering pain (Table 48.3). At present, oral NSAIDs ap-

Table 48.2. Recommended local anesthetic doses for dental blocks

Local Anesthetic	Dog	Cat
Bupivacaine	Up to 2.0 mg/kg	Up to 1.0 mg/kg
Lidocaine	Up to 6.0 mg/kg	Up to 3.0 mg/kg
Mepivacaine	Up to 6.0 mg/kg	Up to 3.0 mg/kg

pear to be the most commonly recommended dispensable medications for short-term treatment of dental pain.¹⁴ When using NSAIDs, appropriate patient selection is important to reduce the risk associated with the use of this class of drugs. If additional analgesics are needed, oral opioids (such as butorphanol tablets, codeine tablets, and morphine tablets) are available that may be combined with the NSAIDs.¹⁵ In recent years, an opioid-like oral agent, tramadol, has demonstrated good analgesic activity for mild to moderate pain.¹⁶ Tramadol is not scheduled and has been shown to be useful for management of postoperative pain in dogs.¹⁷ In addition, a handful of commercially available opioid/NSAID preparations combine an opioid with acetaminophen (e.g., codeine or oxycodone plus acetaminophen) that could be used in dogs to relieve dental pain but not in cats.

Cats may be more difficult for owners to medicate at home, but recent studies have shown that the parenteral form of buprenorphine is well absorbed when administered transmucosally to cats.¹⁸ In this same study, owners were surveyed as to their preferred method of administering medications to cats. Cat owners overwhelmingly chose oral medications as their preferred technique for home administration. The oral administration of buprenorphine and meloxicam (or other NSAID) may provide an effective method of controlling moderate to severe pain in cats after invasive dental manipulation (Table 48.3).

Table 48.3. Dispensable oral medications for dental patients

NSAID		
Acetaminophen	15 mg/kg PO TID	<i>Toxic to cats</i>
Aspirin	10–25 mg/kg PO BID	10–20 mg/kg PO q 48–72 h
Carprofen	2 mg/kg PO BID or 4.4 mg/kg PO SID	1–2 mg/kg PO SID (1–2 doses only)
Ketoprofen	2 mg/kg PO loading dose, then 1 mg/kg SID (max. 5 days)	1 mg/kg PO loading dose, then 0.05 mg/kg SID (max. 3–5 days)
Etodolac	10–15 mg/kg PO SID	—
Meloxicam	0.2 mg/kg PO loading dose, then 0.1 mg/kg PO SID	0.1 mg/kg loading dose, then 0.025 mg/kg PO SID (3–4 days)
Opioid		
Buprenorphine	—	0.010–0.040 mg/kg transmucosally BID to q.i.d.
Butorphanol	0.2–1.0 mg/kg PO q 1–4 h	0.2–1.0 mg/kg PO q 1–4 h
Codeine	1–2.0 mg/kg PO q 6–8 h	0.1–1.0 mg/kg PO q 4–8 h
Morphine	0.3–1.0 mg/kg PO q 4–8 h	—
Tramadol	2–10 mg/kg/day PO divided BID or TID	2–10 mg/kg/day PO divided BID or TID

NSAID, nonsteroidal anti-inflammatory drug.

 Opioids
 NMDA Antagonists
 Combination Analgesics
 Anticonvulsants
 Tricyclic Antidepressants
 Steroids
 Bisphosphonates
Other Cancer Pain-Relieving Modalities

Introduction

We know very little about cancer pain in animals, and very few studies have been published evaluating cancer pain and its alleviation.¹⁻⁴ Given the lack of veterinary clinical studies, the information in this chapter cannot be based solely on peer-reviewed investigations. Rather, it is based on the experience of veterinary clinicians involved in the treatment of cancer patients. Considered extrapolations from human medicine and from veterinary research in other chronically painful conditions, such as osteoarthritis, are relied on, as well.

This chapter reviews the assessment and treatment of chronic cancer pain in dogs and cats. The control of perioperative pain in cancer patients is very important and readers are encouraged to refer to appropriate texts and other chapters in this text for information on perioperative pain control.^{5,6}

General Approach to Cancer-Pain Management

Barriers to effective cancer-pain control in animals include

- Lack of appreciation that many cancers are associated with significant pain
- Inability to assess pain accurately in cancer patients
- Lack of knowledge of drugs, drug therapy, and other pain-relieving techniques

- Lack of communication with clients and lack of involvement of clients in the assessment and treatment phases
- Underuse of nursing staff for assessment and reevaluation of pain in cancer patients

There are four main steps in overcoming these barriers and assuring that chronic pain management is optimized in veterinary patients:

- Assure that veterinarians have the appropriate education and training about the importance of alleviating pain, assessment of pain, available drugs and potential complications, and interventional techniques.
- Educate the client about realistic expectations surrounding pain control and quality of life and convey the idea that most patients' pain can be managed. This involves letting the client know that owner involvement in evaluating the pet and providing feedback on therapy is crucial to success. The veterinarian and owner should both participate in developing effective strategies to alleviate pain. The clients' involvement also helps decrease their feelings of helplessness.
- Thoroughly assess the pet's pain at the start and throughout the course of therapy, not just when it becomes severe.
- Have good support from the veterinary practice or institution for the use of opioids and other controlled substances.

Although pharmacological treatment is the mainstay of cancer-pain treatment, adjunctive nondrug therapies such as acupuncture may play an important role in the management of patients' chronic cancer pain. It must also be remembered that surgery and radiation therapy have very important roles in the management of cancer pain through treatment or palliation of the disease.

A basic approach to cancer-pain management can be summarized:

1. Assess the pain. Ask for the owner's perceptions of the pet's pain or of any compromise in its quality of life.
2. Believe the owner. The owner sees the pet every day in its own environment and knows when alterations in behavior occur. Owners can rarely suggest diagnoses but do know when something is wrong and when their pet is in pain. The veterinarian should become familiar with the owner's terminology when explaining the pet's abnormal behaviors to establish a baseline of communication for further assessment in the home environment once therapy has been initiated.
3. Choose appropriate therapy depending on the stage of the disease. Anything other than mild pain should be treated with

more than one class of analgesic or with an analgesic drug combined with nondrug adjunctive therapy. Also consider concurrent problems and drug therapy; be aware of potential drug interactions and toxicity.

4. Deliver the therapy in a logical, coordinated manner and explain carefully to the owner about any possible side effects.

5. Empower the clients to participate actively in their pet's treatment; ask for feedback and updates on how the therapy is working.

The Importance of Alleviating Pain

The alleviation of pain is important from physiological and biological standpoints, as well as from an ethical perspective.⁷ Pain can induce a stress response in patients that is associated with elevations in adrenocorticotropic hormone, cortisol, antidiuretic hormone, catecholamines, aldosterone, renin, angiotensin II, and glucose, along with decreases in insulin and testosterone.⁸ A prolonged stress response can decrease the rate of healing. In addition, the stress response can adversely affect the cardiovascular and pulmonary systems, fluid homeostasis, and gastrointestinal (GI) tract function.⁸

Veterinarians have an ethical obligation to treat animal pain. Most undertreatment of chronic pain is probably a result of lack of adequate knowledge and resources rather than a lack of concern. Outward show of concern for the pet and family is important for demonstrating a bond-centered approach to cancer therapy and pain management. Most owners who are willing to undergo the emotional stress and financial commitment to cancer therapy have already shown they have a strong attachment to their pet. It is important for the veterinarian to foster good communication surrounding primary therapy and pain treatment and at the same time demonstrate empathy for the owner. In cancer patients especially, pain prevention and treatment are not the only aspects that impact animal welfare, and veterinarians must evaluate all aspects of welfare when making treatment decisions. To help in an evaluation of welfare, *five freedoms*, initially proposed by the Brambell committee in reference to farmed animals, have been suggested as a rubric for the evaluation of welfare.⁹ These may equally be applied to the context of companion animals:⁷

- Freedom from hunger and thirst
- Freedom from physical and thermal discomfort
- Freedom from pain, injury, and disease
- Freedom to express normal behavior
- Freedom from fear and distress

The approach to the treatment of cancer patients should be one that considers all aspects of welfare. For each freedom, the severity, incidence, and duration of perturbation should be considered. For example, for pain, the longer the pain lasts, such as in long-standing painful cancers, the more welfare is compromised.

It is of significant interest that the provision of analgesics significantly reduces the tumor-promoting effects of undergoing and recovering from surgery.¹⁰ Surgery is well known to suppress several immune functions, including natural killer (NK) cell ac-

tivity in animals and people, probably as a result of substances released, such as catecholamines and prostaglandins. This suppression of NK cell activity can enhance metastasis.^{11–13} The reduction of the tumor-promoting effects of surgery by analgesics seems to be due to the alleviation of pain-induced reduced NK cell function, but unrecognized factors other than immune cells probably also play a role.¹⁰ Thus, the provision of adequate perioperative pain management in oncological surgery may protect clinical patients against metastatic sequelae. It may also be that the treatment of the chronic pain may somewhat protect against metastasis and possibly the local extension of cancer. This is an, as yet, unproven but interesting hypothesis.

Assessment of Cancer Pain

Assessment of pain in animals can be very difficult and frustrating. The tolerance of pain in a veterinary patient probably varies greatly from individual to individual, as it does in humans. Coupled with the innate ability of dogs and, particularly, cats to mask significant disease and probably pain, this makes it very difficult to assess pain. Often veterinarians need to rely on human experience to help define pain in animals. The mainstay of pain assessment in cats and dogs with cancer is likely to be changes in behavior. Table 49.1 outlines behaviors that are indicative of pain. The main point to remember is that any change in behavior can be associated with pain. Veterinarians should also allow technicians and other staff members to be involved in the assessment. Technicians and other staff members are usually better able to evaluate pain and quality of life in animals because they spend more time with the patients in the hospital. Thus, they are more likely to be able to converse in a relaxed and informal way with pet owners.

The best and most important people to assess their animal's behavior are the owners. The veterinary surgeon must work closely and communicate effectively with the owner to be able to capture this information. Often owners need education as to what signs to look for, or education that certain behaviors may be indicative of pain. Once very specific changes in behavior can be identified and recorded, these can be used to monitor the effectiveness of analgesic therapy. This approach has proved very sensitive in the evaluation of chronic pain caused by osteoarthritis.¹⁴ In cases where pain does not cause a specific behavioral change, but rather a vague change in an animal's behavior, the owner is still the best person to assess the pet's pain or—as the combination of pain and other welfare considerations is often described—*well-being* or *quality of life*. Capturing this information can also be a very sensitive indicator of the effectiveness and appropriateness of therapy. Physiological variables, such as heart rate, respiratory rate, temperature, and pupil size, have been shown to be unreliable measures of acute perioperative pain in dogs and are therefore unlikely to be useful in chronic pain states.¹⁵

Principles of Alleviation of Cancer Pain

Drugs are the mainstay of cancer-pain management, although nondrug adjunctive therapies are becoming recognized as in-

Table 49.1. Outline of behaviors that may be seen with cancer-associated or cancer therapy-associated pain in cats and dogs.

Behavior	Notes
Activity	Less activity than normal. Very specific activities may be changed: decreased jumping; less playing; less venturing outside; and less willing to go on walks (dogs). Stiff gait, altered gait, or lameness can be associated with generalized pain, but are more often associated with the appendicular or axial musculoskeletal system. Slow to rise and get moving after rest (osteoarthritis, which is often concurrently present).
Appetite	Often decreased with cancer pain.
Attitude	Any change in behavior can be associated with cancer pain: aggressiveness, dullness, shyness, “clinginess,” and increased dependence.
Facial expression	Cats: head hung low, squinted eyes. Dogs: sad expression, head carried low.
Grooming	Failure to groom, caused by either a painful oral lesion or generalized pain
Response to palpation	This is one of the best ways to diagnose and monitor pain. Pain can be elicited by palpation of the affected area or by manipulation of the affected area, which exacerbates low-grade pain to produce transient severe pain. This is manifested as an aversion response from the animal, i.e., the animal attempts to escape the procedure, or yowls, cries, hisses, or bites. Pain is inferred when this occurs.
Respiration	This may be elevated with severe cancer pain.
Self-traumatization	Licking at an area (e.g., a joint with osteoarthritis, bone with primary bone cancer, or abdomen with intra-abdominal cancer) can indicate pain. Scratching can indicate pain (e.g., scratching at cutaneous tumors or scratching and biting at the flank with prostatic or colonic neoplasia). Self-traumatization can also indicate the presence of neuropathic pain, or referred pain.
Urinary and bowel elimination	Cats: failure to use litter box. Dogs: urinating and defecating inside.
Vocalization	Vocalization is rare in response to chronic pain in dogs and cats, but owners of dogs will often report frequent odd noises (whining and grunting) associated with cancer pain. Occasionally, cats will hiss, utter spontaneous plaintive meows, or purr in association with cancer pain. This may be in response to the intermittent severe spontaneous pain associated with neuropathic pain.

creasingly important. The World Health Organization (WHO) has outlined a general approach to the management of cancer pain, based on the use of the following groups of analgesics:¹⁶

- Nonopioid analgesics (e.g., nonsteroidal anti-inflammatory drugs and acetaminophen)
- Weak opioid drugs (e.g., codeine)
- Strong opioid drugs (e.g., morphine)
- Adjuvant drugs (e.g., corticosteroids, tricyclic antidepressants, anticonvulsants, *N*-methyl-D-aspartate [NMDA] antagonists)

The general approach of the WHO ladder is a three-step hierarchy (see Fig. 49.1). Within the same category of drugs, there can be different side effects for individuals. Therefore, if possible, it may be best to substitute drugs within a category before switching therapies. It is always best to try to keep dosage scheduling as simple as possible. The more complicated the regimen is, the more likely is owner noncompliance. Drugs should be dosed on a regular basis, not just as needed, as pain becomes moderate to severe. Continuous analgesia will facilitate maintaining patient comfort. Additional doses of analgesics can then be administered as pain is intermittently more severe. Adjuvant drugs can be administered to help with specific types of pain and anxiety.

There are two potential problems with the use of the WHO

analgesic ladder in veterinary medicine. First, there is very little information from human medicine, and virtually none from veterinary medicine, on which drugs are most effective for a particular type of cancer pain. It may well be that *third tier* drugs are the most effective for a particular condition and therefore best used initially.

The second problem is that such an approach may not be best suited for patients that present with severe pain. Many veterinary cancer patients present at an advanced stage of disease and thus are already in severe pain. Once pain has been present for a period, changes may have occurred in the central nervous system (CNS) that alter the way pain signals are processed. This alteration in processing (*central sensitization*) makes traditional analgesics less effective and requires that multiple classes of drugs be used concurrently to minimize pain. This is known as *multimodal pain therapy*. Once pain is minimized, and central changes are partially reversed, the administration of various classes of analgesic drugs initially used can be decreased. This approach has been termed the *analgesic reverse pyramid* approach.¹⁷ It is currently unknown which of these two approaches (the WHO ladder or the reverse pyramid) is most appropriate and, indeed, one approach may be best at one disease stage and the other later on. The most important aspect in the treatment of cancer pain is that, in the majority of situations, *multimodal therapy* (i.e., concurrent

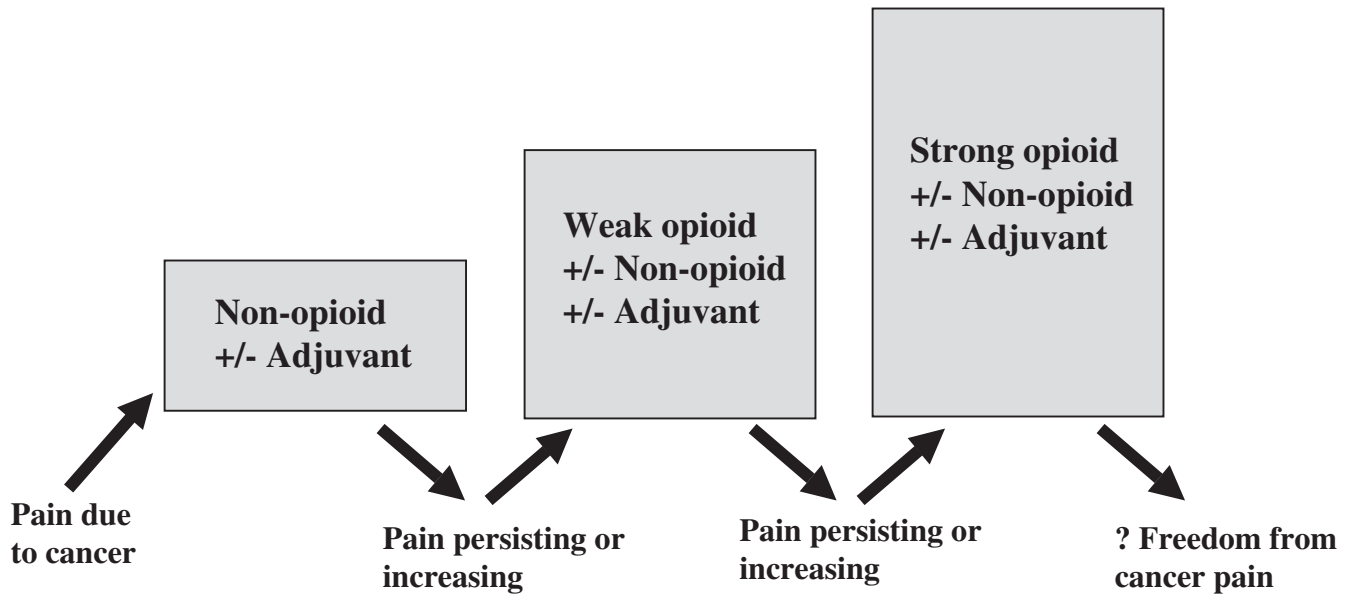

Fig. 49.1. Diagram showing the World Health Organization *analgesic ladder* for the treatment of cancer pain. The three standard analgesics making up this ladder are nonsteroidal anti-inflammatory drugs, opioids (such as codeine), and full μ opioid agonists (such as morphine). Alternatives are substituted as necessary. This simple approach is likely to be superseded by a more complex approach based on the mechanism of pain associated with particular cancer types. The three-step WHO ladder approach is not always suitable for veterinary patients, who often initially present with relatively advanced disease and significant pain.

use of more than one class of drug) is required for successful alleviation of the pain. The drugs that can be used for chronic cancer-pain management are outlined in Tables 49.2 (dogs) and 49.3 (cats).

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

The cyclooxygenase (COX) enzyme exists in (at least) two different forms. This relatively recent finding led to the rather simple designation of one COX enzyme producing *essential prostanoids* (e.g., those involved in maintaining mucosal integrity of the stomach) on a minute-to-minute basis, and another that is activated by tissue trauma and produces *inflammatory or pain-mediating prostanoids*. However, it is not as simple as COX-1 being good and COX-2 bad, because COX-2 has been shown to be expressed constitutively in certain tissues such as the canine kidney (although data are conflicting) and the canine CNS.^{18–20} It is not fully understood what role, if any, COX-2 plays in canine GI mucosa. Simplistic theory would suggest that selective or preferential COX-2 inhibitors (e.g., carprofen, deracoxib, meloxicam, and firocoxib) might be associated with fewer GI side effects than would a nonselective drug. Although clinical experience with COX-2 selective drugs in human patients suggests that fewer side effects occur with these agents (such as celecoxib or rofecoxib) than with nonselective NSAIDs (such as ibuprofen or aspirin), widespread clinical experience is required before a similar statement can be made with respect to COX-2 selective drug use in dogs. Prostaglandins produced by COX-2 are involved in the healing of injured GI tract, and the safety of

COX-2 selective drugs in patients with inflammatory bowel disease or subclinical GI erosion or ulceration is unknown. Theory would also suggest that COX-2 selective drugs are not any safer for the kidney than are the nonselective drugs. Again, widespread clinical experience in dogs is required to substantiate this, although the COX-2 selective drugs used in humans have been found to be associated with a similar incidence of renal toxicity as traditional NSAIDs.²¹ The relevance of this discussion to cancer treatment is that veterinarians need to be very aware of the possible side effects of NSAIDs and communicate this to owners. Very often, because of preexisting disease or concurrent therapy, cancer patients are at greater risk for toxic side effects from NSAIDs.

More recently, research has shown COX-2 plays a significant role in the development and progression of cancer. The production of prostaglandin E₂ by COX-2 has been linked to the promotion of tumorigenesis.²² COX-2 overexpression in cells will inhibit apoptosis, allowing neoplastic cells to continue to live. Other mechanisms by which COX-2 contributes to tumor development include facilitating the adhesion and increasing the invasiveness of cancer cells, increased cell growth, suppression of the immune system, and enhanced angiogenesis.²³

COX-2 overexpression has been demonstrated in a number of premalignant and malignant conditions, including colon cancer, non-small-cell lung cancer, breast cancer, bladder cancer, pancreatic cancer, prostate cancer, and head-and-neck cancer in people.^{24–30} Overexpression of COX-2 in tumors has been linked with a poor prognosis and more aggressive cancer. As a result of these findings, selective COX-2 inhibitors are being used in chemotherapy protocols against these cancers.^{31,32} NSAIDs are

Table 49.2. Suggested doses of analgesics that may be used for the alleviation of chronic cancer pain in dogs^a.

Drug	Dose for Dogs	Comments
Acetaminophen (paracetamol)	10–15 mg/kg PO q 8 h for 5 days Long-term therapy: up to 10 mg/kg every 12 h	This seems to be associated with fewer GI side effects than are regular NSAIDs, and not noted to be associated with renal toxicity. Toxicity has, however, not been evaluated clinically in dogs. It has been combined with regular NSAIDs (e.g., meloxicam or carprofen) in severe cancer pain, but this combination has not been evaluated for toxicity, and increased toxicity is likely to be seen.
Acetaminophen (paracetamol) (300 mg) + codeine (30 or 60 mg)	Dose based on 10–15 mg/kg of acetaminophen	The acetaminophen dose corresponds to 2 mg/kg codeine. Sedation may be a side effect.
Amantadine	3.0–5.0 mg/kg PO q 24 h	This is an NMDA antagonist (although originally marketed as an antiviral agent) that seems to produce a significant level of analgesia when given in combination with an NSAID. Loose stools and excess GI gas can be seen at higher doses for a few days. It should not be combined with drugs such as selegiline or sertraline until more is known about interactions among these drugs.
Amitriptyline	0.5–2.0 mg/kg PO q 24 h	This augments the descending serotonergic system, which is one of the body's endogenous analgesic mechanisms. It is not a "strong" analgesic, but, like amantadine, tramadol, and codeine, is useful when combined with an NSAID or paracetamol. It has not been evaluated for clinical toxicity in dogs.
Aspirin	10 mg/kg PO q 12 h	This causes significantly more GI ulceration than approved NSAIDs. <i>Caution:</i> Do not administer near the time of surgery because platelet function is inhibited.
Butorphanol	0.2–0.5 mg/kg PO up to q 8 h	This may produce sedation at higher doses. It is not a very predictable analgesic and is best used in combination with other analgesics, e.g., NSAIDs.
Codeine	0.5–2.0 mg/kg PO q 24 h	Sedation can be seen at the higher doses.
Carprofen	2 mg/kg PO q 12 h or 4 mg/kg PO q 24 h	—
Deracoxib	1–2 mg/kg PO q 24 h long term	This is one of the most specific COX-2 inhibitors approved for use in dogs with osteoarthritis (USA).
Etodolac	5–15 mg/kg PO q 24 h	(Available only in the USA.)
Fentanyl, transdermal	2–5 µg/kg/h	This can be very useful for the short-term control of cancer pain. For long-term therapy, its usefulness is limited by the need to change the patch every 4 to 5 days and the expense involved.
Gabapentin	3–10 mg/kg PO q 24 h	This has not been evaluated in dogs as an analgesic; it is most frequently used as an antiseizure drug and is rapidly metabolized in dogs. It can be useful for neuropathic pain, such as after limb amputation or for nerve-root tumor pain, or cancers that seem to have a significant component of neuropathic pain (osteosarcoma). Its best effects are seen when used in combination with other analgesics, such as NSAIDs or acetaminophen (paracetamol).
Glucosamine and chondroitin sulfate	13–15 mg/kg chondroitin sulfate PO q 24 h	This can be used in a variety of cancer pain because of its mild anti-inflammatory and analgesic effects. It is best used in combination with an NSAID or other analgesic.
Meloxicam	0.2 mg/kg PO day 1, and then 0.1 mg/kg q 24 h	—
Morphine, liquid	0.2–0.5 mg/kg PO q 6–8 h	This can be useful for dosing smaller dogs when morphine tablets are not suitable. Sedation and (particularly) constipation are side effects that are seen as the dose is increased. Oral morphine may not be as effective in dogs as it is in humans.

(continued)

Table 49.2. Suggested doses of analgesics that may be used for the alleviation of chronic cancer pain in dogs^a (*continued*).

Drug	Dose for Dogs	Comments
Morphine, sustained release	0.5–3.0 mg/kg PO q 8–12 h	Doses higher than 0.5–1.0 mg/kg are often associated with unacceptable constipation according to owners, so the suggested use is 0.5 mg/kg several times a day. However, recent evidence indicates the “first pass” effect for oral morphine is very high in dogs, and analgesic tissue levels may be very difficult to attain.
Pamidronate (one of the bisphosphonate class of drugs)	1–1.5 mg/kg slowly IV, probably once a month (although this has not been defined yet)	This drug inhibits osteoclast activity and thus provides analgesia in patients with a primary or metastatic bone tumor that is causing osteolysis.
Piroxicam	0.3 mg/kg PO q 48 h	Despite its widespread use as a mild chemotherapeutic agent for epithelial tumors, the incidence of side effects in dogs is not known but appears to be quite high at 0.3 mg/kg q 24 h, so suggested use is 0.3 mg/kg q 48 h.
Prednisolone	0.25–1.0 mg/kg PO q 12–24 h Taper to q 48 h, if possible, after 14 days	Do <i>not</i> use this concurrently with NSAIDs. It can be particularly useful in providing analgesia when there is a significant inflammatory component associated with the tumor.
Tepoxalin	10–20 mg/kg PO on day 1, followed by 10 mg/kg daily	This NSAID is a “dual inhibitor” that inhibits both cyclooxygenase and lipoxygenase enzymes. It is likely to be particularly useful in cancer pain where there is a significant inflammatory component.
Tramadol	4–5 mg/kg PO q 6–12 h	This has not been evaluated for efficacy or toxicity in dogs but appears to be a useful adjunctive analgesic (when combined with other analgesics, such as acetaminophen or the NSAIDs) for the treatment of cancer pain in dogs. If sedation is seen, the dose should be reduced.

^aNone of the drugs have been evaluated for efficacy in the treatment of cancer pain. None of these drugs are approved or licensed for use in chronic cancer pain. Some drugs are approved for use in osteoarthritis, and doses are extrapolated from recommended doses for the treatment of osteoarthritis. The doses listed come from the authors’ experience and from the experience of others working in the area of clinical cancer-pain control. GI, gastrointestinal; IV, intravenously; NMDA, *N*-methyl-D-aspartate; NSAID, nonsteroidal anti-inflammatory drug; and PO, per os (orally).

Table 49.3. Suggested doses of analgesics that may be used for the alleviation of chronic cancer pain in cats.^{a,b}

Drug	Cat Dose (mg/kg)	Comments
Acetaminophen (paracetamol)	Contraindicated	It is contraindicated because small doses rapidly cause death in cats.
Amantadine	3.0 mg/kg PO q 24 h	This has not been evaluated for toxicity but is well tolerated by dogs and people, with occasional side effects of agitation and GI irritation. It may be a useful addition to NSAIDs in the treatment of chronic cancer-pain conditions. The 100-mg capsules need to be recompounded for cats, or capsules compounded from the powder drug.
Amitriptyline	0.5–2.0 mg/kg PO q 24 h	This appears to be well tolerated for up to 12 months of daily administration in cats. Occasionally drowsiness is seen (<10%). This drug may be a useful addition to NSAIDs for treatment of chronic pain conditions. ^{74,81}
Aspirin	10 mg/kg PO q 48 h	This can cause significant GI ulceration.

(continued)

Table 49.3. Suggested doses of analgesics that may be used for the alleviation of chronic cancer pain in cats^{a,b} (*continued*).

Drug	Cat Dose (mg/kg)	Comments
Buprenorphine	0.02 mg/kg sublingual q 6–7 h	Recent information from the University of Florida, using a research model, suggests that this provides good analgesia when administered sublingually (20 µg/kg; injectable formulation) and provides good analgesia predictably for 6–7 h (buprenorphine IV provides analgesia for the same period when administered at the same dose). The sublingual route is not resented by cats and may be a good way to provide postoperative analgesia at home. Feedback from owners indicates that, after 2–3 days at this dose, anorexia develops. Smaller doses (5–10 µg/kg) may be more appropriate for long-term administration, especially in combination with other drugs. ⁵⁷
Butorphanol	0.2–1.0 mg/kg PO q 6 h	One study suggests that using this PO after surgery may be beneficial. It is generally considered to be a poor analgesic in cats except for visceral pain, but the authors have found it to be useful as part of a multimodal approach to cancer-pain therapy. ⁸²
Glucosamine/chondroitin sulfate combinations	Ca. 15 mg/kg chondroitin sulfate PO q 12 to 24 h	This combination appears to produce mild anti-inflammatory and analgesic effects in cats more predictably than in dogs. It can be used in conjunction with NSAIDs, opioids, and amantadine.
Ketoprofen	1 mg/kg PO q 24 h; maximum 5 days	This is probably well tolerated as pulse therapy for chronic pain, with a few days rest between treatments. It has also been used by some at 1 mg/kg every 3 days long term or at 0.5 mg/kg every other day long term. A safe long-term dosing regimen has not been established.
Meloxicam	0.1 mg/kg PO on day 1, followed by 0.05 mg/kg PO daily for 4 days, and then 0.025 mg/kg to 0.05 mg/kg every other day	This is particularly well received by cats because of its formulation as a honey syrup. The drop formulation makes it very easy to decrease the dose gradually and accurately. A safe long-term dosing regimen has not been established. ⁸³
Morphine (oral liquid)	0.2–0.5 mg/kg PO TID–QID	This is best compounded into a palatable flavored syrup, but cats usually strongly resent this medication. Morphine may not be as effective in cats as it is in dogs.
Piroxicam	1 mg/cat PO daily for a maximum of 7 days If longer-term medication is considered, suggested use is dosing every other day, but see the note at right	This can be compounded into a palatable liquid, but recent information suggests that the active drug decreases significantly over a 10-day period after compounding in an aqueous solution. In the authors' experience, significant drops in PCV (presumably caused by GI hemorrhage) occur in up to 30% of cats after 2–3 weeks of drug therapy.
Prednisolone	0.25–0.5 mg/kg PO q 24 h	This can be particularly effective in cancers associated with significant inflammation (such as squamous cell carcinoma of the oral cavity in cats). Do <i>not</i> combine it with concurrent NSAID administration.
Tolfenamic acid	4 mg/kg PO q 24 h for 3 days maximum	—
Tramadol	1–2 mg/kg once or twice daily	This has not been evaluated for toxicity in cats and has not yet been used extensively by the authors for treatment of cancer pain in cats. However, early results are encouraging, but toxicity appears to be seen more readily in cats than dogs.
Transdermal fentanyl patch	2–5 µg/kg/h	A 25-µg/h patch can be applied to average-size cats (7.7–11.0 lb; 3.5–5.0 kg). In smaller cats, other methods of providing analgesia should be sought because it is not recommended to cut patches in half, and covering half of the patch produces unpredictable results. The decay in plasma levels following patch removal is slow. ^{84,85}

^aNone of these drugs have been evaluated for efficacy in the treatment of cancer pain. None are approved or licensed for use in the treatment of chronic cancer pain. Some are approved for treatment of inflammatory or painful conditions in cats in certain countries, and doses for the control of cancer pain are extrapolated from these. The doses listed come from the authors' experience and from the experience of others working in the area of clinical cancer-pain control. GI, gastrointestinal; IV, intravenously; NSAID, nonsteroidal anti-inflammatory drug; PCV, packed cell volume; and PO, per os (orally).

^bAdapted from Lascelles⁸⁶ and from Tranquilli et al.⁸⁷

also being used to protect against cancer in people genetically at risks for certain cancers, such as colon cancer, although it seems that some NSAIDs may be more effective than others.^{33–35} Basic research has also shown that COX-2 inhibitors may enhance the effects of radiation of tumors.³⁶

Significant research has recently been directed toward examining the role of COX-2 in dogs with cancer. In dogs, COX-2 is overexpressed in a number of carcinomas, including bladder and renal, mammary, intestinal, cutaneous (squamous cell), and nasal, and, in some sarcomas, such as osteosarcoma.^{37–40} A number of investigators have examined the anticancer properties of NSAIDs (to date, mainly only those of piroxicam) in canine tumors. Administration of piroxicam causes regression of, and slows the progression of, rectal tubulopapillary polyps.⁴¹ Piroxicam has also been shown to have anticancer effects in canine transitional cell carcinoma and canine oral squamous cell carcinoma.^{42–47} In multicentric lymphoma, there was no apparent benefit to adding piroxicam to doxorubicin.⁴⁸

NSAIDs have been the mainstay of therapy for chronic pain, especially in osteoarthritis. The choice among available NSAIDs can be bewildering, but a few key points follow:

- On a population basis, all NSAIDs appear equally effective in relieving pain associated with osteoarthritis, but for a given patient one drug may be more effective than another. This is probably even truer for cancer pain, where the mechanisms of pain may be very different from one patient to another.
- GI side effects associated with NSAID use appear to be more common with drugs that preferentially block COX-1 over COX-2, although COX-2-inhibiting drugs have the potential to exacerbate GI injury when there is preexisting pathology. This results from inhibition of the beneficial role that the COX-2 enzyme may play in GI healing.
- There is no difference in renal toxicity between COX-1 selective drugs and COX-2 selective drugs. Both COX-1 and COX-2 are constitutively expressed in the kidney.
- Liver toxicity with NSAIDs is an idiosyncratic event that can happen with any NSAID.

Monitoring

If the NSAID chosen is effective and does not cause significant adverse effects, it should be continued. If not, therapy may be changed to another NSAID, provided the animal did not experience a serious side effect (e.g., GI bleeding, azotemia, or hepatopathy). If serious toxicity occurs, the patient should be carefully evaluated and the benefits of continued NSAID therapy weighed against the potential for further adverse events. Changing therapy to another class of drugs (e.g., opioids) may be the safest strategy if the patient's tolerance for NSAIDs is low. If another NSAID is chosen, the patient should be monitored closely for toxicity. This consists of two aspects:

- Informing the owner of the potential for further toxicity and what signs to watch for (lethargy, anorexia, depression, vomiting, melena, and increased water ingestion).
- Regular blood work (and urinalysis) to evaluate renal function (urea, creatinine, and urine specific gravity) and liver func-

tion (alkaline phosphatase and alanine aminotransferase and, if these enzymes are raised, bile acids). A baseline should be obtained when NSAID therapy is initiated and parameters monitored regularly thereafter. The reevaluation is done more frequently if multiple drugs are used, because there is no information on clinical toxicity associated with combinations of analgesics administered chronically.

NSAIDs in Cats

Cats have generally longer, but variable and inconsistent, rates of biotransformation and excretion of NSAIDs when compared with other species. All of the kinetic studies performed in cats have been on single doses, and no studies have yet examined the metabolism of chronically administered NSAIDs.^{49–52} However, given that most of the NSAIDs have a relatively long half-life in cats, chronic dosing at the dosing level and frequency described for dogs is likely to be more dangerous for cats than for dogs.

No NSAIDs have been licensed for chronic administration (>5 days) in cats. A number of available NSAIDs can probably be used relatively safely (Table 49.3); however, no NSAID has been fully evaluated for safe use in cats. The key to safe chronic NSAID administration in cats is to individualize the dose by using the smallest effective dose or extend the dosing interval relative to other species. Since half-lives can be longer and more variable, some cats may metabolize drug at a rapid rate, requiring more frequent dosing, whereas other cats may accumulate drug to toxic levels unless the dosing interval is increased or the dose is reduced. Cats are more prone to toxicity associated with NSAIDs than are dogs; therefore, blood and urine should probably be analyzed even more frequently than recommended for dogs.

Analgesics for Cancer-Pain Relief

If pain relief with NSAIDs is inadequate, oral opioid medications, such as morphine or tramadol, can be administered. Transdermal fentanyl patches can also be used. Fentanyl, morphine, or tramadol can be used for dogs that cannot be given NSAIDs, although adverse effects may be more common. Acetaminophen has been used in conjunction with NSAIDs (except in cats), although safety data on combined use are lacking. Other agents that are used to treat chronic pain include amantadine (an NMDA antagonist); anticonvulsants, such as gabapentin; and tricyclic antidepressants, such as amitriptyline. These can all be combined with NSAIDs.

Acetaminophen

Acetaminophen (paracetamol) is a nonacid NSAID, though many pharmacologists do not consider it an NSAID because it probably acts by different mechanisms than do most currently marketed NSAIDs. Although its mechanism of action is poorly understood, it has been suggested that it acts on a variant of the cyclooxygenase enzyme (COX-3), which is present in CNS tissues of dogs.^{53,54} With any chronic pain, there are always CNS changes, so centrally acting analgesics can be very effective for what seems a peripheral problem, such as many cancers.

Although highly toxic in cats, even in small quantities, acetaminophen can be effectively used to control pain in dogs. No studies of toxicity in dogs have been done, but, if toxicity is seen, it will probably affect the liver, and thus the drug should be used cautiously in dogs with liver dysfunction. It can be used on its own or in combination with codeine and is initially dosed at about 10 to 15 mg/kg PO bid. The authors often use it as the first line of analgesic therapy in dogs with renal compromise where NSAIDs cannot be used, or in dogs that appear to be otherwise intolerant to NSAIDs (e.g., vomiting or GI ulceration).

Opioids

Many veterinarians may be unfamiliar with the use of opioids outside the perioperative period, but opioids can be a very effective part of a multimodal approach (i.e., the use of NSAIDs or adjunctive analgesics with concurrent use of opioids). Adverse effects of opioids can include behavior changes, diarrhea, vomiting, occasionally sedation, and constipation with long-term use. It is very often the constipation, and occasionally the sedation seen, which owners seem to object to most, especially with the administration of oral morphine. The opioids that have been used clinically most often to alleviate chronic cancer pain are oral morphine, transdermal fentanyl, oral butorphanol, transmucosal buprenorphine, and oral codeine. None of these drugs has been fully evaluated for clinical toxicity when administered long term, nor for efficacy against chronic cancer pain. It is important to realize that dosing must be done on an individual basis, and adjustment of the dose to produce analgesia without undesirable side effects requires excellent communication with clients. Recent studies have indicated that certain preparations of prolonged-release oral morphine and oral methadone may not reach effective plasma concentrations in dogs when dosed at the currently recommended levels.^{55,56} Much work has to be done to better evaluate the efficacy and safety of long-term oral opioids in dogs.

Opioid Use in Cats

There is currently no information on the long-term use of oral opioids for chronic pain in cats. Interestingly, there seems to be significant individual variation in the level of analgesia obtained with certain opioids, especially morphine and butorphanol, in the acute setting. Buprenorphine appears to produce predictable analgesia when given sublingually in cats.⁵⁷ Compared with humans, the sublingual route appears to result in near 100% bioavailability in cats; this may be a result of differences in ionization in the alkaline environment (pH 8 to 9) of the cat mouth compared with that of humans (pH 6.5 to 7.0). Sublingual administration of buprenorphine is well accepted by cats, with no resentment or salivation, so there is no need to compound the injectable solution. The small volume required makes administration simple. Based on clinical feedback from owners, this is a very acceptable technique for them to perform at home. However, inappetence can occur after several days of treatment. Slightly lower doses can usually overcome this problem. When administered concurrently with other drugs, longer dosing intervals appear to be all that is required to minimize the potential for toxicity.⁵⁷

NMDA Antagonists

Since NMDA receptor appears to be important for the induction and maintenance of central sensitization, the use of NMDA receptor antagonists would appear to offer benefit in the treatment of pain where central sensitization has become established.^{58–61}

Ketamine, tiletamine, dextromethorphan, and amantadine possess NMDA-antagonist properties, among other actions. Ketamine is not useful for the management of chronic pain in the injectable formulation that is currently available. However, intraoperative microdose ketamine appears to provide beneficial effects for a variety of surgical procedures, including limb amputations, and may decrease the incidence of chronic pain following surgery. Other recent publications suggest a benefit of using ketamine perioperatively (an intravenous bolus [0.5 mg/kg] followed by a continuous intravenous infusion [10.0 µg/kg/min] prior to and during surgery), particularly in patients that have pain caused by neoplasia prior to surgery.^{62,63} A lower continuous intravenous infusion rate (2.0 µg/kg/min) may be beneficial for the first 24 h postoperatively and an even lower rate (1.0 µg/kg/min) for the next 24 h. In the absence of an infusion pump, ketamine can be mixed in a bag of crystalloid fluids for administration during anesthesia.

Dextromethorphan has received attention as an orally administered NMDA receptor antagonist for use in human patients suffering from chronic pain. Although it appears effective in some people, dogs do not make the active metabolite after oral administration of dextromethorphan, probably negating its use as an analgesic in dogs.⁶⁴

Amantadine has been used for the treatment of neuropathic pain in humans.^{65,66} It does not appear to have the undesirable CNS adverse effects associated with ketamine administration. Amantadine has been used in dogs as an adjunctive drug for the alleviation of chronic pain, particularly in osteoarthritis and cancer. It is used as an adjunct to NSAIDs, and it appears to augment pain relief with a low incidence of adverse effects (mainly agitation and diarrhea over the first few days of administration). It usually takes about 5 to 7 days to be effective and is usually used long term. Suggested doses for dogs and cats are listed in Tables 49.2 and 49.3. Amantadine should probably not be used in patients with congestive heart failure, nor in patients on selegiline, sertraline, or tricyclic antidepressants.

Combination Analgesics

Tramadol is a synthetic derivative of codeine and is classified as an opioidergic/monoaminergic drug.^{67,68} It has been found to be effective in the alleviation of pain associated with osteoarthritis in humans, as part of a multimodal approach.^{69–72} Studies establishing dosing regimens and effectiveness in veterinary species are limited. Tramadol and its metabolite have agonist action at the µ opioid receptor and also facilitate the descending serotonergic system, which is part of the body's endogenous analgesic system. Tramadol has been used in many parts of the world to treat perioperative pain in animals and is occasionally used to treat chronic pain. The doses listed in Tables 49.2 and 49.3 are for the regular (not prolonged release) form of the drug. It has not been evaluated for toxicity in dogs or cats.

Anticonvulsants

Gabapentin is a structural analogue of γ -aminobutyric acid (GABA) and was introduced as an antiepileptic drug, although its GABAergic actions appear minimal. It is thought to act by modulating the α_2 -delta subunit of calcium channels, thereby decreasing calcium influx and so neurotransmitter release. It appears to be useful for treating neuropathic pain and central sensitization in some patients, although effectiveness in humans (and probably veterinary patients) is unpredictable. It is metabolized rapidly in dogs and is most often used for its anticonvulsive properties. It appears to have some analgesic properties at low doses administered two or three times daily.

Tricyclic Antidepressants

The tricyclic antidepressant amitriptyline appears to be effective in cats for pain alleviation in interstitial cystitis, and many practitioners have anecdotally reported efficacy in other chronically painful conditions in cats and dogs.^{73,74} Amitriptyline has been used daily for periods of up to 1 year for interstitial cystitis, and few side effects have been reported. There are no other studies of its possible analgesic effects in dogs or cats. It should probably not be used concurrently with amantadine until more is known about drug interactions.

Steroids

These have a mild analgesic action, are anti-inflammatory, and can produce a state of euphoria. Steroids are often used to palliate cancer and cancer pain in cats and dogs. They should not be used concurrently with NSAIDs because of the increased risk of serious adverse effects.

Bisphosphonates

Bone pain induced by primary or metastatic bone tumors is thought to be caused mainly by osteoclast activity; therefore, drugs that block osteoclast activity should markedly reduce bone pain.^{75,76} Bisphosphonates inhibit osteoclast activity and can thus produce analgesia. There is very little information on their use in dogs for palliation of bone pain, but drugs such as pamidronate are being used, and early anecdotal reports suggest effectiveness in approximately 40% of cases.¹

Other Cancer Pain-Relieving Modalities

Local or whole body radiation can enhance analgesic drug effectiveness by reducing metastatic or primary-tumor bulk.⁷⁷ Radiation dose should be balanced between the amount necessary to kill tumor cells and that which would affect normal cells. Mucositis of the oral cavity and pharynx can develop after radiation to the neck, head, or oral cavities, resulting in impaired ability to eat and drink. Therapies to treat mucositis include analgesics, sucralfate, 2% viscous lidocaine, and green-tea rinses. Intravenous administration of strontium 89 has also been shown to provide analgesia related to bony metastases in approximately 50% of humans, but its use is uncommon in veterinary patients.

Acupuncture can be used as a pain-relieving modality, often

when conventional therapy does not work. It is also useful in conjunction with other therapy to allow lower doses of drugs to be used that may have significant side effects. While some practitioners have difficulty accepting acupuncture because of traditional Chinese medical explanations that may be scientifically untenable, it is important to remember that there are documented physiological theories and evidence for its clinical effects in animals.^{78,79}

In general, acupuncture analgesia is extremely useful for treatment of pelvic, radius/ulna, and femoral bone pain, as well as cutaneous discomfort secondary to radiation therapy. Acupuncture may also help alleviate nausea associated with chemotherapy and some analgesics, as well as promote general well-being. Acupuncture can be provided through simple needle placement or by needle placement combined with electrical stimulation (of high or low frequency, although most types of pain respond to low-frequency stimulation).⁸⁰

Nutraceutical products may contain a variety of compounds, but the main ones are glucosamine and chondroitin sulfate. These are often recommended for osteoarthritis therapy, and there is evidence that they provide mild anti-inflammatory and analgesic effects. They may be of benefit in the alleviation of chronic cancer pain, but only when used as part of a multimodal approach. Interestingly, based on the authors' experience, the analgesic effect appears to be more predictable in cats than in dogs.

- Long-Term Patient Management

Introduction

Veterinarians are asked to assess and treat orthopedic pain almost daily. In many cases, surgical correction of the orthopedic disease is not an option, and a treatment plan for managing ongoing chronic pain must be devised. If surgery is indicated, a plan for both anesthesia and perioperative analgesia must be designed. If trauma is the cause of the orthopedic injury, the anesthetic plan includes assessment and management of shock and injuries to other body systems. Aggressive treatment of pain associated with acute orthopedic injuries will help prevent progression to chronic pain. Once chronic pain is present, sensitization of the central nervous system may make pain control more difficult. Drug combinations, using multiple classes of drugs, are often required to obtain adequate pain relief.

Patient Evaluation

Documenting a patient's history helps to determine the chronicity of the orthopedic injury. Acute pain is more likely with traumatic or recent injury and a good response to normal doses of analgesics would be expected. If injury is more chronic, anatomical and biochemical changes in pain processing may be present, indicating a more complex approach to pain management may be required. Selection of appropriate anesthetic and analgesic drugs is influenced by general health status and the type of pain present.

The physical exam should include all body systems. Examination of the cardiovascular system should include evaluation of mucous membrane (MM) color, capillary refill time (CRT), heart rate, pulse rate, pulse quality, cardiac auscultation over all four heart valves, and blood pressure. Evaluation of the respiratory

system should include rate and depth of ventilation, as well as auscultation of all lung lobes, larynx, and trachea. Evaluation of the neurological system is particularly important in trauma and older patients. Mentation should be noted, along with any other neurological deficits.

A basic laboratory evaluation is performed on all orthopedic patients undergoing anesthesia and surgery. Testing in young, healthy patients should include determination of packed cell volume (PCV), total plasma solids, blood urea nitrogen, and blood glucose. This minimal laboratory evaluation is designed to aid in the recognition of disease processes not related to the surgical problem. More complete testing is performed on trauma patients, patients with any type of localized or systemic disease, and in apparently healthy older patients. Additional testing may include a complete blood count (CBC), serum chemistry profile, electrolyte analysis, endocrine testing, electrocardiogram, and determination of blood gas or infectious disease profile. Thoracic radiographs should be performed on trauma patients to rule out pneumothorax, pulmonary contusion, or diaphragmatic hernia.

Patient Preparation

If physical exam or laboratory values for PCV, total plasma solids, or blood urea nitrogen indicate preexisting dehydration, the patient should have fluid deficits replaced intravenously. An adequate amount of the appropriate fluid (e.g., isotonic, hypertonic, hypotonic, or colloid) should be administered prior to induction of anesthesia. Recommended preanesthetic PCVs for dogs and cats are at least 30% to 34% and 25% to 29%, respectively. PCV will likely decrease after anesthetic induction, because of the vasodilatory effects of the anesthetic drugs, depressed compensatory reflexes, intravenous (IV) fluid administration, and surgical blood loss.¹ If the PCV is less than 25%, bovine hemoglobin glutamer 200 (Oxyglobin; Biopure, Cambridge, MA), whole blood, or packed red blood cells should be administered prior to the administration of any anesthetic drugs. Cardiac arrhythmias should be evaluated and treated, if necessary, prior to anesthesia and surgery. Hypothermia can be corrected by providing an external heat source, pain is managed with analgesic drugs, and acid-base or electrolyte abnormalities are addressed.

Food should be withheld for at least 8 h before anesthesia, but water can remain available until 2 h prior to administration of preanesthetic drugs.² This regimen will help avoid regurgitation of foodstuff, decrease gastric acidity, and minimize dehydration.

Premedication

Drugs are given prior to induction of anesthesia in order to produce mild sedation, decrease anxiety, provide analgesia, improve muscle relaxation, decrease salivary and respiratory secretions, and suppress vomiting and regurgitation. Additional reasons to use preanesthetic drugs include possibly reducing unwanted anesthetic effects by decreasing doses of induction and maintenance drugs, providing smooth anesthesia induction and recovery, and contributing to postoperative analgesia. Moderate dosing is usually preferable to the administration of a large dose of a single drug. Commonly used classes of preanesthetic drugs include antimuscarinics, benzodiazepines, opioid analgesics, phenothiazine tranquilizers, α_2 -adrenergic agonists, and dissociatives.

The antimuscarinics, atropine and glycopyrrolate, can be used to decrease salivary secretions and to treat vagally mediated bradycardia associated with anesthetic and anesthetic-adjunctive drugs. Antimuscarinic administration should be avoided in patients with tachyarrhythmias and in patients with glaucoma or keratoconjunctivitis sicca. Antimuscarinics decrease tear formation and relax the iris sphincter muscle, causing mydriasis. Antimuscarinics may also increase the viscosity of respiratory secretions and should be used with caution in patients with pulmonary infections. However, muscarinic receptor block may facilitate bronchodilation and may improve some indices of respiratory function when conditions such as asthma are present.

Atropine is a small, unionized molecule that crosses the blood-brain and placental barriers. Though rare, overdose may cause seizures or altered mentation. The effect of atropine lasts approximately 1 h. Glycopyrrolate is a large, ionized molecule that does not cross the blood-brain barrier or placenta in significant quantities. It is less likely to induce tachyarrhythmias than is atropine, and overdose will usually not cause central nervous system toxicity. Vagal inhibition induced by glycopyrrolate lasts 2 to 3 h, and secretions are decreased up to 7 h.

The benzodiazepines, diazepam and midazolam, which are often used in compromised or geriatric patients, have minimal effect on cardiovascular function and have no useful analgesic activity. Both drugs are reversible with the benzodiazepine receptor antagonist flumazenil. Diazepam is supplied in a propylene-glycol vehicle, and uptake of diazepam after intramuscular (IM) or subcutaneous (SC) injection is slower and unpredictable. Diazepam should be administered slowly intravenously because the propylene glycol can cause pain, hemolysis, thrombophlebitis, and cardiotoxicity if administered rapidly.³ Diazepam cannot be physically mixed with water-soluble drugs without risk of precipitate formation. It also begins to adsorb into plastic within a few minutes of contact, resulting in the appearance of decreased potency. In contrast, midazolam is in an aqueous vehicle and can be administered SC or IM with rapid and complete uptake and minimal pain on injection.

The addition of an opioid analgesic to premedication combinations in orthopedic patients will enhance sedation, enable a decrease in maintenance drugs, and contribute to, but not replace, postoperative analgesia. Opioids commonly used in IM or SC preanesthetic drug combinations for patients with orthopedic

pain include oxymorphone, hydromorphone, morphine, and buprenorphine. Oxymorphone, hydromorphone, and morphine are full μ -receptor agonists and may be most effective for patients experiencing, or anticipated to experience, moderate to severe perioperative pain. They provide excellent analgesia and may have useful sedative properties. The μ opioid agonists may precipitate panting, which is seldom problematic.

Buprenorphine is usually classified as a partial μ , δ , and ORL-1 (nociceptin) opioid receptor agonist and a κ opioid receptor antagonist.^{4,5} Buprenorphine binds with high affinity to all opioid receptors, providing a longer analgesic effect (approximately 6 to 8 h). Buprenorphine may be effective in the treatment of mild to moderate pain, but is usually a less effective analgesic than the pure μ agonists for severe pain. Butorphanol is usually classified as a partial μ antagonist and a κ and δ agonist.⁶ Butorphanol has a brief analgesic action, particularly in dogs, and is usually only effective against mild pain. Both butorphanol and buprenorphine can antagonize μ receptor-mediated actions of oxymorphone, hydromorphone, or morphine. However, the net effect of combinations of opioids on analgesia may be a function of dose or route of administration. Butorphanol has better sedative properties than buprenorphine. It is the authors' opinion that butorphanol is inappropriate for managing the pain intensity experienced by most orthopedic patients. These patients would be better served by choosing an opioid with greater analgesic efficacy.

Arguably, the most commonly used phenothiazine tranquilizer in veterinary medicine is acepromazine. Its onset of action is 30 to 60 min after SC or IM injection. Acepromazine has no inherent analgesic effects, but may potentiate opioid analgesia. Acepromazine has α_1 -adrenergic antagonist properties and may cause vasodilation and hypotension. Tranquilization can be overridden by stress or excitement and should not be solely relied on for chemical restraint. Acepromazine predisposes patients to hypothermia, may potentiate organophosphate toxicity and anesthetic hypoventilation, and can increase vagal tone, resulting in bradycardia.⁷ It may also cause splenic sequestration of circulating erythrocytes, resulting in rapid decreases of PCV by up to 50% within 30 min of administration.⁷

The use of epinephrine to treat hypotension or cardiac arrest is relatively contraindicated when acepromazine overdose has occurred. α -Adrenergic blockade along with β_2 -adrenergic agonism results in paradoxical vasodilation and additional cardiovascular collapse (i.e., *epinephrine reversal*).⁷ The most effective treatment for phenothiazine overdose is aggressive IV fluid administration and vasoconstrictors with minimal β_2 -adrenergic agonist activity, such as phenylephrine, ephedrine, or norepinephrine. After fights, trauma, or other stressful incidents, patients that have increased amounts of circulating endogenous catecholamines may also experience cardiovascular collapse because of epinephrine reversal and are not good candidates for phenothiazine administration. Acepromazine should be used with caution in patients with cardiac dysfunction, decreased cardiac reserve, hepatic dysfunction, or general debilitation, and in pediatric and geriatric patients. It has been considered by many as contraindicated in patients with a history of seizure activity. It should not be used in patients exhibiting signs of shock, trauma,

hypovolemia, or organophosphate toxicity. Clinically used doses of acepromazine are not consistent with the label dose and generally are approximately one-tenth the recommended label dose.

α_2 -Adrenergic agonists (e.g., medetomidine and xylazine) may be used in preanesthetic drug combinations. Unlike phenothiazines, α_2 -adrenergic agonists have both profound sedative and mild analgesic properties, with sedation lasting longer than analgesia. All available α_2 -adrenergic agonists are reversible with the selective α_2 -adrenergic antagonist atipamezole. The α_2 -adrenergic agonists cause decreased insulin release, hyperglycemia, diuresis, and potentially vomiting. The sedative effects can be overridden by pain, excitement, or stress. α_2 -Adrenergic agonists may alter thermoregulation and, after high-dose administration, may make it difficult to raise peripheral veins for catheterization. Patients given α_2 -adrenergic agonists may experience bradycardia, second-degree atrioventricular heart block, muscle twitching (jactitations), prolonged sedation, and pale or bluish mucous membranes. The effects on arterial blood pressure depend on route of administration, dose, and species, but are generally biphasic with an initial period of vasoconstriction and hypertension lasting 20 to 40 min, followed by a longer period of vasodilation and hypotension. α_2 -Adrenergic agonists are absolutely contraindicated in patients with shock, hypotension, severe anemia, exercise intolerance, cardiac disease, increased afterload, or uncontrolled arterial hemorrhage. They are generally contraindicated in patients with respiratory disease or pulmonary dysfunction, hepatic disease, renal disease, debilitation, or stress caused by heat, cold, fatigue, or extremely high altitude. The onset of action of xylazine can be from 3 to 15 min, with sedation lasting 1 to 2 h and analgesia lasting 15 to 30 min.⁸ Medetomidine is more specific for the α_2 receptor compared with xylazine, and sedation lasts approximately 2 to 4 h, with analgesia lasting a considerably shorter time. Following IM injection of an α_2 -adrenergic agonist, anesthesia should not be induced for approximately 20 min to allow maximal sedative and anesthetic sparing effects to occur. Higher doses of medetomidine usually do not increase sedation, but prolong the effect. Clinically useful doses of medetomidine are considerably less than the labeled doses, especially if combined with an opioid analgesic or benzodiazepine agonist.

Dissociative anesthetic combinations given in low doses have been used as immobilization to facilitate catheterization or induction of anesthesia. The proprietary combination of the dissociative tiletamine and benzodiazepine zolazepam (Telazol) can be used to premedicate dogs and cats. This drug combination may provide enough sedation to decrease the dose of subsequent anesthetics by 50% or more. Patients receiving this drug combination may experience vomiting, salivation, excess respiratory secretions, muscle twitching or rigidity, dysphoria, and pain at the injection site. Dogs may vocalize or experience erratic or prolonged recoveries. Telazol provides only mild somatic analgesia and should not be used alone for procedures that precipitate moderate to severe pain (i.e., orthopedic procedures).

There are many potential preanesthetic protocols. In general, the combination of an opioid analgesic with a sedative-tranquilizer produces the most reliable and predictable results. The addition of

glycopyrrolate (0.01 mg/kg) SC, IM, or IV, or atropine (0.04 mg/kg) SC or IM or 0.01 mg/kg IV, may be appropriate, especially with protocols known to precipitate profound bradycardia.

General Anesthesia for Orthopedic Procedures

Preanesthetic Management

General anesthesia is a reversible process that induces immobilization, muscle relaxation, unconsciousness, and freedom from pain. It is important to have all necessary drugs and equipment ready in advance. This includes the appropriate breathing circuit, correct-size endotracheal tube and reservoir bag, changing CO₂ absorbent if necessary, checking the anesthesia machine and breathing circuit for leaks, and ensuring an adequate oxygen and anesthetic supply. Being prepared for any complication before drug administration is the key to successful anesthetic administration.

Placement of an IV catheter is recommended for all patients undergoing general anesthesia. Use the largest bore possible to enable rapid infusion of fluids and drugs in an emergency. Fluids may be bolused to dehydrated patients at this time. Other support prior to anesthetic induction includes preoxygenating patients via facemask for 1 to 2 min. This creates an increased oxygen partial pressure in the functional residual capacity, allowing more time for intubation before hemoglobin desaturation occurs. The application of sterile eye ointment will aid in keeping the cornea moist during anesthesia. It is best to avoid the use of triple-antibiotic eye ointments in feline patients because there have been some recent reports of anaphylactic reactions.⁹ The operating room and prep tables should be padded appropriately, and an external heat source should be supplied. Checking MM color, CRT, heart rate, and respiratory rate prior to anesthesia enables the recognition of unwanted side effects from preanesthetic drugs.

Induction

Induction of general anesthesia in orthopedic patients is best accomplished using injectable drugs. Injectable inductions are preferred because they allow a more rapid loss of consciousness, less patient struggling, earlier control of the airway, and less danger of injury to the patient and staff. Popular drugs for IV induction include propofol (2 to 4 mg/kg IV), thiopental (5 to 15 mg/kg IV), and the combination of diazepam and ketamine. Induction doses will vary with the general health and age of the patient. Administration of preanesthetics can considerably reduce induction dose requirements. Ketamine causes a central release of catecholamines resulting in tachycardia, increased cardiac output, and increased blood pressure. However, in catecholamine-depleted patients, ketamine may act as a direct myocardial depressant and decrease cardiac output.

Immediately after anesthetic induction, an endotracheal tube is placed and the cuff inflated. Avoid overinflation of the endotracheal tube cuff to avoid tracheal crush injury or tracheal rupture. The patient's respiratory rate, heart rate and rhythm, MM color, CRT, and other parameters are checked immediately after induction and at intervals of 5 min or less. In animals with lung injury

caused by trauma, pneumothorax can occur as a consequence of positive-pressure ventilation during anesthesia. When a pneumothorax is anticipated or is present, placement of a chest-drainage catheter shortly after induction allows management of what might be an anesthetic emergency during the surgical procedure. If not needed, the catheter is removed prior to recovery.

Anesthesia Maintenance

Orthopedic procedures are usually longer than 30 to 45 min, and inhalant anesthetics are preferred to injectable drugs for procedures of this duration. Isoflurane, halothane, sevoflurane, or desflurane can be used. All inhalant anesthetics cause some degree of vasodilation, hypotension, myocardial depression, and respiratory depression, necessitating appropriate anesthetic monitoring and intraoperative adjustments. Other effects may include postoperative nausea, vomiting, ileus, and cardiac arrhythmias.

Analgesic and Adjunctive Techniques

Orthopedic pain is typically classified as severe, and patients with orthopedic injuries are at risk of becoming chronic pain patients. Aggressive pain management at the time of initial injury or surgery helps to prevent progression to chronic pain.¹⁰ In particular, patients undergoing procedures that involve severing large portions of muscles and large nerves, such as leg or tail amputation, require local anesthetic blockade of nociceptive impulses to the spinal cord. Chronic pain patients undergoing surgery to correct orthopedic disease may already have sensitized central nervous systems, thus requiring adjunctive techniques to manage their pain. Techniques used to provide additional analgesia for orthopedic patients include preoperative administration of nonsteroidal anti-inflammatory drugs (NSAIDs) if no contraindication to their use is present, ongoing provision of opioid analgesics by using transdermal patches, IV administration of opioid analgesics given as repeated bolus injections or as a continuous infusion, local anesthetic techniques, and epidural administration of analgesic drugs. Ketamine IV continuous-rate infusions (CRIs) with opioids and/or lidocaine have been described. Adjunctive analgesic techniques will decrease overall anesthetic requirement hopefully lessening the incidence and severity of unwanted side effects. Ongoing administration of sedatives, such as midazolam by CRI, may also allow for a reduction in the concentration of inhaled anesthetic gases.

Risks associated with preoperative NSAID administration include increased bleeding and exacerbation of renal disease.^{11,12} Preoperative NSAID administration should therefore be limited to well-hydrated healthy patients, with normal coagulation and hemostasis parameters, that are at minimal risk of developing hypotension during the surgical procedure. IV fluids should be administered and blood pressure monitored in all patients given a preoperative NSAID.

Ongoing administration of opioid analgesics throughout the surgical procedure provides additional intraoperative and postoperative analgesia. Fentanyl can be administered as an IV CRI throughout surgery. A loading dose of 5 to 20 $\mu\text{g}/\text{kg}$ is given slowly, followed by 0.3 to 0.7 $\mu\text{g}/\text{kg}/\text{min}$. Fentanyl patches are not generally relied on for intraoperative and immediate postop-

erative opioid delivery, but if used for this purpose, the patch should be placed on the animal at least 12 h before the start of surgery. The location of the patch is selected so that the patch will not come into direct contact with a heating pad during surgery, because heat can increase the absorption of fentanyl. Longer-acting opioids, such as oxymorphone or hydromorphone, can be administered in repeated IV bolus doses of 0.05 to 0.1 mg/kg, as needed. The effects of buprenorphine last 6 to 8 h; thus, repeated administration during surgery is usually not necessary if buprenorphine is given as a premedication.

Local anesthetic blocks are often used to inhibit nociceptive input to the central nervous system during surgical manipulations. Blockade of the infraorbital or maxillary nerve can be used when performing procedures that involve the maxilla. The mandibular nerve can be blocked when procedures involve the mandible. The foot can be desensitized by several techniques: ring block, blocks of the radial, median, and ulnar sensory nerves, and IV regional anesthesia (i.e., Bier block). The front limb can be desensitized from the elbow distally by performing a brachial plexus block. When amputating a body part, nerves are blocked with long-acting local anesthetics (e.g., bupivacaine) prior to being severed.

Lumbosacral epidural administration of opioids can be used for both forelimb amputations, which are at risk of causing chronic ghost pain, and for rear-limb procedures. Morphine alone is used for forelimb procedures, because it is water soluble and will travel cranially. Opioids are typically combined with long-acting local anesthetics to provide sensory blockade for hind-limb, pelvic, and tail procedures.

IV infusions of midazolam can increase muscle relaxation and decrease the amount of inhalant anesthetic drug necessary to maintain surgical anesthesia. The loading dose of midazolam is approximately 0.1 mg/kg IV followed by a CRI of 0.5 to 1.5 $\mu\text{g}/\text{kg}/\text{min}$ IV. Midazolam has fewer cardiovascular depressant effects when compared with inhalant anesthetics. Patients with unstable cardiovascular function may benefit from decreased inhalant anesthetic doses.

Monitoring

Merril C. Sosman once stated, “You see only what you look for. You recognize only what you know.”¹³ Patient monitoring requires the use of one’s eyes, ears, and hands in addition to electronic monitors. Monitoring heart rate, pulse, MM color, CRT, chest excursions, reservoir-bag movement, depth of anesthesia, and pulse quality is easily accomplished and gives vital clues as to how well patients are maintaining normal physiology. Electronic monitors that can be used to evaluate patient physiology under anesthesia include Doppler ultrasound, oscillometric and direct arterial blood pressure monitors, electrocardiogram monitors, pulse oximeters, thermometers, respiratory gas monitors, and blood chemistry analyzers.

The three most common unwanted side effects of anesthetic drugs are hypotension, hypothermia, and hypoventilation. Hypotension is present when mean arterial blood pressure in dogs falls below 70 mm Hg, or when systolic arterial blood pressure falls below 90 mm Hg in dogs and 100 mm Hg in cats.¹⁴ The

most common causes of hypotension in orthopedic patients are relative or absolute hypovolemia and drug effects. Therapies for hypotension include decreasing the depth of anesthesia, increasing the administration rate of IV fluids from maintenance levels (10 to 20 mL/kg/h) to as much as 90 mL/kg/h (for limited periods), and supporting circulation by the administration of inotropic drugs and vasopressors. Dopamine may be administered as a constant rate infusion at 2 to 5 $\mu\text{g}/\text{kg}/\text{min}$ or dobutamine at 5 to 20 $\mu\text{g}/\text{kg}/\text{min}$. Alternatively, ephedrine may be given as an IV bolus of 0.1 to 0.25 mg/kg.

Temperature is easily monitored using a handheld thermometer or integrated temperature probe attached to a multiparameter monitor. Due to muscle relaxation, rectal temperature may be as low as 1°C (2°F) less than core body temperature. Hypothermia can be slowed or reversed by providing an external heat source. Desirable heat sources include circulating hot-water blankets, hot-water bottles, forced hot-air blankets, and resistive heating units with temperature control probes. Care should be taken to avoid thermal burns when placing plastic or metallic objects near the heat source and patient. Patients can also be warmed by administering warmed IV or lavage fluids, wrapping the extremities in an insulator-like bubble wrap, avoiding evaporative cooling by not prepping with alcohol, and keeping ambient temperatures warm. Dangerous methods of warming patients include the use of electric heating pads and infrared lamps, because of the increased risk of thermal injury. Hyperthermia is treated by removing heat sources, cooling the patient with alcohol or cool-water baths, and the administration of cool IV fluids. It is important to rule out malignant hyperthermia in patients that may be predisposed to this syndrome. It is not uncommon for Nordic breeds to become hyperthermic under anesthesia without the severe electrolyte imbalance that occurs with malignant hyperthermia syndrome. Cats may develop hyperthermia in response to higher doses of some opioids.¹⁵

Adequacy of ventilation may be assessed by observing movement of the reservoir bag for adequate inspiratory volume or, better, by monitoring end-tidal carbon dioxide (ETCO₂). Capnometers or capnographs are more useful than pulse oximetry for early detection of hypoventilation because arterial carbon dioxide, and therefore ETCO₂, will elevate due to hypoventilation before hemoglobin will desaturate, especially in patients breathing 100% oxygen. Additionally, pulse oximeters do not assess blood pressure and become inaccurate in the presence of hypotension, vasoconstriction, anemia, and pigmented tissues. Pulse-oximeter probes may compress vascular beds in small patients and may need to be moved periodically.

Supportive Care

It is vital to patients undergoing long periods of orthopedic repair that physiological parameters are maintained as close to normal as possible during the perianesthetic period. This mandates good supportive care for all patients undergoing surgery. As stated previously, supportive care includes the use of IV fluids to aid circulating blood volume to vital organs, provision of an external heat source to prevent hypothermia, assisted or mechanical ventilation in those patients with inadequate spontaneous ventilation,

proper patient positioning in natural anatomical alignment, and correction of specific physiologic derangements.

IV fluids will replace fluid losses and fill the increased vascular space that results from vasodilation induced by anesthetic drugs. Indications for fluid therapy include hypotension, decreased oxygen delivery, hypovolemia, dehydration, electrolyte disorders, metabolic disorders, and acid-base disturbances. Fluid selection is based on an individual patient's needs. Isotonic crystalloids are used to replace fluid from dehydration (e.g., preanesthetic fasting), hypovolemia, vasodilation, and hypotension, for normovolemic hemodilution, and to maintain plasma volume and promote renal blood flow and urine production. Approximately 4 L of isotonic crystalloid are needed to increase plasma volume by 1 L.¹ Isotonic crystalloids should be administered by a constant infusion because they are redistributed into the interstitial space within 30 to 60 min. They are recommended for all anesthesia patients at maintenance rates of 10 to 20 mL/kg/h and should be warmed to body temperature before administration. In hypotensive patients, boluses of 10 to 20 mL/kg can be administered in an attempt to increase blood pressure; however, boluses should not exceed a total volume of 90 mL/kg/h or decrease the PCV below 25%. Examples of isotonic crystalloids are Normosol-R, Isolyte-S, Plasmalyte 148, 0.9% NaCl, and lactated Ringer's solution.

Colloids are indicated in hypovolemia, hypotension, hypoalbuminemia, and for isovolemic hemodilution. They are distributed only within the plasma; therefore, it takes only 1 L of colloid to increase plasma volume by 1 L. The effect of most colloids lasts between 3 and 24 h. Examples of colloid fluids include dextran 40, dextran 70, hydroxyethyl starch, gelatin, albumin, plasma, and Oxyglobin. Synthetic colloids such as dextrans and hydroxyethyl starch may affect coagulation and should be administered judiciously in animals with the potential for ongoing hemorrhage. Polymerized hemoglobin solutions (i.e., Oxyglobin) can be used to replace intraoperative blood loss without delay for crossmatching, but have been associated with systemic hypertension and increased free-radical production.^{16,17} Rapid administration of large doses of colloids in cats can lead to pulmonary edema and pleural effusion. Perhaps the best use of colloids is to administer lower doses (5 mL/kg) to reduce the amount of crystalloid fluids needed to maintain blood pressure and oxygen delivery.

Blood-replacement products should be considered if intraoperative hemorrhage is greater than 10% of total blood volume or PCV falls below 20%. Blood volume in dogs is approximately 8% to 10% body weight and in cats is 6% of body weight.¹ Estimating blood loss can be difficult. A commonly used rule of thumb is that one soaked 3 × 3-inch gauze holds 10 mL and ten soaked Q-tips hold 1 mL. Evaluating the PCV of fluid in the suction bottle can also guide an estimate of blood loss. The blood on drapes, surgeon gown and gloves, table, and floor must also be taken into account. If there is a question as to when critical blood loss is occurring, measure the patient's PCV intraoperatively and treat accordingly. For an accurate measurement, take blood for the PCV directly from a peripheral vein and do not dilute the sample with excess heparin or EDTA.

Proper patient positioning and padding is important, especially during long procedures, in arthritic patients and patients with intervertebral disk disease. Patients should be positioned to maintain normal anatomical alignment, and large muscle groups should be well padded. It is important to avoid unnecessary stress on joints and to roll patients with the spine aligned. When rolling patients, the endotracheal tube should be disconnected to avoid tracheal mucosal damage caused by twisting of the tube. Occasionally, the tube can be occluded if it is twisted.

Recovery

Pain can have severe detrimental effects within the postoperative period. Effects include delayed or poor wound healing, increased incidence of infection or sepsis, increased incidence of tumor metastasis, cardiovascular stress or compromise, increased metabolism with a negative energy balance, increased tissue catabolism, and a prolonged convalescence.¹⁸ Therefore, it is essential to provide adequate pain relief to all orthopedic patients even though they may not show outward signs of pain or distress.

Some techniques for providing postoperative analgesia require preoperative and intraoperative planning. Fentanyl patches are best placed before surgery, because therapeutic levels of fentanyl will not be present until 8 to 12 h after placement. Provision of a wound infusion catheter for ongoing administration of local anesthetics into the wound requires placement of the catheter during surgery (Box 50.1). Single intra-articular injections of local anesthetics, morphine, and/or ketamine are performed at the conclusion of the surgical procedure. Placement of an epidural catheter for management of severely painful patients is best performed while the animal is still anesthetized.

Patients that awaken and are dysphoric may risk reinjuring the surgical site. They may need a tranquilizer to calm them and to potentiate analgesic drugs. Acceptable postoperative tranquilizers include diazepam, midazolam, medetomidine, or acepromazine at low doses. Most orthopedic patients require systemic opioid analgesics for at least 24 h after surgery (Table 50.1). Typical regimens include IV CRI of morphine, hydromorphone, or fentanyl, or periodic IV injections of oxymorphone, hydromorphone, or buprenorphine. The IV CRI of a mixture of morphine (3.3 µg/kg/min), lidocaine (50 µg/kg/min), and ketamine (10 µg/kg/min) provides excellent analgesia in dogs.¹⁹ Wound infusion catheters can also provide excellent analgesia for cats and dogs undergoing major surgery.

Continuing to provide adequate padding, an external heat source, and a quiet environment are all essential for a smooth and uneventful recovery. Physiological monitoring should be continued during the postoperative period until patients are awake, aware, responsive, and resting quietly. Physical therapy is begun in the immediate postoperative period to reduce swelling and pain and to maintain range of motion in the joints operated on.

Patients are transitioned to oral analgesic drugs for discharge to the owner's care. Orthopedic patients are typically given analgesics for at least 1 week after surgery, and often for much longer periods. If analgesic requirements suddenly change, or are prolonged, the surgery site should be reassessed to rule out reinjury,

Box 50.1

Wound infusion catheters are sold commercially (ON-Q Soaker Catheter; I-flow, Lake Forest, CA). Commercially available catheters are associated with less liability. Homemade medical devices carry additional risks and liabilities for veterinarians. In an emergency, a homemade catheter can be made from the following materials:

- 1 Five French 16- to 22-inch red rubber catheters
- 1 Insulin syringe with a 27- to 28-gauge needle
- 1 Empty sterile 3-mL syringe
- 1 Cigarette lighter
- 1 Sterile mosquito forceps
- 1 Sterile scissors
- 1 Injection cap
- 6 4 × 4-inch gauze sponges
- 1 Syringe loaded with slightly more than 1 mg/kg 0.25% bupivacaine (0.5 mg/kg for cats)

This catheter may be made in advance and then sterilized, or made up while you are gowned and gloved for surgery. Using sterile technique, cut the end off the red rubber catheter, removing its side holes. Clamp the cut tip within the jaws of the mosquito forceps and apply (or if you are gloved in, have your assistant hold the lighter) flame to the jaws of the forceps to heat them to a temperature that melts and seals the end of the catheter. Take care to avoid flaming the catheter, because the rubber will singe and turn black. One trick is to begin gently rocking the hemostat to cause the tubing to swing back and forth; when sufficiently heated, it will break off easily. In most instances, the tip will be effectively sealed. Once heating is complete, remove the forceps and attempt to inject some air into the catheter with the empty sterile syringe. If it is sealed correctly, the syringe plunger will bounce back after you attempt to push in some air. Next, place the catheter on a stack of five 4 × 4-inch gauze sponges and poke holes in it with the insulin syringe's needle. Beginning 0.5 cm back from the sealed tip, and spacing the holes no more than 0.5 cm apart, stab all the way through the center of the catheter so the needle enters the sponges underneath (the sponges keep the needle from puncturing through your tray drape). Work your way up the catheter, rotating it as you go to each new spot to avoid having all the holes in a row. Create a section of punctures long enough to cover the entire wound, plug the luer end of the catheter with the injection cap, and prime the system with bupivacaine. When properly made, the catheter will leak droplets of anesthetic along the entire working surface. Place the catheter in the deepest layer of the wound and make sure to position a portion of it over any transected large nerves. Don't anchor it firmly with any sutures. If the closed wound will be wider than 1 inch on either side of the catheter, it may help to place two or more, running in parallel to each other, to help distribute the anesthetic over a larger surface area. The catheter(s) should exit from the most dorsal part of a wound on the side of the body or from one end of a long horizontal incision. Close the wound and administer the local anesthetic. If using 0.25% bupivacaine, administer 2 mg/kg or less, repeat the injection at 6- to 8-h intervals for as long as needed (usually 1 to 3 days), and then pull the catheter. In cats, give 0.5 mg/kg every 6 to 8 h, with a total daily dose < 2 mg/kg. Intermittent administration should be performed by injecting through an injection cap attached to the luer adapter. An in-line bacterial filter (e.g., Acrodisc; Pall BioPharmaceuticals, East Hills, NY) further reduces the risk of contamination.

Table 50.1. Analgesic drugs used in dogs and cats^a.

Drug	Dose for Dogs (mg/kg)	Dose for Cats (mg/kg)
Acetaminophen	10–15 PO q 8 h for 5 days Long-term therapy: ≤10 q 8 h	Toxic
Acetaminophen (300 mg) + codeine (60 mg)	Acute pain: 5–10 of acetaminophen (=1–2 of codeine) q 8	Toxic
Amantadine	3 PO q 24	3 PO q 24
Aspirin	10 PO q 12 h, <i>not near surgery</i>	10 PO q 48–72 h, <i>not near surgery</i>
Bupivacaine 0.5% solution	Up to 2, at site q 4–6 h Maximum is 6 on day 1, 4/day thereafter	Up to 1, at site q 4–6 h Maximum is 2/day
Bupivacaine (preservative-free 0.25% solution)	1 mL/5 kg epidural q 4–6 h	Epidural not recommended
Buprenorphine	0.01–0.03 IM, IV, SC q 6–8 h	0.01–0.03 IM, IV, SC q 6–8 h 0.01–0.03 PO q 6–12 h
Butorphanol	Not recommended	0.2–0.4 IV, IM SC q 2–4 h 0.5–1.0 PO q 6–8 h
Carprofen	2 PO, SC, IV q 12 h or 4 PO, SC, IV q 24 h	1–4 PO, SC, or IV once
Deracoxib	3–4 q 24 h 1–2 q 24 for chronic use	Not recommended
Etodolac	5–15 PO q 24 h	Not recommended
Fentanyl, injectable	2–5 µg/kg/h IV	2–5 µg/kg/h IV
Fentanyl, transdermal	Patch to provide 2–5 µg/kg/h	25-µg patch; in small cats, cover half the patch
Gabapentin	1.25–10.0 PO q 24	1.25–10.0 PO q 24
Glucosamine and chondroitin sulfate	13–15 chondroitin sulfate PO q 24–48 h	15–20 chondroitin sulfate PO q 24–48 h
Hydromorphone or oxymorphone	0.05–0.2 IV, IM, SC q 2–4 h or 0.05 mg/kg/h IV	0.02–0.05 IV, IM, SC q 2–4 h
Ketamine (to prevent central sensitization)	0.5–2.0 IV bolus, then 1–2 mg/kg/h	0.5–2.0 IV bolus, then 1–2 mg/kg/h
Ketoprofen	1–2 IV, SC q 24 h for 3 days, or 1 PO q 24 h for 5 days	0.5–1.0 IV, SC q 24 h for 3 days, or 0.5–1.0 PO q 24 h for 3 days
Lidocaine 1%–2% solution	Up to 7, at site q 1–2 h or 1–2 mg/kg/h CRI IV or into wound	Up to 2, at site, q 1–2 h; IV not recommended; or 0.5 mg/kg/h into wound
Lidocaine 5% topical patch (Lidoderm)	Applied to affected area of skin per label directions	Safety is unclear in cats
Medetomidine (adjunct to opioid)	0.001–0.005 IV, IM	0.001–0.005 IV, IM
Meloxicam	Acute pain: ≤0.2 PO IV SC once, then ≤0.1 q 24 h Long-term therapy: ≤0.1 q 24 h	Acute pain: ≤0.1 PO IV SC once, then ≤0.05 PO q 24 h for 3 days Long-term therapy: ≤0.02 q 48–72 h
Methadone	0.5–2.2 SC, IM, 0.1–0.5 IV	0.1–0.5 SC, IM, 0.05–0.1 IV
Morphine	0.05–1.0 IV q 1–4 h 0.1–0.5/h IV infusion 0.2–2.0 IM, SC q 2–4 h 0.5–1.0 PO q 6–8 h	0.02–0.1 IV, q 1–4 h 0.2–0.5 SC, IM q 3–4 h 0.2–0.5 PO q 6–8 h (in capsule)
Morphine (preservative free)	0.1 epidural q 8 h 0.05 spinal q 8 h	0.1 epidural q 8 h 0.05 spinal q 8 h
Naproxen	2 PO q 48 h	Toxic
Piroxicam	0.3 PO q 48 h	Controversial
Polysulfated glycosaminoglycan	5 IM weekly	No established dose, dog dose used by some
Prednisolone	0.5–1.0 PO q 12–24 h, taper to q 48 h	2 PO q 12–24 h, taper to q 48 h
Tepoxalin	10 PO q 24 h	Not recommended
Tramadol	2–5 PO q 8–12 h	No established dose, dog dose used by some
Xylazine (adjunct)	0.05–0.1 IV	0.05–0.1 IV

^aAll drugs are available in the United States. Not all drugs are approved for use in dogs and cats. CRI, continuous-rate infusion; IM, intramuscular; IV, intravenous; PO, per os (oral); and SC, subcutaneous.

infection, or other surgical complications. Tramadol-NSAID combinations, opioid-NSAID combinations, and NSAIDs alone can all be acceptable choices for longer-term analgesic therapy (Table 50.1). Transmucosal buprenorphine can be used in cats (Table 50.1). To maintain patients on individualized, optimal analgesic protocols, it is important to evaluate analgesic needs and patient well-being often.

Long-Term Patient Management

Management of chronic orthopedic pain requires a partnership between the veterinarian and the owner. The goal of long-term pain management is to provide good quality of life. The owner can be relied on to evaluate how well the animal is functioning within its normal daily activities. Weight control and routine controlled exercise, including physical rehabilitation, are essential elements in the management of orthopedic disease and require an ongoing commitment from the owner. Pharmacological approaches to chronic pain management involve a “stepladder” approach. After establishing a baseline pain-control regimen, additional drugs are added in to obtain better analgesia or to manage progressively worsening pain. The owner must assess efficacy at each step, using assessments that have been individualized for the specific patient (can climb the three porch stairs, can get up on the green couch, etc.). Nonpharmacological approaches to treatment of chronic pain, such as rehabilitation therapy, acupuncture, or therapeutic massage, require a large time commitment. Enrollment of the owner as a key element of the treatment and assessment team helps to ensure optimal pain management.

In most instances, NSAIDs are the first-line drugs for the treatment of orthopedic pain. Baseline serum chemistry and CBC should be determined and urinalysis should be performed when chronic dosing is anticipated or preexisting disease(s) are present. Renal disease, liver disease, hyperadrenocorticism, ongoing corticosteroid therapy, and evidence of gastrointestinal bleeding or occult blood loss are contraindications to initiating NSAID therapy. If there are no contraindications, an NSAID is chosen and a trial period is initiated. If the animal tolerates the NSAID without adverse effects, efficacy is evaluated by the owner. On a population basis, there is no difference in efficacy between different NSAIDs, but in individual patients efficacy can vary greatly.²⁰ Adverse events associated with NSAID therapy include inappetence, vomiting and diarrhea, acute idiosyncratic liver toxicity, perforating duodenal ulcer, gastrointestinal hemorrhage, and renal disease. Owners should be adequately informed of potential complications, and the owner information handouts provided by pharmaceutical manufacturers should be given to owners when drugs are dispensed.

NSAIDs may be used intermittently in the early stages of orthopedic pain, particularly if a period of sustained activity is anticipated. Once an animal is dependent on NSAIDs to maintain normal daily movements, adjunctive drugs should be considered. Tramadol and acetaminophen or acetaminophen with codeine (dogs only) may be added at this stage.²¹ If there are contraindications to normal NSAID use, the adjunctive and opioid drugs become the preferred treatment. Nondrug therapy (e.g., weight control, ongoing rehabilitation medical therapy and exercise, use

of diets or dietary supplements containing anti-inflammatory compounds, and acupuncture) is used to slow the progression of pain and disability. As pain progresses, more potent opioids, such as oral morphine, are initiated.²² If managed well, comfortable and active lives can often be reestablished.

Horses with Colic

Cynthia M. Trim and James N. Moore

Introduction
Impact of Endotoxemia on Physiological Status
Preparation for Anesthesia
Anesthetic Protocols
Hypoventilation and Hypoxemia During Anesthesia
Cardiovascular Performance During Anesthesia
Recovery from Anesthesia

Introduction

Diseases of the gastrointestinal tract are the most common causes of colic that necessitates surgical correction. Intestinal displacement or obstruction causes abnormalities in fluid and electrolyte balance and renal function that predispose horses to risks of anesthetic overdose and circulatory failure during anesthesia. A serious consequence of intestinal hypoperfusion is endotoxemia that induces adverse changes in cellular and cardiovascular system function. Increased intra-abdominal pressure from intestinal distension causes lung collapse, hypercarbia, and hypoxemia in anesthetized horses. Ventilation is further compromised by pneumothorax in horses with concurrent diaphragmatic rupture.

Preanesthetic evaluation of each horse with colic is an essential component of case preparation to determine the horse's fluid requirements before induction of anesthesia, to anticipate and plan for the most probable complications, and to assess the need to adjust anesthetic dose rates. Administration of anesthesia must incorporate flexibility and particular attention to physiological monitoring devices to ensure timely and appropriate actions designed to maintain physiological parameters within acceptable ranges.

Impact of Endotoxemia on Physiological Status

In equine veterinary practice, endotoxemia has been associated with the diseases characterized by intestinal inflammation or ischemia. Based on several clinical studies, approximately 30% to 40% of horses presented to university hospitals with clinical signs of colic have endotoxins in their circulation.¹⁻⁴ Consequently, endotoxemia is a common complicating factor in horses being anesthetized for emergency abdominal surgery.

Endotoxin, which is a structural component of the outer cell wall of Gram-negative bacteria, is comprised of a hydrophilic region and a hydrophobic region.⁵ The presence of the two regions accounts for the formation of micellar aggregates when endotox-

ins enter biological fluids, such as plasma or peritoneal fluid. The hydrophilic region of endotoxin consists of an inner core, an outer core, and the O-specific polysaccharides. The polysaccharides account for serotype specificity of endotoxins among different bacterial strains. The hydrophobic region, which includes a unique fatty acid-rich portion termed *lipid A*, is responsible for the majority of the deleterious effects caused by endotoxins.^{6,7} Because the core and lipid A regions of endotoxins have been well conserved, these portions are used in vaccines designed to generate antibodies to neutralize endotoxins from different Gram-negative species.

A horse's intestinal tract normally contains endotoxins as they are released from Gram-negative bacteria when they die or multiply rapidly. These endotoxins are retained within the intestinal lumen by the intestinal mucosal barrier, which is composed of epithelial cells, their secretions, and resident bacteria.⁵ Some disease processes, such as intestinal ischemia or inflammation, damage this mucosal barrier, allowing endotoxins to enter the systemic circulation. Endotoxins also cross ischemic or inflamed intestine and enter the peritoneal cavity, where they stimulate the synthesis of inflammatory mediators. In at least one clinical study of horses with colic, endotoxins and inflammatory mediators were detected more commonly in peritoneal fluid than in plasma samples obtained from these horses.⁸

When endotoxins enter the circulation, they form aggregates, which interact with a plasma protein named *lipopolysaccharide (LPS)-binding protein*. LPS-binding protein is an acute-phase protein synthesized by hepatocytes.⁹ LPS-binding protein transfers individual endotoxin molecules from the endotoxin aggregates to a cell surface receptor called *CD14* on mononuclear phagocytes. CD14 is a pathogen pattern recognition receptor that identifies endotoxin as part of a pathogen. CD14 exists either as a membrane-bound form or as a soluble form in biological fluids. Soluble CD14 interacts with endotoxin and LPS-binding protein, and then with cells, such as endothelial cells, that lack membrane-bound CD14. This interaction renders the endothelial cells responsive to endotoxins.¹⁰

Interaction among endotoxin, LPS-binding protein, and CD14 increases the sensitivity of cells to endotoxin. Although CD14 plays an important role in the cellular response to endotoxins, this receptor lacks a transmembrane component and thus cannot by itself activate the cell in response to endotoxin. In the late 1990s, biologists discovered a family of 10 receptor proteins, called *Toll-like receptors*, that also are pathogen pattern recognition receptors. Unlike CD14, the Toll-like receptors have trans-

membrane and intracellular components, allowing them to communicate between the exterior and interior aspects of the cell.¹¹ Toll-like receptor 4 is responsible for delivery of the endotoxin signal to the interior of the cell and is assisted in this function by an associated protein called MD-2.¹² Stimulation of Toll-like receptor 4 results in activation of genes encoding for inflammatory mediators such as tumor necrosis factor α (TNF- α) and cyclooxygenase 2, as well as those encoding for anti-inflammatory mediators such as interleukin 10.¹³

Serum concentrations of TNF- α increase shortly after in vivo administration of endotoxin and correlate with hypotension, hemoconcentration, metabolic acidosis, and disseminated intravascular coagulation.¹⁴ TNF- α initiates these responses by increasing the synthesis of other inflammatory mediators (including the interleukins, eicosanoids, and tissue factor), stimulating the acute-phase response and fever. Several clinical studies in horses have revealed correlations between increases in serum concentrations of TNF- α and prognosis for survival.^{15,16} Increased concentrations of TNF- α also have been documented in peritoneal fluid from horses with naturally occurring intestinal diseases.⁸

Arachidonic acid, a 20-carbon fatty acid in cell membrane phospholipids, is metabolized by cyclooxygenase to vasoactive substances such as thromboxane A₂ and prostaglandins I₂, E₂, and F₂ α . There is considerable information regarding the cyclooxygenase metabolites of arachidonic acid, which mediate many of the early hemodynamic effects of endotoxemia.¹⁷

Tissue factor, otherwise known as thromboplastin or procoagulant activity, is a glycoprotein that is synthesized primarily by monocytes and macrophages. Because tissue factor remains associated with the surface of these cells, it is exposed to coagulation factor VII in plasma. As a result, cells that synthesize tissue factor in response to endotoxin may become a focus for the formation of microthrombi. Tissue factor activity increases in equine monocytes exposed to endotoxin in vitro, in horses with experimentally induced endotoxemia, and in horses with naturally occurring diseases characterized by colic.^{18,19} In a clinical study of horses with colic, the severity of the increase in tissue factor activity correlated inversely with prognosis.¹⁹

In addition to the synthesis of proinflammatory mediators in response to endotoxins, there is considerable evidence that the synthesis and release of anti-inflammatory mediators also is increased. The most widely studied of these anti-inflammatory mediators is *interleukin 10*, a cytokine that deactivates mononuclear phagocytes and inhibits the synthesis of proinflammatory cytokines.²⁰ The results of studies in other species indicate that neutralization of interleukin 10 increases both production of TNF- α and lethality. There also is evidence indicating that susceptibility to infectious agents increases if the synthesis and release of anti-inflammatory mediators becomes the predominant response.²¹

Preparation for Anesthesia

Preparation for anesthesia includes all the procedures implemented for elective anesthesia, such as checking the anesthetic and monitoring equipment, assembling anesthetic and emer-

gency drugs, and preanesthetic evaluation of the patient. Preparation of the patient should include treatment of hypovolemia, critical electrolyte abnormalities, and severe metabolic acidosis. Preanesthetic fluid therapy commonly includes infusion of at least 20 mL/kg of balanced electrolyte solution to expand circulatory blood volume. Horses with evidence of impaired cardiovascular function, such as weak pulses and prolonged capillary refill, given hypertonic (7.5%) saline before anesthesia, 2 to 4 mL/kg over 10 min, are less likely to develop hypotension immediately after induction of anesthesia. It is important to infuse balanced electrolyte in the following 1 to 2 h after hypertonic saline administration to prevent dehydration. Hypocalcemia can be treated with 23% intravenous (IV) calcium borogluconate, 0.5 mL/kg.

In addition to the aforementioned approaches to preparing patients for anesthesia and surgery, three additional therapeutic approaches should be considered when endotoxemia is suspected: (a) minimizing the movement of endotoxin into the circulation, (b) interfering with the interaction between endotoxins and the inflammatory cells, and (c) preventing the synthesis, release, or action of inflammatory mediators.

For horses with intestinal ischemia, the decision for surgery must be made as early as possible to remove the affected intestine and, hopefully, reduce the transmural movement of endotoxin across the damaged mucosa. Although the vast majority of horses with endotoxemia are not bacteremic, some clinicians elect to include *antimicrobial agents* in the treatment of horses undergoing emergency abdominal surgery. Based on recent experimental studies with isolated equine leukocytes, killing of *Escherichia coli* bacteria with β -lactam antimicrobial agents significantly increases both the release of endotoxin and cellular synthesis of TNF- α when compared with the effects elicited by amikacin or the combination of amikacin and ampicillin. Consequently, it may be advantageous to administer polymyxin B or serum containing antiendotoxin antibodies to neutralize endotoxin when β -lactam antimicrobials are used.²²

Currently, two approaches are used in an effort to neutralize endotoxin before it activates inflammatory cells. The first of these involves administration of antibodies directed against the conserved core and lipid A regions of endotoxin. Serum or plasma products enriched in these antibodies are commercially available and have been used in clinical and experimental trials with conflicting results. In some studies, *antiendotoxin antibodies* have been of benefit in experimental endotoxemia and in horses with colic.^{23–25} The results of other studies have failed to identify the same positive effects.^{26–28} A common treatment regimen involves administration of 1.5 mL/kg IV of the antiendotoxin serum diluted at least twofold and preferably 10- to 20-fold in balanced IV fluids. Controlled clinical trials with strict entrance criteria are needed to compare the efficacy of antiendotoxin antibodies and nonspecific immunoglobulins. In such trials, the treatments would have to be instituted as early as possible in the course of the disease to give this method of treatment an opportunity to be successful.

Alternatively, *polymyxin B*, an antibiotic that binds tightly with lipid A, may be used to prevent endotoxin from interacting with

the horse's inflammatory cells.^{26,29} Although many clinicians initially expressed concern about the known toxic side effects of this drug, it appears that the concentrations needed to bind endotoxin are far less than those that cause the toxic effects. As a result, polymyxin B has been evaluated in several experimental studies and currently is being used in clinical cases. Based on the results of those studies, polymyxin B is used at 1000 to 5000 units/kg two to three times daily.^{26,30} It also has been recommended that particular attention be paid to maintaining fluid-replacement therapy and periodic monitoring of serum creatinine concentration.³⁰

A mainstay in the treatment of endotoxemia is the administration of drugs that interfere with the synthesis of inflammatory mediators. Currently, the most common types of drugs used for this purpose are the *nonsteroidal anti-inflammatory drugs* (NSAIDs). NSAIDs exert their beneficial effects by inhibiting cyclooxygenase, the enzyme responsible for generation of prostaglandins and thromboxanes.³¹ These arachidonic acid metabolites have been associated with many of the early hemodynamic responses to endotoxin. Of the two primary cyclooxygenase isoforms, it appears that the inducible isoform (cyclooxygenase 2 [COX-2]) is responsible for the increased synthesis of prostanoids in response to inflammatory stimuli, such as endotoxin.³² The constitutive isoform (COX-1) is more responsible for maintaining mucosal and renal blood flow.³³ The results of studies comparing nonselective NSAIDs indicate that flunixin meglumine and ketoprofen are most effective at preventing endotoxin-induced synthesis of prostaglandins and thromboxane and clinical signs of endotoxemia. With the toxic side effects of NSAIDs (gastrointestinal ulceration and renal papillary necrosis) being of concern, a study was performed to determine whether a reduced dosage of flunixin meglumine (0.25 mg/kg) might be effective in an experimental model of endotoxemia.³⁴ As a result of that study, use of this reduced dosage of flunixin meglumine has become standard practice in many clinical settings. However, no clinical studies have been performed to test whether this form of treatment is efficacious or how long it should be continued after surgery. With the development of new selective COX-2 inhibitors, it will be interesting to compare their effectiveness in endotoxemic horses with naturally occurring gastrointestinal diseases.

Pentoxifylline is another drug that has been used in the treatment of endotoxemic horses. Although it reduced endotoxin-induced production of cytokines, thromboxane, and expression of tissue factor in studies in vitro, its beneficial effects in endotoxemic horses in vivo appear very limited.³⁵ Additionally, only slight benefits of either drug alone were detected when pentoxifylline and flunixin meglumine were used in combination in a study of experimental endotoxemia.³⁶ However, because of its reported ability to increase the erythrocyte deformability and, as a result, improve microvascular blood flow, pentoxifylline is used widely in horses with laminitis.³⁷

Horses with colic that have clinical signs consistent with endotoxemia (i.e., alterations in mucous membrane color and capillary refill time, decreased gastrointestinal sounds, increased heart and respiratory rates, and evidence of dehydration) are candi-

dates for treatment. Although the primary goal should be to identify the underlying cause of endotoxemia, treatment usually must be started before a definitive diagnosis can be made. In these situations, it is reasonable to administer flunixin meglumine and either polymyxin B or antiendotoxin serum diluted in balanced IV fluids. Many clinicians also treat horses with pentoxifylline in an attempt to prevent acute laminitis.

Anesthetic Protocols

There is no universal choice of anesthetic agents for induction and maintenance of anesthesia in horses with colic. This author's preference for premedication of adult horses is a combination of xylazine (up to 1.1 mg/kg IV), butorphanol (0.02 mg/kg IV), and diazepam (0.05 mg/kg IV), with ketamine (up to 2.2 mg/kg IV) for induction of anesthesia. Anesthesia is maintained with isoflurane or sevoflurane in oxygen with controlled ventilation. Premedication may be considerably decreased or omitted if sedatives or opioids have been recently administered during the preoperative evaluation period. Romifidine or detomidine are other sedatives that can be used as substitutes for xylazine. Small doses of detomidine (0.004 mg/kg) can be used with reduced doses of xylazine (up to 0.8 mg/kg) to increase the analgesia and sedation over that usually provided by xylazine alone. Xylazine, romifidine, and detomidine produce dose-dependent decreases in intestinal motility; therefore, doses administered should be as low as possible.

Horses with colic may become hypotensive for a variety of reasons during anesthesia, including hypovolemia, acidosis, endotoxemia, effects of anesthetic drugs, increased intra-abdominal pressure, and aortocaval syndrome. *Guaifenesin* decreases mean arterial pressure in proportion to the dose administered and, therefore, lower-than-usual dose rates for guaifenesin should be used for horses with colic when guaifenesin is included in the anesthetic protocol. Guaifenesin is a useful muscle-relaxing drug for induction of anesthesia in excited or violent horses because it may facilitate tracheal intubation and transportation of the horse to the surgery room. Unfortunately, even when blood pressure is satisfactory immediately after induction of anesthesia when the horse is in lateral recumbency, arterial pressure frequently decreases dramatically when the horse is turned onto its back for hoisting or positioning on the surgery table. Horses that need immediate induction of anesthesia because abdominal distension is causing life-threatening hypoventilation and cardiovascular collapse can be supported by infusion of dobutamine and nasal insufflation of oxygen throughout induction. Rapid intubation and controlled ventilation with oxygen are advisable before transportation to the surgery room.

There are pronounced differences in cardiovascular function in horses maintained under anesthesia with halothane or isoflurane. *Isoflurane* anesthesia causes less depression of the cardiovascular system than does halothane, thereby allowing cardiac output, arterial oxygen tension, and muscle blood flow to remain higher during controlled ventilation.³⁸⁻⁴¹ After anesthesia is discontinued, the duration of recumbency is largely determined by the adjunct anesthetic agents administered, the temperament of the

horse, and the features of the environment used for recovery (e.g., pads, lighting, and sound). However, elimination of isoflurane is more rapid than halothane, and this decreases the duration of ataxia after standing. *Sevoflurane* is eliminated even more rapidly than isoflurane, and that may result in a better quality of recovery, a factor that may be a persuasive argument for using sevoflurane for anesthesia in sick horses.^{42,43} All inhalation agents cause vasodilation and progressive decreases in arterial blood pressure with increasing depth of anesthesia. This may result in a worsening of hypotension in dehydrated, endotoxemic horses. Various anesthetic manipulations may be necessary to maintain mean arterial blood pressure above 70 mm Hg.

Inclusion of an *opioid* in anesthetic protocols has long been recommended for balanced anesthesia in humans. Inclusion of the opioid is to provide analgesia and contribute to the central nervous system depression provided by the combination of drugs used for induction and maintenance of anesthesia. A dilemma in equine anesthesia is that some opioids induce central nervous system stimulation, characterized primarily by increased locomotor activity, an untoward effect limiting the choice of opioids that can be used in horses. Intuitively, inclusion of an opioid in anesthetic management seems to be a logical step to providing analgesia. Analgesia by opioid use has been demonstrated in conscious horses by using a variety of experimental models. However, studies of several opioids have failed to confirm that these agents consistently reduce inhalation anesthetic requirements in horses.^{44–46}

Butorphanol is licensed for use in horses and provides significant sedation. As a result, butorphanol is often used for premedication and to facilitate a smooth induction of anesthesia. The effect of this opioid lasts about 1 h, so repeated injections or continuous infusion must be given for continued effect. One published study has confirmed that infusion of butorphanol at 0.024 mg/kg/h in healthy awake horses maintains constant blood butorphanol concentrations.⁴⁷ Butorphanol can be administered conveniently during anesthesia by adding it to 0.9% saline to achieve a concentration of 1 mg/mL. The solution is then administered with a syringe pump that enables the infusion rate to be closely regulated. Although butorphanol does not significantly reduce an animal's requirement for an inhalant agent, our clinical impression is that its inclusion in the anesthetic regimen adds positively to the overall anesthetic effect.

Although *morphine* has been used intraoperatively as an analgesic in horses under anesthesia,⁴⁸ the results of another investigation failed to identify any reduction in inhalation agent requirement when a low dose of morphine was administered.⁴⁶ Furthermore, efforts to provide additional analgesia by using higher doses of morphine resulted in excitement during recovery from anesthesia.⁴⁶ Morphine also causes significant depression of intestinal motility, thereby further reducing the advisability of its systemic use in horses with colic.

Continuous infusion of *lidocaine* (loading dose 2.5 mg/kg, followed by an infusion of 0.05 mg/kg/min) has been reported to decrease the isoflurane requirement by 25% in healthy horses anesthetized for elective surgery.⁴⁹ Thus, one purpose for administering lidocaine during anesthesia is to reduce the dose-

dependent vasodilation that occurs with inhalation anesthetics and to maintain a higher arterial blood pressure.⁵⁰ A second reason for administering lidocaine is its potential to provide analgesia and decrease postoperative hyperesthesia induced by surgery. In a recent study in which lidocaine was administered as a continuous infusion,⁴⁹ no significant differences in mean arterial pressure, arterial blood gases, or plasma concentrations of cortisol and nonesterified fatty acids were identified between horses administered lidocaine and horses not administered lidocaine. There is some evidence in other species that systemic administration of lidocaine may have analgesic activity and prevent induction of central hyperalgesia. As evidence of this, the results of a recently published investigation of human patients undergoing major abdominal surgery determined that patients who received lidocaine during anesthesia needed less morphine during the first 72 h after surgery.⁵¹

A third potential benefit to the administration of lidocaine may be the ability to modulate the inflammatory response.⁵² In rabbits, for example, lidocaine given intravenously immediately after an endotoxin bolus prevented the adverse hemodynamic and cytokine responses to endotoxemia.⁵³ In rats, systemic or topically applied lidocaine reversed the secretory change in the intestinal wall induced by intestinal obstruction.⁵⁴

Endotoxemia and postoperative ileus are both serious consequences of colic in horses. In a survey of 54 horses undergoing anesthesia and surgery for colic, endotoxin was detected in the circulation during anesthesia in 20 horses (37%), and endotoxemia developed after the start of surgery in 9 of the 20 horses.⁵⁵ The incidence of postoperative ileus has been reported to be as high as 20% and imposes considerable morbidity and hospitalization costs.⁵⁶ The effects of lidocaine on intestinal function have been studied in clinical colic patients by using a loading dose of lidocaine (0.65 mg/kg IV), followed by infusion of the drug (0.025 mg/kg/min) through anesthesia and then at twice that rate after anesthesia.⁵⁷ The control horses received an equal volume of saline, and the investigators were blinded as to the treatment. Of the horses, 64% had large colon disease and 28.6% required small intestinal resections. Measured intraoperative serum lidocaine concentrations were from 0.39 to 2.72 µg/mL (mean, 1.06 µg/mL). No differences were obtained between horses given lidocaine and control horses for presence of gastrointestinal sounds on auscultation, time to passage of first feces, duodenal or jejunal wall thickness, or maximum duodenal and jejunal cross-sectional area as judged by percutaneous ultrasonography. Significant differences were measured between the groups for minimum jejunal cross-sectional area and diameter. The authors concluded these small changes were not sufficient to assess the influence of lidocaine on postoperative ileus. Another study of risk factors associated with postoperative ileus in horses identified increased odds for ileus in horses that had a small intestinal lesion, high preoperative hematocrit, and anesthesia duration exceeding 3 h for lesions not involving small intestine.⁵⁶

Significant difficulties arise in interpreting data from clinical studies when a variety of treatments are used. Evaluation of the impact of treatments on postoperative events should take into ac-

count use of *hypertonic saline* because hypertonic saline has been shown to modulate inflammatory responses in patients in shock. Recent studies using a model of intestinal ischemia and reperfusion in laboratory animals have demonstrated that hypertonic saline decreases mucosal injury and decreases ileus.⁵⁸ Other investigations have demonstrated that hypertonic saline dramatically improves survival rate in animal models of hemorrhagic shock and sepsis.⁵⁹

Hypoventilation and Hypoxemia During Anesthesia

Hypoventilation is a common complication in horses during anesthesia for colic surgery. Controlled ventilation is advisable to avoid the adverse consequences of severe hypercarbia. Ventilation with a tidal volume of 10 mL/kg at a respiratory rate of 10 breaths per minute will result in normocarbia in horses undergoing elective procedures. Peak inspiratory pressure in these animals is usually about 20 to 24 cm H₂O. Higher pressures will be needed to deliver an adequate tidal volume in horses with abdominal distension. Pressures exceeding 40 cm H₂O may cause alveolar rupture, however, and, until the abdomen has been opened and the colon decompressed, adequate ventilation may not be achieved even at these pressures in some horses with colonic distention. The risk of pulmonary damage in these horses can be reduced by limiting the peak inspiratory pressure to 40 cm H₂O and permitting some degree of hypercarbia to occur. Although elevations in PaCO₂ can be confirmed by blood-gas analysis, capnography may or may not provide an accurate estimate of PaCO₂ in these patients. The difference between end-tidal CO₂ and PaCO₂ in colic horses is greater than in healthy horses, and PaCO₂ during controlled ventilation has been reported to be 10 to 13 mm Hg higher than end-tidal CO₂.^{60,61} In fact, the difference between end-tidal CO₂ and PaCO₂ may be as high as 25 mm Hg in some animals and is greater during spontaneous ventilation. One way of dealing with this problem is to use blood-gas analysis at the beginning of anesthesia to determine whether a large difference exists and then use capnography as a guide for the remainder of the anesthetic period. Ventilation of horses for colic surgery to end-tidal CO₂ values of 30 to 40 mm Hg in the absence of blood-gas analysis will maintain PaCO₂ values close to the normal range in the majority of horses.

Lung collapse may be sufficient to result in hypoxemia (PaO₂ < 60 mm Hg). Occasionally, opening the abdomen and decompression of the intestines will enable a sufficient increase in ventilation to expand the lung and improve oxygenation. More frequently, however, PaO₂ does not increase until after anesthesia. Maneuvers such as changing the ventilatory pattern or imposing positive end-expiratory pressure (PEEP) are not often successful in increasing PaO₂. Horses with hypoxemia often survive anesthesia, rendering the impact of hypoxemia on morbidity speculative. Interestingly, in a survey of 600 horses anesthetized for colic surgery, hypoxemia was present in 17%, and the survival rates for these horses and horses with normal oxygenation were not different (C.M. Trim, unpublished data).

Cardiovascular Performance During Anesthesia

Decreased cardiovascular performance commonly occurs in horses during anesthesia for colic surgery. Consequently, one of the first priorities is to maintain mean arterial pressure above 70 mm Hg. Horses that have insufficient fluid therapy before anesthesia will need rapid volume expansion to counter vasodilation caused by inhalation anesthetics. A balanced electrolyte solution, such as acetated or lactated Ringer's solution, should be infused at 10 mL/kg/h in horses with a normal fluid balance and at an increased rate in horses that are volume depleted. Hypertonic (7.5%) saline (4 mL/kg IV) can be administered over 10 min as a rapid infusion to counteract hypovolemia. Increases in cardiac output and mean arterial blood pressure have been measured for 1 h after infusion of hypertonic saline in horses subjected to endotoxemia⁶² or hemorrhage.⁶³

Vasoactive drugs, such as dobutamine, dopamine, and ephedrine, are used to increase cardiac output and blood pressure during anesthesia. Dobutamine (0.5 to 5.0 µg/kg/min) is frequently effective in correcting anesthetic-induced hypotension. Potential adverse effects of dobutamine treatment are bradycardia and tachycardia. Dobutamine infusion may induce bradycardia, with or without second-degree heart block, that is sufficient to decrease arterial blood pressure further. Management of second-degree heart block includes decreasing the dose rate of the dobutamine and administering ephedrine, atropine (0.005 to 0.01 mg/kg), or dopamine to increase the heart rate and blood pressure. Endotoxemia may alter the sensitivity of cardiac β receptors such that administration of dobutamine has less effect on cardiac output and causes tachycardia. Techniques to increase arterial blood pressure then must focus on efforts to expand blood volume and decrease the concentration of anesthetic delivered. Dopamine (3.0 to 6.0 µg/kg/min) is used to increase renal blood flow in horses with increased serum creatinine concentrations, to increase cardiac output, and to increase heart rate in horses with advanced atrioventricular heart block. Ephedrine is most effective in animals with excessive vasodilation, because ephedrine-induced vasoconstriction increases venous return to the heart. Ephedrine (0.06 mg/kg IV bolus) has been reported to increase cardiac output and mean arterial blood pressure in anesthetized horses for 30 to 40 min.⁶⁴ Arterial pressure in anesthetized horses with colic also can be increased by an infusion of a 23% solution of calcium gluconate (100 to 200 mL per adult horse) given over 15 min. Significant increases in cardiac output and mean arterial pressure have been measured in healthy anesthetized horses during infusion of calcium gluconate.⁴⁰ An infusion rate of 0.1 mg/kg/min effectively improved cardiac function in horses anesthetized with isoflurane, whereas a higher dose rate of 0.4 mg/kg/min was necessary to improve cardiac function in horses anesthetized with halothane. Preanesthetic determination of serum electrolyte concentrations will identify some horses with colic that are hypocalcemic, and treatment of these horses with calcium gluconate before anesthesia is warranted. Of concern is the potential adverse impact of exogenously administered calcium in critically ill horses with cardiovascular failure, endotoxemia, or hypoxemia.

Assessment of cardiovascular system function must include interpretation of mean arterial pressure with systolic-diastolic pressure difference, arterial pressure waveform, capillary refill time (CRT), and mucous membrane color to arrive at an estimate of cardiac output. A low systolic pressure, dramatic fluctuations in systolic pressure with the ventilator cycle, flattened arterial waveform, and prolonged CRT are indicators of low cardiac output. Further, increases in arterial pressure after vasoconstriction, such as that induced by onset of surgery, may be accompanied by any change in cardiac output, including a decrease resulting from an excessive increase in afterload.⁶⁵

Hypotension that is primarily caused by vasodilation and that is unresponsive to both fluid loading and catecholamines may be countered by decreasing the inspired concentration of the inhalation agent. Under such circumstances, administration of sedatives, opioids, or injectable anesthetics will be necessary to maintain the desired lack of response to surgery. Continuous infusions of either lidocaine, ketamine, or a mixture of guaifenesin-ketamine-xylazine have been used to provide sufficient additional analgesia to reduce the inspired inhalant concentration. Collectively, any of these treatments may result in an increase in mean arterial pressure, because of a reduction in anesthetic agent-induced vasodilation.^{49,50} Inclusion of a morphine epidural nerve block may provide additional analgesia. Definitive studies that include measurement of cardiac output are needed to ascertain the effects of different treatments on overall cardiovascular performance. It is unclear whether these treatments allow a decreased inhalation agent requirement by providing sedation or analgesia or both.

Cardiac dysrhythmias are an occasional complication in horses anesthetized for colic surgery. The concurrent presence of atrial fibrillation and gastrointestinal disease can result in hypotension that is difficult to treat. If the usual therapies to improve cardiovascular function fail to produce an adequate mean arterial pressure, administration of *quinidine* (up to 10 mg/kg in divided IV boluses) is the recommended treatment. Premature ventricular depolarizations also develop in a small number of horses as a consequence of endotoxemia. Treatment is not always necessary, but lidocaine can be used to decrease the frequency of abnormal beats when arterial blood pressure is decreased by the dysrhythmias.

Recovery from Anesthesia

Controlled ventilation can be continued up to the time the horse is disconnected from the anesthesia machine, where a demand valve should be available to continue ventilation in the recovery stall. Sometimes reducing the depth of anesthesia before the end of surgery to ensure rapid return of spontaneous ventilation is not feasible, especially when horses must be hoisted from the surgery table or if the time required to transport a horse from the surgery room to the recovery stall is long. Although oxygenation is maintained for some minutes when a horse becomes apneic after being disconnected from the anesthesia machine, PaO₂ values will decrease dramatically in horses breathing room air spontaneously early in the recovery period. This author's preference is to control ventilation with a demand valve and oxygen for the

first 10 min of recovery and then to allow the horse to breathe spontaneously with oxygen insufflated at a rate of 15 L/min into the nose or endotracheal tube. The nasogastric tube is removed for recovery from anesthesia.

Some anesthesiologists prefer to leave the endotracheal tube in place while a horse recovers from anesthesia, whereas others prefer to remove it once the horse can swallow. However, if regurgitation around the nasogastric tube has occurred during anesthesia or if the nasal mucosa is congested and swollen, the endotracheal tube should remain in place until the horse is sternal or stands.

The usual methods to discourage horses from attempting to stand too early, such as positioning the horse on pads or an air cushion in a warm, quiet recovery room with dim lighting, should also be applied to horses after colic surgery. Often supplemental sedation is provided in the form of xylazine (0.2 mg/kg IV) given approximately 5 min after the inhalant is discontinued. Assistance to a standing position using ropes tied to the halter and tail should be considered when factors that contribute to ataxia are present, such as horses that are more than 20 years of age, rectal temperature less than 35.5°C (96°F), hypotension during anesthesia, clinical evidence of endotoxemia, and an anesthesia time that exceeds 3 h.

Analgesia is continued into the postoperative period by using nonsteroidal anti-inflammatory agents and continuous infusions of butorphanol and lidocaine. The results of one published investigation of butorphanol administration by continuous IV infusion documented a significant delay in the time to passage of feces when compared with values for horses that were not given butorphanol (median times of 15 and 4 h, respectively).⁴⁷ Preliminary evaluation of a transdermal fentanyl patch (Duragesic) to provide analgesia in horses has identified evidence of analgesia for conditions involving visceral pain.⁶⁶ One investigation of the pharmacokinetics of transdermally applied fentanyl described rapid absorption and blood concentrations exceeding 1 ng/mL by 3 h after application of two 10-mg transdermal fentanyl patches to healthy adult horses.⁶⁷ Serum concentrations of this magnitude were sustained for 32 h, thus offering a convenient method of supplying a constant level of analgesic drug.

- Summary

Introduction

Several minimally invasive advanced diagnostic and therapeutic procedures have become more commonly used over the last decade because of increased availability of the technology and expertise in application and interpretation. General anesthesia or sedation is usually required to assure patient immobility during these procedures. Animals vary greatly in physical status and underlying disease processes. Thus, the saying “There is no *one* ideal anesthetic protocol” applies aptly to these patients. Because many of the procedures discussed in this chapter may be considered to be elective, minimally invasive, and of short duration, an anesthetic protocol that will provide a rapid recovery is desirable. Perianesthetic considerations are presented for selected minimally invasive diagnostic techniques, including laryngoscopy, bronchoscopy, bone marrow aspiration, thoracic drain placement, and esophagostomy tube placement; for advanced imaging techniques, including computed tomography (CT), magnetic resonance imaging (MRI), and ultrasonography; and for radiation therapy. With a few exceptions, these procedures are not considered lifesaving, but rather diagnostic, and should be planned to minimize the potential adverse effects of general anesthesia or sedation.

The approach to anesthetic management should be kept simple, with the following principles in mind:

1. Identify and correct (when possible) underlying patient problems to minimize anesthetic risk.

2. Formulate an anesthetic protocol that will work in the existing environment and that can be readily adapted to each individual patient and its unique disease process(es).
3. Apply effective and adequate monitoring tools that will alert the anesthetist to potential problems so that quick and effective correction can be instituted.
4. Provide appropriate supportive therapy (as guided by underlying patient disease and information provided by monitoring devices).

Laryngoscopy and Bronchoscopy

Laryngoscopy is used in evaluating laryngeal disease—specifically, laryngeal paralysis. Sedation is required to facilitate relaxation of the jaw, but must be carefully selected to have a minimal effect on laryngeal function. It can be challenging to keep patients adequately sedated without affecting laryngeal function. A neuroleptanalgesic combination of an opioid and benzodiazepine (Table 52.1) is adequate for most patients. These drugs have the advantage of preserving laryngeal function and being reversible if respiratory distress develops. Challenge with doxapram (1.0 mg/kg intravenously [IV]) to increase respiratory activity may be used if evaluation is hindered by drug-induced respiratory depression.

Bronchoscopy is performed in dogs and cats for evaluation of airway disease and to perform bronchoalveolar lavage. Many of the patients presented for laryngoscopy and bronchoscopy are at increased risk for development of hypoxemia. Preoxygenation should accompany both procedures, and the anesthetist should always be prepared to take control of the airway by intubation and application of ventilatory support. During the bronchoscopy, oxygen may be delivered to smaller patients via an endoscope (working channel). Larger patients may be intubated and connected to oxygen by a breathing system; a Y-piece aperture may be used to pass the endoscope into the trachea. An opioid-benzodiazepine combination for sedation, followed by administration of low-dose propofol to effect, is commonly used to facilitate bronchoscopy (Table 52.1).

Thoracic Drain Placement

Thoracostomy tube placement may be required to manage pleural space disorders, such as pneumothorax, pyothorax, and chylothorax. These patients are often high risk, especially animals

Table 52.1. Suggested anesthetic doses for protocols for diagnostic procedures^a

Premedication: opioid-benzodiazepine combination	
Opioids (IV, IM, or SC; IV administration of morphine is not recommended)	
Butorphanol	0.2–0.4 mg/kg
Buprenorphine	0.01–0.04 mg/kg
Morphine	0.4–1.0 mg/kg
Hydromorphone	0.1–0.2 mg/kg
Oxymorphone	0.05–0.1 mg/kg
Benzodiazepines (diazepam: IV only; midazolam: IV, IM, or SC)	
Diazepam	0.1–0.4 mg/kg
Midazolam	0.1–0.3 mg/kg
Antagonists	
Naloxone (opioid)	0.001 mg/kg
Flumazenil (benzodiazepine)	0.01–0.02 mg/kg
Induction	
Propofol	2–6 mg/kg IV
Etomidate	0.5–2.0 mg/kg IV
Ketamine	2–5 mg/kg ^b IV, IM
Maintenance	
Inhalation anesthesia: isoflurane or sevoflurane	
Propofol CRI	0.4 mg/kg/min
Propofol IB	0.5–2.0 mg/kg

CRI, continuous-rate infusion; IB, intermittent bolus; IM, intramuscular; IV, intravenous; and SC, subcutaneous.

^aThese protocols pertain to dogs and cats.

^bKetamine for induction is administered IV at 5 mg/kg combined with a benzodiazepine at 0.25 mg/kg and given to effect. For feline immobilization, 2 mg/kg IM is used with a benzodiazepine-opioid combination.

with pneumothorax and concurrent pulmonary contusions. In dogs, thoracic drain placement can often be performed using sedation in combination with a local anesthetic technique, such as infiltration or intercostal nerve block (see Chapter 20). To assure airway control, oxygen delivery, and provision of ventilatory support throughout the procedure in patients with respiratory distress or with hypoxemia, general anesthesia may also be used and may be superior. For cats, general anesthesia is preferred. Reversible agents with mild cardiopulmonary effects, such as the combination of a benzodiazepine with butorphanol or buprenorphine (Table 52.1), provide adequate sedation for most patients. For general anesthesia, a rapid-sequence induction to gain control of the airway is recommended. Propofol, benzodiazepine-ketamine combination, or etomidate (Table 52.1) are good induction choices, providing for relatively rapid recoveries.

Bone Marrow Aspiration

This is performed to evaluate bone marrow disease and to stage certain cancer patients. Protocol selection should be based on the individual patient; depending on the level of an animal's activity, bone marrow aspiration may be performed in dogs with local in-

filtration alone or in combination with sedation. Uncooperative dogs and the majority of cats may require general anesthesia. The aforementioned protocols for thoracostomy tube placement are appropriate.

Esophagostomy Tube Placement

This is used to provide enteral nutrition for both dogs and cats. General anesthesia is required to protect the airway in case of regurgitation and the endotracheal tube facilitates placement of the esophageal tube. The aforementioned protocols for thoracostomy tube placement are applicable for this procedure.

For the procedures listed earlier, identification of an individual animal's underlying disease, anticipation of and planning for potential complications, and close monitoring throughout the anesthetic period will help to assure a successful outcome, regardless of the anesthetic agents used.

Computed Tomography and Magnetic Resonance Imaging

General Considerations

CT and MRI were first introduced in 1972 and 1980, respectively. Routine clinical use of CT and MRI technology has evolved recently as availability of equipment and expertise in interpretation have increased. Anesthetic management for CT and MRI presents a unique challenge in that there is no painful stimulation during the anesthetic period; thus, response to a noxious stimulus does not provide a method for assessing anesthetic depth. The majority of scans are performed with the patient in dorsal recumbency; this position has the most significant detrimental effects on ventilation and perfusion matching. And patient access is usually limited during both CT and MRI. Depending on unit configuration, patients placed in a magnet are often difficult to access, so subjective evaluation, such as assessment of pulse quality and mucous membrane color, may not be feasible. With CT, although patient access is not problematic, exposure of the anesthetist to radiation is an issue, and direct patient assessment while the scan is being performed is discouraged.

Contrast Agents for CT and MRI

An additional consideration is the common use of contrast for both MRI and CT. While reaction to contrast administration appears to be relatively uncommon in animals, anesthetists must be aware of this potential complication. Intravenous iodinated contrast is often given to patients during a CT scan. These contrast agents consist of meglumine and/or sodium salts of iothalamate or diatrizoate (Table 52.2) and are ionic and hyperosmolar, which contributes to their side effects. Adverse reactions to these contrast agents include hypotension, tachycardia, and depressed ST segments and prolonged Q-T intervals on the electrocardiogram (ECG).¹ One case of cardiac arrest has been reported in a dog after intravenous (IV) administration of iodinated contrast media.² Adverse reactions are usually seen in the first 5 to 10 min following administration and are potentiated by dehydration; thus, normal hydration status is essential prior to the CT contrast

Table 52.2. Properties of contrast agents used for diagnostic imaging

Ionic, hyperosmolar iodinated contrast media					
Brand Name	Cation	Anion	mg I/mL	Osmolality (mOsm/kg H₂O)	Viscosity at 37°C
Conray	Meglumine	lothalamate	282	1400	4
Conray 400	Sodium	lothalamate	400	2300	4.5
Hypaque 76	Meglumine 66% Sodium 10%	Diatrizoate	370	2016	9
Hypaque 50%	Sodium	Diatrizoate	300	1515	2.34
Hypaque 60%	Meglumine	Diatrizoate	282	1415	4.12
Renografin 76	Meglumine 66% Sodium 10%	Diatrizoate	370	1940	8.4
Renografin 60	Meglumine 52% Sodium 8%	Diatrizoate	290	1450	4
Nonionic, low-osmolar iodinated contrast media					
Brand Name	Generic Name	mg I/mL	Osmolality (mOsm/kg H₂O)	Viscosity at 37°C	
Omnipaque	Iohexol	140	322	1.5	
		180	408	2	
		240	520	3.4	
		300	672	6.3	
		350	844	10.4	
Isovue	Iopamidol	150	342	1.5	
		200	413	2	
		300	616	4.7	
		370	796	9.4	
Visipaque	Iodixanol	270	290	6.3	
		320	290	11.8	
Ultravist	Iopromide	300	607	4.9	
		370	774	10	
Optiray	Ioversol	160	355	1.9	
		240	502	3	
		300	651	5.5	
		320	702	5.8	
		350	792	9

administration. Humans are at risk for serious reactions if they have any of the following preexisting conditions: diabetes mellitus, renal insufficiency, congestive heart failure, hypovolemia, multiple myeloma, hypertension, or combined hepatic and renal failure.¹ No specific treatment is necessary following a mild reaction to the contrast media; however, fluid administration rate should be increased for treatment of mild hypotension and tachycardia. If an anaphylactic reaction does occur, administration of epinephrine, diphenhydramine, and/or corticosteroids is indicated. Fluid administration rate for patients with underlying renal disease should be increased to 20 mL/kg during the first 30 min

of anesthesia to promote contrast clearance and to maintain adequate renal perfusion.

All contrast agents used in MRI contain a paramagnetic element: gadolinium. These contrast agents present a lower osmotic burden to the patient, and smaller volumes are required compared with CT contrast agents. There have been no reported cases of adverse reactions to MRI contrast agents in animals, but allergy-type symptoms, hypotension, hypertension, vasodilation, tachycardia, nausea, vomiting, and headache have been reported in humans. An increased administration rate of IV fluids should be used to treat hypotension and tachycardia.³

MRI Safety Considerations

MRI safety is an important concern in anesthesia monitoring because ferromagnetic objects are attracted toward the magnet; therefore, projectile-related accidents can occur. Traditional anesthetic equipment and monitors may be unsafe, may be damaged, may malfunction, or may interfere with image generation when used in the MRI suite. The MRI consists of a strong static magnetic field, gradient magnetic fields, and radiofrequency (RF) fields. Any ferromagnetic object has the potential to be drawn into the bore of the magnet, causing injury to the patient or personnel in the room. The influence of the MRI scanner on equipment depends on the strength of the magnet, proximity to the magnet bore, the amount of ferromagnetic material present, and the design of the circuitry.⁴ Also, the RF fields and the applied magnetic gradient fields in the room can affect the function and accuracy of the monitoring equipment, or, conversely, the monitoring equipment can alter the quality of the images obtained. Ferromagnetic equipment within the room should be replaced with nonferromagnetic or minimally ferromagnetic metal, such as stainless steel, brass, or aluminum. Alternatively, ferromagnetic equipment may be securely anchored to a wall or the floor as far away from the bore of the magnet as possible. Monitoring equipment may be adapted by placing the devices outside of the room and using long connecting wires. If possible, oxygen tanks should be located outside of the MRI suite, or tanks made of aluminum should be used.

Several companies sell MRI-compatible anesthesia and monitoring equipment. Keep in mind the definitions of MRI safe and MRI compatible. *MRI safe* means that the device, when used in the MR environment, has been demonstrated to present no additional risk to the patient or other individual, but may affect the quality of the diagnostic information. *MRI compatible* means that a device is MR safe and, when used in the MR environment, has been demonstrated neither to significantly affect the quality of the diagnostic information nor to have its operations affected by the MR unit.⁴ Some companies market their product as MRI compatible, but the instruction manuals must be carefully read because there have been several reports of “MRI compatible” monitoring equipment being propelled into the bore of the magnet.^{5,6} Instructions for such potentially hazardous equipment state that the item must be placed a certain distance away from the magnet.^{6,7} Ideally, equipment should be checked by a biomedical engineer responsible for the area before it is brought into the vicinity of the MRI scanner. Some companies that supply MRI-compatible or MRI-safe anesthetic equipment and monitors are listed in Table 52.3.

Special consideration should also be given to patients with any type of metallic implants, such as hemoclips, patent ductus arteriosus (PDA) occlusion coils, or pacemakers. Ferromagnetic hemoclips can dislodge and migrate, causing internal damage. An electrical current can be induced in PDA coils, causing thermal damage, and pacemaker leads or generators can dislodge. The magnetic field may cause the pacemaker generator to malfunction or readjust. An electrical current in the lead wire may produce enough heat to cause injury. If a metallic implant is located in the region that is being imaged, severe image artifacts often occur, resulting in a nondiagnostic study.

One other safety issue that may occur in the MRI suite is magnetic quenching. If the liquid helium that surrounds and cools the superconducting solenoid of the magnet rapidly escapes, it can displace the oxygen in the room, causing hypoxia to the patient and personnel present. Ideally, oxygen sensors should be placed in MRI suites.

Ultrasonography

This has been used in veterinary medicine since the late 1970s and has become a routine diagnostic procedure for animals. Most animals tolerate ultrasonographic evaluation without sedation or anesthesia, but sedation may be necessary in fractious, aggressive, or painful animals. Ultrasound-guided organ or tissue biopsies are becoming more common as a method for collecting samples less invasively. Small animals usually tolerate the procedure well with sedation and local anesthetic infiltration, but general anesthesia may be more effective in some individuals. Local anesthetic infiltration alone or with mild sedation, combined with proper restraint, is effective for collecting biopsy samples in standing horses, cows, and other large animal species.

Radiation Therapy

External beam radiation is used to treat many types of neoplasia in small animals. Treatment usually consists of multiple small doses of radiation daily for a curative intent or larger, less frequent doses for pain palliation. Treatment times per dose last anywhere from about 1 min up to 7 or 8 min. Therefore, patients must remain motionless and be precisely positioned for radiation therapy. Since most animals receive their radiation doses daily and remain in the hospital for up to 4 weeks or go home nightly, a profound sedation or general anesthetic protocol should be used that is easily administered and has a quick recovery time. During treatment, personnel cannot be present in the therapy room to directly monitor the animal because of radiation safety. Remote monitors or cameras focused on the patient and in-room monitors should be used to assess the patient.

Patient Preparation

The procedures presented in this chapter, though essential to the well-being of the individual patient, are largely elective. Ade-

Table 52.4. Disease processes that may be present in patients presented for computed tomography (CT), magnetic resonance imaging (MRI), and ultrasonography

Organ or Organ System: Examples
Skull: orbital, nasal, sinus, and oral tumors
Brain: tumors, cerebrovascular bleeding (stroke), and hydrocephalus
Spinal cord: tumors, intervertebral disk disease, and trauma
Musculoskeletal: soft tissue and skeletal tumors, and ligament and cartilage damage
Thorax: intrathoracic masses, effusions, and pneumonia
Cardiac: masses, murmurs, and arrhythmias
Abdomen: abnormalities associated with the liver, pancreas, adrenal glands, spleen, kidneys, ureters, and bladder

This list is not exhaustive but is based on the literature and personal experience of the authors. As a general rule, CT is superior for skeletal imaging, whereas MRI is superior for soft tissue imaging. Movement artifact can be problematic for abdominal and thoracic MRI, depending on the speed and sophistication of the scanner. CT may provide superior images for body cavity structures.

quate preanesthetic patient assessment, including physical examination and laboratory evaluation (complete blood count, chemistry panel, and urinalysis), is essential for successful outcome. Fortunately, since the aforementioned techniques may be considered to be advanced techniques, a thorough workup has already been performed in many of the presenting patients. For marrow and organ biopsy, a coagulation profile should also be evaluated. Table 52.4 provides some examples of disorders that may exist in patients presented for MRI, CT, and ultrasound procedures. Readers are directed to Chapters 36 to 51, which address anesthetic management of system-specific diseases, for additional anesthetic management considerations.

Protocol Selection

When formulating an anesthetic plan, reversibility, familiarity (comfort zone), and maintenance of homeostasis by provision of adequate supportive care and monitoring should be addressed. Since the technique itself will vary minimally among patients, an anesthetic plan that will meet the needs of the majority of patients and will be compatible with the facility is desirable. The drugs used should be short-acting and/or reversible; some options are listed in Table 52.1. For premedication, an opioid alone or combined with a benzodiazepine has relatively mild cardiopulmonary effects and will provide sedation and reduce induction and maintenance requirements. These drugs can be reversed with an opioid antagonist, such as naloxone, and the benzodiazepine antagonist flumazenil, if necessary (Table 52.1). Acepromazine premedication may be beneficial for healthy animals that are difficult to restrain or aggressive, if there are no patient contraindications. Acepromazine facilitates a smooth but somewhat prolonged recovery, so benefits should be weighed against this disadvantage. Intramuscular ketamine (2 to 4 mg/kg),

with an opioid-benzodiazepine combination, may be beneficial in fractious cats to provide sedation and immobilization. Induction options include propofol, etomidate, ketamine, and inhalation agents. Propofol is probably most frequently used because of its short duration of action, but can be detrimental in animals with underlying hypotension that remains uncorrected prior to induction. Etomidate may provide a better alternative in cardiovascular-compromised patients. Ketamine with a benzodiazepine represents an alternative method of induction, but recovery may be prolonged (compared with etomidate, propofol, and inhalation agents). Contraindications for ketamine use, such as a history of seizures and the presence of increased intracranial pressure, are particularly germane to patients undergoing MRI and/or CT. Induction with an inhalation agent via face mask may be used if rapid control of the airway is not an issue, if the patient is tractable, and if the induction room is well ventilated. However, this method is recommended only when other options present unacceptable patient risk. A major disadvantage to mask induction is waste-gas pollution and subsequent exposure of personnel. Anesthesia for MRI and CT is most commonly maintained with an inhalation agent. Isoflurane and sevoflurane both facilitate a rapid recovery. Anesthesia machines and ventilators that are MRI compatible or MRI safe are available, and some suppliers are listed in Table 52.3. If an MRI-compatible anesthesia machine is not available or if a traditional machine cannot be configured from outside the MRI room, anesthesia can be maintained with propofol by using a constant rate infusion or intermittent bolus technique (Table 52.1). Maintenance with propofol should always include intubation, supplemental oxygen, and a method for ventilatory support.

Monitoring

General Considerations

Considering the diversity of patient signalment, physical status, and organ system abnormalities, and irregardless of the relatively short duration of the procedures, one or more monitoring devices should be applied to every individual patient to help assure its well-being. Monitoring techniques could include continuous ECG, pulse oximetry, capnography, blood pressure monitoring, and measurement of end-tidal anesthetic gas concentration (ET_{agent}). Application should be tailored to the individual and to the procedure. For example, pulse oximetry is especially important for assessing patients at risk for developing hypoxemia, such as during bronchoscopy and thoracostomy tube placement. Capnography is useful for intubated patients at risk of hypoventilating (thoracostomy tube placement). Readers are referred to Chapter 19 for a detailed description of the information afforded by these devices.

Monitoring for MRI and CT

Considering the challenge of patient accessibility and the diversity of patient presentation, several monitoring tools should be applied to maximize patient safety. Essential monitoring devices include capnography, pulse oximetry, and continuous ECG. Capnography ($ETCO_2$) and pulse oximetry (SpO_2) provide con-

tinuous, noninvasive methods of assessing adequacy of ventilation, perfusion, and oxygenation, and also provide an assessment of respiratory rate and pulse rate, respectively. The capnographic waveform provides an early warning to the anesthetist that a problem is developing. Noninvasive or invasive blood pressure monitoring and ET_{agent} monitoring are also recommended. Anesthetic agents compromise cardiovascular homeostasis and, in the absence of a surgical stimulus, hypotension should be anticipated, especially if underlying cardiovascular abnormalities are present. Use of blood pressure monitoring will alert the anesthetist to the development of hypotension so that supportive measures can be instituted (increase in fluid administration rate, administration of an inotrope, or decrease in anesthetic depth). ET_{agent} reflects an agent's alveolar partial pressure and thus closely approximates arterial and brain anesthetic partial pressures (once equilibration is reached). The minimum alveolar concentration (MAC) has been reported for inhalant agents commonly used for a variety of animals. Although many factors, such as premedications administered, will affect patient inhalation agent requirements, maintaining an ET_{agent} concentration of 1.2 to 1.4 MAC is considered to be appropriate for most animals. Some suppliers that offer MRI-compatible monitoring equipment are listed in Table 52.3. Additional information regarding MRI-compatible equipment has been published.^{5,6}

Monitoring patients undergoing MRI can be difficult for many reasons in addition to patient inaccessibility. Some scanners are extremely loud during image acquisition, making direct cardiopulmonary auscultation impossible. The gradient magnetic fields and RF fields are capable of generating electrical currents in metal wires, so ECG leads can burn a patient's skin. Burns caused by ECG leads during MRI have been cited in the literature on human patients⁸ and have been reported to occur during animal imaging. Electrical current induction can occur within a loop of wire in a pulse oximetry unit, which can severely burn patients. To avoid patient injury, it is important that MRI-compatible lead connections be used. Additionally, the MRI may interfere with ECG waveforms, making it difficult to evaluate the rhythm trace.

Patients anesthetized for MRI and CT require intravenous fluid administration to maintain adequate perfusion and the application of monitoring devices to identify and address alterations in homeostasis proactively. Availability of mechanical

ventilation to provide intermittent positive-pressure ventilation (IPPV) is important during diagnostic imaging. Application of IPPV in combination with capnography will enhance patient management by assuring ventilatory homeostasis. Increased intracranial pressure caused by trauma or brain tumor is a common presenting sign in patients undergoing CT and MR imaging. Maintaining these patients in a mildly hypocapnic state (e.g., $PaCO_2 = 30$ mm Hg) will improve anesthetic outcome by minimizing the detrimental effects of increased $PaCO_2$ on intracranial pressure.⁹

Summary

Anesthetic management of patients presented for advanced diagnostic and therapeutic techniques should include thorough preoperative patient assessment, a protocol that addresses patient needs, and application of effective monitoring tools and supportive therapy throughout the anesthetic period.

Introduction

In many veterinary practices, after the induction of anesthesia, no one is assigned the task of anesthetist to monitor anesthesia and be vigilant for untoward events that might result in accidental morbidity and mortality. As with most unwanted events, the anticipation of possible complications and having a plan of action already prepared will facilitate successful resolution of the problem. Since the onset of general anesthesia upsets the physiological equilibrium of patients and can bring them closer to harmful outcomes, preparation to manage these problems is even more critical. Monitors that display vital parameters such as oxygen saturation of hemoglobin, end-tidal carbon dioxide, blood pressure, and heart rhythm are available to facilitate early detection of critical events such as bradycardia, changes in oxygen availability, and hypoventilation. Veterinarians who vigilantly monitor have a better opportunity to respond quickly to a harmful trend before a disaster occurs.

Anesthetic Risk

The risk of death from disease or related surgery is usually greater than the risk of death from anesthesia. However, anesthesia involves the controlled administration of potentially toxic

drugs and thus carries a risk of organ dysfunction and damage, delayed recovery, and death. Mistakes are not necessarily reversible, and death can occur suddenly and often without warning when patients are not appropriately monitored. The goal of anesthetists should be to manage the risks associated with anesthesia and the perioperative period, affording patients the best chance of a successful outcome. *Risk management* is a term developed by the insurance industry and adopted by the health care industry to describe processes used to prevent injury, litigation, and financial loss.^{1,2} The real aim of this process is to use analysis of adverse events to prevent similar injuries to subsequent patients. Risk management starts with an unbiased and nonjudgmental review and analysis of all “critical events” causing real or potential patient harm. The next step is formation or modification of standard operating procedures. For example, in aviation, accident investigation begins with discovery of the facts by an independent board (National Transportation Safety Board) and then analysis and publication of the findings. There is also an anonymous reporting system (Aviation Safety Reporting System) that involves the documentation and analysis of events that were considered hazardous by the participants but did not lead to an accident. These aviation review procedures provide a model for the improvement of anesthesia safety in both human and veterinary medicine. A commitment to the highest-quality patient care will ultimately lead to the routine performance of such analyses by medical providers.

Species-Related Risk

Advances in medical technology and pharmacology, as well as the increase in training of anesthesiologists, veterinarians, and licensed technicians, have done much to decrease the inherent risks associated with anesthesia. The risk of anesthetic-related death in people is estimated at between 1:10,000 and 1:200,000.³⁻⁵ The rate of anesthetic-related death among dogs and cats anesthetized in private practice has been assessed at 0.1%.⁶ Horses present an inherently greater challenge during anesthesia because of unique anatomical, physiological, and behavioral factors. Several studies suggest an anesthetic-related mortality rate of between 0.08% and 0.9% in healthy horses.^{7,8} Postanesthetic lameness caused by myopathies and neuropathies reportedly occurs in 6.4% of anesthetized horses.⁹ Emergency cases, including colics, are associated with an apparent mortality rate of 31.4%.¹⁰ Another retrospective analysis of cases from a single facility using a fairly standardized anesthetic protocol found an incidence of anesthetic-related mortality of 0.12% (L.

Bidwell, personal communication, 2004). In this study of 21 deaths from among 17,961 equine anesthetics, the incidence of cardiac arrest was 0.06% (10 deaths), that of long-bone fractures was 0.04% (8 deaths), and that of myoneuropathies 0.02% (3 deaths). When interpreting studies of comparative anesthetic-related morbidity and mortality, it should be remembered the definitions of the anesthetic period may vary and often include additional surgical and disease risk factors.

High-Risk Patients

Based on clinical experience, the small animal patients that are associated with a high risk of adverse outcome from anesthesia and surgery include geriatric (especially hyperthyroid) cats; post-trauma cases with pulmonary pathology, hemothorax, or pneumothorax or pulmonary hemorrhage; and cases of acute head trauma and severe intra-abdominal hemorrhage. Patients requiring a high level of care and commitment to achieve a good outcome include neonates; those with low body weight or morbid obesity; and patients undergoing portosystemic shunt occlusion or cardiac, intracranial, or intraocular surgery.

The procedures or conditions associated with high risk of adverse outcome in equine patients include advanced age, heavily muscled young horses, extreme emaciation, ethmoidal hematoma, or guttural pouch mycosis with severe hemorrhage, septic shock, and intra-abdominal hemorrhage. Periparturient mares also have a greater risk of adverse outcome.^{11,12}

Cardiovascular Emergencies

Hemorrhage and Fluid Loss

Blood loss during surgery may be insidious or obvious. Body fluids may also be lost during surgery to transudation, sequestration, or evaporation. Extravasation of fluid to a nonfunctioning or se-

questered edema space is commonly referred to as *loss to the third space*, the first and second spaces being the intracellular and extracellular spaces. These losses may reduce circulating blood volume significantly. Regardless of cause or route of loss, a decrease in circulating blood volume is not well tolerated by anesthetized patients.

Quantifying blood loss is important but can be difficult, so the severity of hemorrhage is often assessed by its impact on the patient. Severe blood loss causes tachycardia, reduced arterial pressure, pale mucous membranes, decreased pulse pressure, and decreased area under the arterial pulse wave.^{13,14} Packed cell volume decreases only during resuscitation or fluid shift into the vascular space, but base deficit increases as changes in bicarbonate, and venous pH correlate with blood volume lost.¹⁵ All of the aforementioned changes have been reported in anesthetized horses, with one difference: Tachycardia in response to blood loss is not usually observed in horses that are under anesthesia.¹⁶ Physiological responses to blood loss may be blunted or masked by anesthetic and anesthetic adjunctive drugs (e.g., α_2 -agonists), further emphasizing the need for appropriate monitoring for early detection and correction of hypovolemia.

Shed blood can be replaced with crystalloids, colloids such as plasma, hemoglobin-based oxygen-carrying solutions, dextrans, whole blood, or a combination of these solutions (Table 53.1). In most situations, hypertonic solutions do not seem to have a distinct advantage over isotonic crystalloid solutions.¹⁷ Crystalloid solutions such as lactated Ringer's or Plasmalyte are usually administered at threefold the volume of shed blood, as a rough guideline for resuscitation. The main advantage of crystalloid solutions is their low cost. Colloid solutions such as whole blood, plasma, hydroxyethyl starch, and hemoglobin-based oxygen carriers can be used as a substitute for crystalloids.¹⁸ Hemoglobin-based oxygen-carrying solutions (e.g., Oxyglobin) are relatively

expensive but have a long shelf life, and do not require cross-matching.¹⁹ The use of colloids has the advantage of sustaining colloid osmotic pressure while preserving plasma volume but has the disadvantage of being more expensive than crystalloid solutions.

Acute hemorrhage of greater than 20% of the blood volume or a decline in pack cell volume to less than 20% because of the

combined effects of blood loss and crystalloid fluid administration can be treated with an appropriate mass of red blood cells by either transfusion of whole blood, packed red cells, or 10 to 30 mL/kg of a hemoglobin-based oxygen carrier.^{20,21} Hemoglobin-based oxygen-carrying solutions or red blood cells are preferred because of the need for restoring adequate hemoglobin concentrations to carry oxygen to the tissues. Smaller amounts of surgi-

cal hemorrhage, not associated with severe decreases in the hemoglobin concentration, can be replaced with crystalloids (e.g., lactated Ringer's) or colloids rather than blood.

Cardiac Dysrhythmia

Most dysrhythmias are caused by preexisting medical conditions, administration of premedications, anesthesia induction and maintenance agents, and surgical stimulation. Dysrhythmias require treatment if they reduce cardiac output, cause sustained tachycardia, or are likely to initiate dangerous ventricular dysrhythmias.

Canine gastric dilation/volvulus or multiple trauma often precipitates dysrhythmias that may require treatment prior to induction of anesthesia.^{22,23} Dysrhythmias following gastric dilation/volvulus presumably have their origin in acid-base imbalance, electrolyte disturbance, myocardial ischemia, circulating cardiac stimulatory substances, and/or autonomic nervous system imbalance. Treatment involves correcting physiological abnormalities and administering lidocaine or procainamide. It is absolutely imperative that ventricular premature contractions (VPCs) be differentiated from ventricular escape beats before administration of antiarrhythmic drugs, because suppression of an escape rhythm can cause immediate asystole and death. If the sinus rate is low, an intravenous atropine injection of 0.02 mg/kg may increase the sinus rate and invoke overdrive suppression, which may inhibit the dysrhythmia. VPCs and ventricular tachycardia resulting from a traumatized myocardium are commonly treated with lidocaine or procainamide. If possible, surgery should be delayed 2 to 4 days or until the dysrhythmias have subsided.

Several of the popular drugs used as preanesthetic medication can predispose patients to conduction abnormalities. Atropine or glycopyrrolate can cause sinus tachycardia and increase myocardial work and oxygen consumption. Phenothiazine tranquilizers reportedly predispose the heart to sinus bradycardia, sinus arrest, and, occasionally, first-degree and second-degree heart block, although it has also been shown to protect against VPCs. Xylazine causes bradycardia and second-degree atrioventricular blockade and decreases the epinephrine threshold for VPCs. The μ -receptor agonist opioids morphine, hydromorphone, fentanyl, and oxymorphone will also precipitate a slowing of heart rate via increased vagal efferent activity. The anesthesia induction agents thiopental and ketamine have been reported to increase the likelihood of dysrhythmia formation after epinephrine administration during halothane anesthesia.^{24,25} This multidrug interaction has also been described for thiopental and isoflurane.²⁴

Other factors responsible for the development of the dysrhythmias during the surgical period include altered arterial carbon dioxide partial pressure (PaCO₂), altered PaO₂, altered pH, and autonomic reflexes from surgical manipulation, as well as central nervous system disturbances and cardiac disease. Because most perioperative dysrhythmias do not seriously affect cardiac output, treatment can be discrete. Changing to a different inhalation anesthetic, using intermittent positive-pressure ventilation, or increasing the depth of anesthesia may eliminate the dysrhythmia.^{26,27} Other treatments for controlling ventricular dysrhythmias include correcting blood-gas abnormalities or administering

a small quantity of intravenous lidocaine (0.5 mg/kg) or procainamide (1.0 mg/kg).

Allergic Reactions

Allergic reactions involving anesthetics are uncommon but could occur after sensitization to a drug. Allergic or anaphylactic reactions are mediated by the immune system. They are more commonly associated with repeated exposure to an allergen, but cross-reactivity may be seen with some preexisting allergies (e.g., allergies to eggs and to egg proteins in propofol). Anaphylactic reactions following thiopental administration have been reported.^{28,29} Intravenous injection of the intravenous contrast agent diatrizoic acid (Hypaque; Amersham Health, Princeton, NJ) has caused tachypnea, bronchoconstriction, and mucoid diarrhea in dogs. Allergic reactions are treated with intravenous fluids, antihistamines, and corticosteroids. Epinephrine should be administered in severe reactions accompanied by severe bronchoconstriction or cardiovascular collapse. Many unexpected responses to anesthetic and anesthetic adjunctive drugs have been labeled as "allergies" by veterinarians; however, proper diagnosis is crucial because it may have serious ramifications for future anesthetic delivery.

Cardiac Arrest

Successful treatment of cardiac arrest requires early diagnosis. The brain is the organ most susceptible to hypoxia or ischemia, because serious brain injury develops after only 4 or 5 min of cardiac arrest. The brain injury can be multifactorial, including the rapid loss of high-energy phosphate compounds during ischemia, cell structural damage during reperfusion, progressive brain hypoperfusion especially in certain areas, and suppression of protein synthesis in selectively vulnerable neurons.³⁰ Once the diagnosis of cardiac arrest has been confirmed, all efforts must be toward developing effective blood flow and reestablishing a heartbeat. Cardiopulmonary resuscitation (CPR) with external cardiac massage appears to be ineffective in protecting the brain from injury and should be only part of the initial resuscitation protocol. If unsuccessful, time should not be wasted with external CPR in lieu of more effective internal techniques.³¹

Cardiac arrest is diagnosed when some or all the signs listed in Table 53.2 are present. When the heartbeat or peripheral pulse cannot be palpated, the systolic blood pressure is generally less than 50 mm Hg. In this circumstance, the heart may actually have a weak beat, but cardiac output is probably very low and true cardiac arrest imminent. A nonpalpable weak heartbeat along with a regular rhythm has been termed *pulseless electrical activity* (PEA), formerly known as electrical mechanical dissociation. This type of functional cardiac arrest occurs with anesthesia overdose and from many other causes, such as hypovolemia, acute cardiogenic decompensation, severe acidosis, or hypoxemia. It is important to look for correctable causes of PEA during the first moments of resuscitation to improve the odds of success. Other forms of cardiac arrest include asystole and ventricular fibrillation. The three types of cardiac arrest can be

Table 53.2. Signs of cardiac arrest.

differentiated with an electrocardiogram (ECG) or by direct observation of the heart during thoracic surgery or internal CPR.

Cardiopulmonary Resuscitation

When any or all of the signs listed in Table 53.2 are present, the traditional *ABCD* protocol for treatment of cardiac arrest must be started immediately. *A* refers to *airway* and reminds the resuscitator that a patent airway is a necessity. Endotracheal intubation is the best method of insuring a patent airway. The goal of *B*, *breathing*, is to supply high concentrations of oxygen to the alveoli and to eliminate carbon dioxide. Intermittent positive-pressure ventilation is usually instituted in intubated patients, although, when breathing room air and using chest compressions only (no artificial ventilation), dogs have maintained adequate gas exchange and oxygen saturation greater than 90% for longer than 4 min.³² The real value of artificial breathing has been questioned for routine resuscitation in people.³³ The current recommendations for a breathing rate of 10 to 24 breaths/min may be too high.³⁴ Assuming there is enough blood flow to provide a reading, the pulse oximeter can be useful as a guide to determine respiratory rate. Simply ventilate at a rate that maintains hemoglobin saturation at 90% or higher.

C refers to *cardiac massage*, which can be either external (thoracic) or internal. External thoracic massage is thought to produce cardiac output by one or a combination of two methods. The *thoracic pump theory* holds that blood moves out of the thoracic cavity during the compression half of the CPR cycle because of a buildup of internal thoracic pressure (Fig. 53.1). This mechanism is thought to occur primarily in animals with a body weight greater than 15 to 20 kg. Evidence for the thoracic pump theory includes the phenomenon of cough CPR in humans and artificial cough CPR in dogs.^{35,36} The *cardiac pump theory* explains blood flow in smaller animals or animals with a narrow side-to-side thoracic width and refers to actual mechanical compression of the myocardium by the thoracic wall during CPR systole (Fig. 53.2). Blood flow in some patients may be produced by a combination of the cardiac and thoracic pump mechanisms. Whatever the reason for forward blood flow, it appears that external thoracic massage is not very protective of the brain, because CPR performed for more than 3 or 4 min is often associated with significant neurological injury.³⁷ Because traditional external thoracic massage is apparently ineffective in many patients, various maneuvers have been proposed to improve blood flow during CPR. For example, *interposed abdominal compression (IAC)*³⁸ involves manually compressing the abdomen in counterpoint to

Fig. 53.1. External thoracic massage administered to a larger dog that probably derives blood flow primarily from the thoracic pump mechanism. The resuscitator, standing at the dog's back, is applying thoracic compressions over interspace 4 or 5 at the level of the costochondral junction. In larger dogs, the thoracic compressions may not mechanically contact the heart, so all blood flow is derived from increased intrathoracic pressure. The right hand is supplying a counterforce for thoracic compressions with the palm of the left hand. The compression rate for this dog should be from 80 to 100 beats/min.

Fig. 53.2. External thoracic massage administered to a cat with blood flow derived from the cardiac pump. The thoracic walls contact the heart with each compression. Note that only the thumb and fingers of the right hand compress the thorax, while the left hand stabilizes the cat. The compression rate should be from 100 to 120 beats/min.

the rhythm of the chest compression. The physiological reason for improvement of blood flow is that compression of the abdominal aorta responds like an intra-aortic balloon pump and that pressure on the abdominal veins primes the right heart and pulmonary vasculature in preparation for the next thoracic compression.³⁹ This method of augmenting external CPR has been asso-

ciated with improved survival in people and vital organ perfusion in dogs.^{40,41} Utilization of IAC-CPR in over 100 dog CPR labs as part of a clinical anesthesia rotation demonstrated that venous return and arterial blood pressure improved for about 1 min, after which hemodynamics began to fail again (A. T. Evans, personal observation). Another way of improving blood flow during CPR is to simultaneously ventilate at the time of thoracic compression. Simultaneous ventilation-compression (SVC) CPR has improved carotid blood flow during resuscitation of animals.⁴² Opposing evidence has also been presented that shows that the mitral valve of dogs may actually close in response to rhythmic increases in intrathoracic pressure.⁴³ Despite this evidence to the contrary, SVC-CPR probably improves blood flow during CPR of large dogs when the thoracic pump is the primary mechanism in generating blood flow.

Open thoracic or internal CPR is more effective at perfusing the heart and brain during the critical beginning minutes of CPR.^{44–46} Higher blood pressure and cardiac output can be achieved with internal CPR. Most veterinary practices are well equipped to perform internal CPR because controlled ventilation and thoracotomy can be performed. The limiting factor in its employment is often the surgical inexperience of the attending veterinarian or the “do not resuscitate” wishes of the animal owner. Although it can be a difficult subject to broach, it is desirable to ascertain prior to the procedure the owner’s wishes concerning CPR, in writing, in the event that cardiac arrest should occur during anesthesia and surgery. Valuable time may be lost trying to contact owners. Whichever method of CPR is chosen, there are some guidelines for CPR technique that, when followed, can improve success. The animal should be in right lateral recumbency with the resuscitator standing at its back (Fig. 53.1). The thoracic or cardiac compression rate should be 80 (large dogs) to 120 (cats) per minute.^{47,48} A longer compression time will augment forward blood flow when using the thoracic pump mechanism.

The recommendations for *D, definitive* or *drug therapy*, start with the immediate use of epinephrine. Epinephrine should be administered early, preferably into a central vein or alternatively into a peripheral vein, intrabronchially, or directly into the chamber of the left ventricle.⁴⁹ For intrabronchial administration, use a flexible catheter wedged into a distal bronchus.⁵⁰ For intracardiac placement, use a long, 22-gauge needle inserted at the left thoracic fourth or fifth interspace and costochondral junction. For intravenous administration, a dose of 0.05 to 0.1 mg/kg is used, whereas bronchial administration requires 0.05 to 0.1 mg/kg diluted to a 2- to 3-mL volume with saline. The dose for intracardiac epinephrine is 0.025 to 0.05 mg/kg. Even though intracardiac epinephrine seems appealing as a way of efficiently delivering the drug to the heart, the technical difficulty of positioning the needle in the chamber of the left ventricle when the heart cannot be palpated, along with the potential for myocardial or coronary vascular injury, makes this technique the least advantageous. Since the goal of CPR is to revive the heart as soon as possible, early administration of epinephrine is crucial, and it should be given immediately after diagnosis of cardiac arrest.

The use of vasopressin in asystolic cardiac arrest has been recommended as a new standard of care in people.⁵¹ The interest in

vasopressin as treatment for cardiac arrest was due to an observation in the early 1990s that endogenous vasopressin levels were greater in survivors of cardiac arrest than in patients that died.⁵² The resuscitation success from the injection of vasopressin compared with epinephrine may be because the heart continues to consume oxygen after epinephrine injection (especially with tachycardia that often follows successful epinephrine-assisted resuscitation), whereas vasopressin augments coronary blood flow through an increase in systemic vascular resistance and increased diastolic perfusion pressure without an accompanying tachycardia.^{53,54} In people, epinephrine may be potentially detrimental in early asystolic cardiac arrest because exogenous epinephrine could be expected to potentiate hypoxemia and advancing acidosis, which could further impair the pressor effects of epinephrine.⁵¹ Tracheal administration of vasopressin (1.2 units/kg) in anesthetized dogs has resulted in systolic, diastolic, and mean blood pressure increases that last longer than 1 h.⁵⁵ Although research into the effects of vasopressin in treating cardiac arrest in dogs is scarce, an intravenous dose of 0.8 units/kg has been suggested for treatment of shock-refractory ventricular fibrillation, pulseless ventricular tachycardia, asystole, and PEA.⁵⁶

Lidocaine is used after resuscitation if ventricular dysrhythmias are compromising cardiac output. The use of lidocaine during ventricular fibrillation to improve the results of electrical defibrillation is being reevaluated.⁵⁷ Lidocaine is usually given as an intravenous bolus at a dose of 0.5 mg/kg. Amiodarone has also been recommended for shock-refractory ventricular tachycardia or fibrillation in people.⁵⁸ Because of its vasodilatory effects on the coronary circulation, amiodarone (5 mg/kg intravenously) is best administered in combination with epinephrine.⁵⁹ Metabolic acidosis from hypoxia and ischemia, and respiratory alkalosis caused by iatrogenic hyperventilation during treatment of cardiac arrest, commonly occur during resuscitation.⁶⁰ The immediate use of bicarbonate is controversial, because metabolic acidosis is slow to develop during CPR and is somewhat neutralized by an ensuing respiratory alkalosis. Respiratory alkalosis is caused by external thoracic compression and controlled ventilation during CPR. Sodium bicarbonate (1 mEq/kg) administered after 10 min of resuscitation will improve the chance of return of spontaneous circulation and may play a role in mitigating postresuscitation cerebral acidosis.^{61,62} However, bicarbonate administration can result in production of carbon dioxide as metabolic acid is neutralized. Careful monitoring of PaCO₂ can be a guide to adequate ventilation postresuscitation to avoid paradoxical cerebral acidosis.

Atropine or glycopyrrolate are important drugs to administer during CPR because reflex bradycardia may have contributed to the initial cardiac arrest. In addition, bradycardia often occurs after a heartbeat has been established. Atropine at 0.02 to 0.04 mg/kg or glycopyrrolate at a dose of 0.01 mg/kg intravenously will enhance the automaticity and conduction of both sinoatrial and atrioventricular nodes.⁶³

In dogs and cats, pulseless electrical activity is apparently more common than ventricular fibrillation.⁶⁴ Asystole, observed as a flatline ECG, is the next most common form of cardiac arrest, with ventricular fibrillation the least common. It is fortu-

Fig. 53.3. Placement of direct-current paddles for defibrillation of the heart during cardiac arrest. An area under the paddles has been shaved and electrode jelly applied to the paddles. Administer a shock of approximately 3 to 5 joules (watts/second) per kilogram of body weight. Sequential discharges of increasing energy of 50% at each shock may be more effective at converting fibrillation.

itous that ventricular fibrillation is the least common expression of cardiac arrest, because most veterinary practices do not have access to a direct-current defibrillator. If a direct-current defibrillator is available, clip the hair from a small area from each side of the thorax. After applying electrode gel to each paddle, firmly apply the paddles to the thorax (Fig. 53.3) and administer a shock of approximately 3 to 5 joules (watts/seconds) per kilogram of body weight. Sequential discharges of increasing energy may be more effective at converting fibrillation.⁵⁶ Internal defibrillation requires a smaller electrical discharge: a total of 10 to 50 joules. Alcohol should not be used for ECG lead placement during CPR because alcohol is highly flammable and may be ignited by a defibrillator.

Internal Cardiopulmonary Resuscitation

After administration of epinephrine, and after attention to airway (A) and breathing (B) of the CPR protocol, begin external thoracic massage. It seems reasonable to start external CPR even though success rates are low with this method. Some animals respond positively to one or two doses of epinephrine and 1 or 2 min of external CPR. These appear to be primarily animals in PEA or asystole. If there is no response after 2 min, one should quickly begin the more productive internal CPR technique.⁶⁵ Unfortunately, many practitioners may not feel confident about performing a thoracotomy when they have little or no previous experience with this procedure. There is little to lose, however, when a patient is in cardiac arrest and has not responded to initial resuscitation attempts. Emergency thoracotomy can be accomplished quickly in an arrested animal. Clip the hair from the left thorax at the fifth interspace. Spray or wipe the area with an antiseptic solution and incise the skin starting 1 inch from the spine to within 1 inch of the sternum. With surgical scissors, con-

tinue incision through the various tissue layers, avoiding the internal thoracic artery near the sternum. Bluntly penetrate the pleura, extend the incision, and spread the ribs. If the abdomen is open during surgery, a transdiaphragmatic approach has been used (especially during diaphragmatic hernia surgery) to reach the heart in a timely manner. Reach into the thorax and begin cardiac massage at a rate of 80 to 120 compressions per minute. Depending on its size, the heart can be massaged with fingers, one hand, or two hands.⁶⁶ Epinephrine can now be easily administered into the left ventricle as required. If the resuscitation is successful and mental alertness improves, the patient can be anesthetized to complete closure of the thoracic incision. The thorax should be flushed with warm, sterile physiological saline and closed in a routine manner. Infection is rare after emergency thoracotomy in people and, from clinical experience, uncommon in dogs.^{67,68} An algorithm for patients with confirmed cardiac arrest is presented in Fig. 53.4.

Postresuscitation Care

Once there is a return of spontaneous circulation, attention must be directed toward limiting the neurological injury and other sequelae produced by the cardiac arrest. Intensive care must be provided to address blood-gas abnormalities, respiratory insufficiency, hypotension, cardiac dysrhythmias, and temperature. Clinical trials in people have demonstrated neurological benefit of mild therapeutic hypothermia (32°C to 34°C) in survivors of out-of-hospital cardiac arrest.⁶⁹ Mild hypothermia should be instituted as soon as possible after resuscitation and maintained for at least 12 h. Cooling methods that may work in smaller animals involve surface cooling of the head and neck, as well as circulation of cool air over the patient's body. Tympanic membrane temperature can be used as a proxy for brain temperature. Application of mild hypothermia may improve the rather dismal success rate of cardiac and brain resuscitation in animals.

After successful CPR, the use of intravenous antibiotics has been recommended to counter the potential septicemia that can follow ischemic insult of the integrity of the lining of the gastrointestinal tract. Administration of osmotic diuretics such as mannitol (0.5 to 1.0 g/kg intravenously) after resuscitation has also been recommended to counter cerebral edema secondary to ischemia.

Perivascular Injection

Among all of the injectable anesthetics in use today, the perivascular injection of thiopental has likely caused more local tissue damage than all other anesthetics put together, primarily because of its very alkaline pH. It is, however, unusual for a perivascular slough to occur if the concentration of thiopental is 2.5% or less. If thiopental is inadvertently injected, perivascular treatment should consist of infiltration of the area with saline to dilute the thiopental, lidocaine to vasodilate capillaries and increase absorption, and corticosteroids to decrease the inflammatory response. Propofol, ketamine, and etomidate normally do not cause tissue sloughing if accidentally injected perivascularly. In horses or cattle, glycerol guaiacolate is irritating and will likely cause a tissue

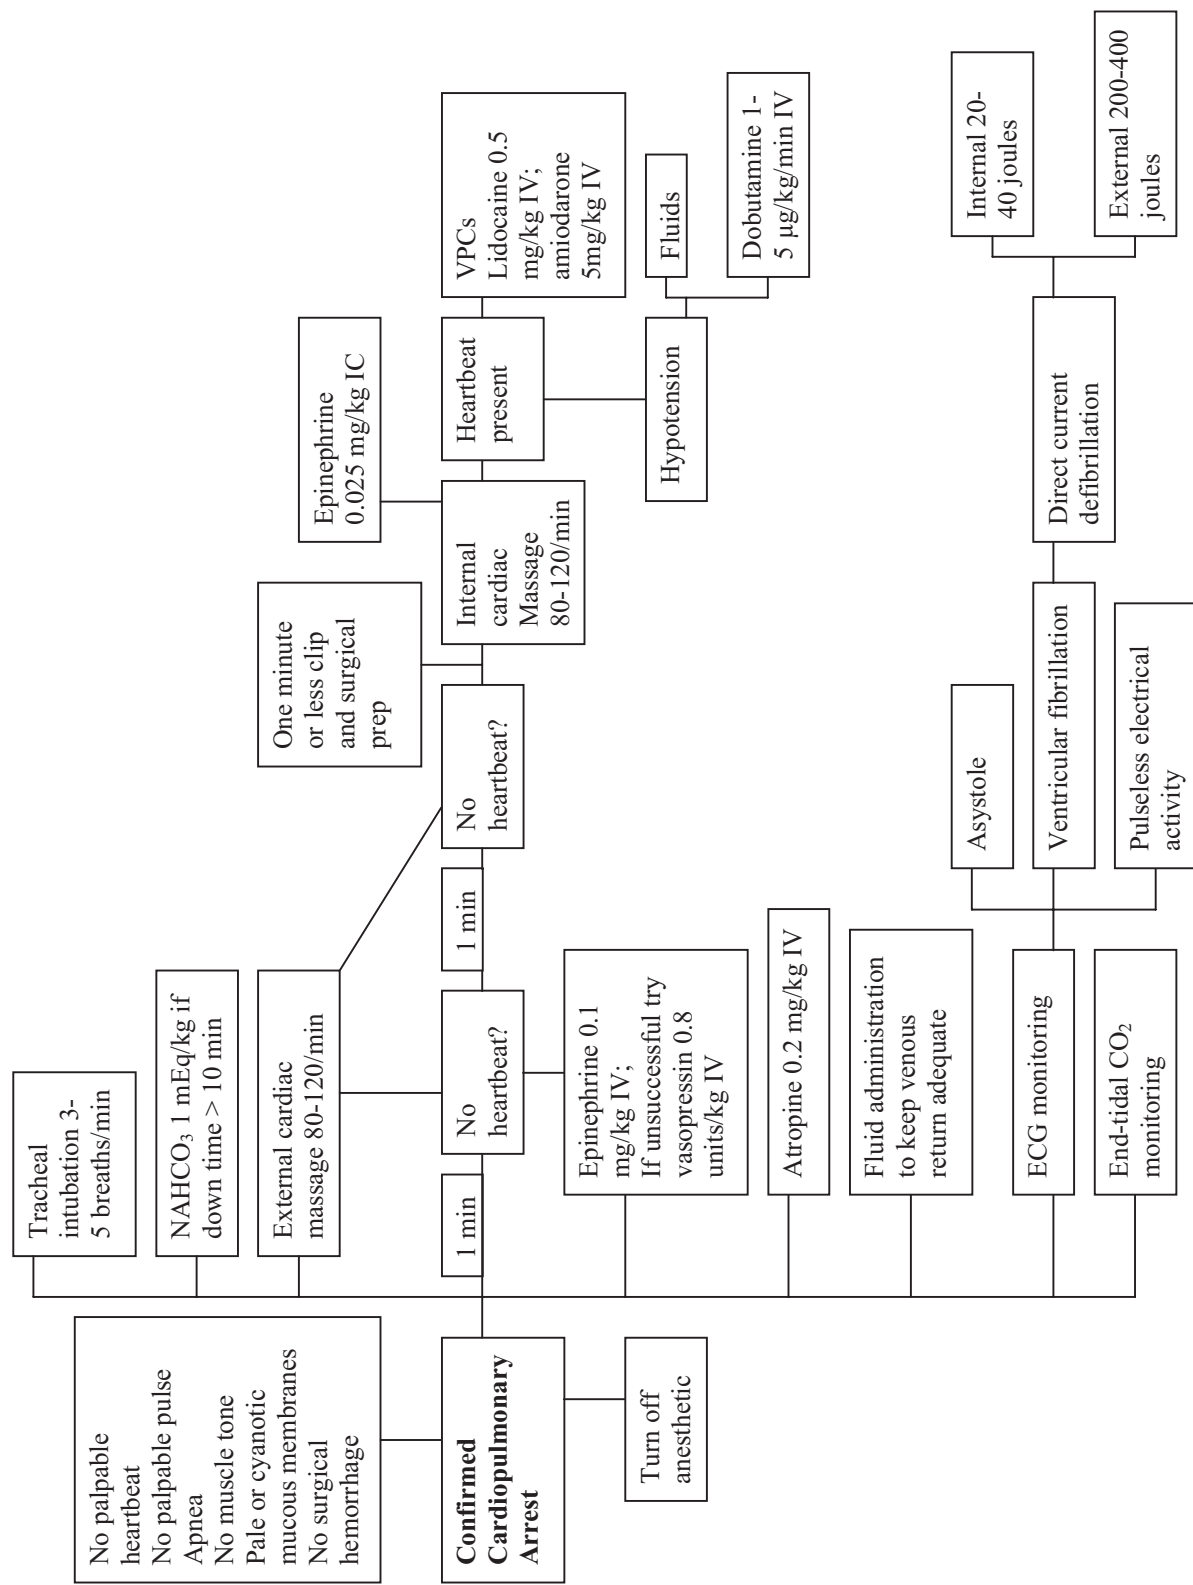

Fig. 53.4. An algorithm for cardiopulmonary resuscitation (CPR). This simplified protocol for CPR is used to resuscitate animals that might be able to survive cardiac arrest. Because early restoration of brain perfusion is the most important goal, a quick decision for internal cardiac massage is required. ECG, electrocardiogram; IC, intracardiac; IV, intravenously; NaHCO₃, sodium bicarbonate; and VPCs, ventricular premature contractions.

slough if a large volume is injected or infused outside the intended vessel. Many catecholamine solutions including dopamine can lead to tissue necrosis after perivascular injection. Intense α_1 -receptor-mediated vasoconstriction is likely the cause.

Respiratory Insufficiency

Respiratory depression is defined by an increase in PaCO_2 , and not by a decrease in respiratory rate alone. It is common for respiratory rate to decrease with a decrease in the level of activity and awareness (e.g., sleep), but tidal volume typically increases to compensate, resulting in no net change in PaCO_2 . During anesthesia, respiratory insufficiency is common because many factors alter the chemoreceptor responsiveness to carbon dioxide, leading to elevated PaCO_2 . Causes include the administration of opioids and other sedatives prior to anesthesia, the relative overdose of induction agents, positioning for surgery, respiratory depressant effects of inhalants, surgical trauma, recovery from bronchial alveolar lavage, and excessive use of opioids during recovery. The use of opioids with or without tranquilizers prior to induction of anesthesia to provide sedation and analgesia often results in a patient being well sedated but with depressed ventilatory drive. High doses of μ -receptor agonists such as oxymorphone, hydromorphone, and morphine are more likely to produce respiratory depression than is the κ -receptor agonist butorphanol. In addition, the decreased responsiveness to increased carbon dioxide tensions during halothane, isoflurane, or sevoflurane anesthesia tends to cause hypoventilation, although surgical stimulation often overrides some anesthetic-induced loss in respiratory drive.^{70,71} In addition to the depressant effects of inhalants on responsiveness to increased PaCO_2 , subanesthetic doses depress the peripheral chemoreceptors such that hypoxia does not stimulate a ventilation response.^{72,73} Hypoxia often occurs during recovery from anesthesia after diagnostic bronchial alveolar lavage (BAL). Although BAL with volumes of up to 4 L have only transient effects in healthy dogs, BAL can lead to increased morbidity and mortality in dogs and cats with severe respiratory disease.^{74–76} During BAL, supplemental oxygen can be administered by insufflation with a small rubber tube placed in the trachea alongside the bronchoscope (Fig. 53.5). After the procedure, oxygen should be administered by endotracheal tube, mask, or chamber until the pulse-oximeter readings remain at 90% saturation or higher while room air is breathed. Airway obstruction may also occur after ear-ablation surgery. Soft tissue swelling in the posterior pharynx may be severe enough to require a tracheostomy for relief.

Apnea is common during routine anesthesia. It occurs during induction after the administration of thiobarbiturates or propofol, during maintenance of anesthesia with ketamine, when controlled ventilation is discontinued, and as a consequence of deeper-inhalation anesthesia. Apnea occurring at induction is generally transient and is treated by low-frequency intermittent ventilation that is adequate to maintain hemoglobin-oxygen saturation at greater than 90%. Apnea occurring later during anesthesia, especially in spontaneously breathing animals, must be quickly recognized and treated with decreasing anesthetic concentrations and/or high-frequency positive-pressure ventilation. Apnea late in

Fig. 53.5. Placement of a red rubber tube into the trachea for insufflation of oxygen during bronchial alveolar lavage. The red rubber tube via an extension is connected to the oxygen line that normally connects the anesthesia machine with the circle.

anesthesia is usually caused by excessive depression of the respiratory centers of the brain secondary to high anesthetic concentrations, or because of decompensation associated with severe neurological disease such as hydrocephalus or intracranial neoplasia.

Generally, apnea during induction of anesthesia with thiobarbiturates or propofol is caused by a relative overdose or a fast bolus injection.⁷⁷ Ketamine and diazepam in a 1:1 mixture by volume is commonly used for anesthesia in cats. Apnea often occurs, especially when anesthesia is maintained with supplemental isoflurane. This combination of drugs, each of which is a respiratory depressant alone, can induce a persistent respiratory depression. If, in response to respiratory depression, assisted or controlled ventilation is employed, PaCO_2 will often be reduced below the arterial or alveolar PCO_2 level at which cats will remain apneic (apneic threshold). Decreased functional residual capacity (FRC) during anesthesia can increase hypoxia by lowering alveolar ventilation-perfusion ratios (V_A/Q) and expanding atelectatic areas. This occurs because the FRC is close to or less than the closing volume (CV) of the lung. The CV is the volume of the lung at which small airways begin to close. When the tidal volume is less than the CV, small airways remain closed throughout the breathing cycle, and atelectasis increases. If the CV of some airways remains within the tidal volume range, then there is some air exchange during inspiration and expiration, though not the normal amount. This partial ventilation decreases the V_A/Q . These lung changes are prevalent in older animals and during anesthesia. Intermittent positive-pressure breathing and positive end-expiratory pressure (PEEP) can be used to diminish the hypoxia that occurs from changes in FRC.

Equipment Malfunction

Routine equipment maintenance and leak tests should be used to reduce the chances of anesthesia-machine malfunctions. Com-

Fig. 53.6. Because of condensation of humidified exhaled gases on the dome and valve, this exhalation check valve has become lodged in the open position, enabling rebreathing of expired gases. An end-tidal carbon dioxide monitor would detect this equipment problem.

mon equipment malfunctions include “channeling” of gas flow through the carbon dioxide-absorbent canister, “sticking” of the exhalation check valve in the open position, interruption of oxygen supply, and kinking of the endotracheal tube. All of these equipment malfunctions can be rapidly detected with the routine use of a capnograph and pulse oximeter during inhalant or injectable anesthesia. *Channeling* occurs when gas flow through the carbon dioxide-absorbent canister is uneven, resulting in early termination of carbon dioxide absorption. If the pathway is through the center of the canister, there is not likely to be any observable change in color of the carbon dioxide absorbent, although the end-tidal carbon dioxide monitor should indicate increased rebreathing of exhaled gases (i.e., elevation of inspired carbon dioxide). Another cause of increased rebreathing of exhaled gases involves a malfunction of the exhalation check valve. The accumulation of moisture from humidified exhaled gases condensing on the cooler anesthesia machine parts can cause the check valve to remain in the open position (Fig. 53.6). In this situation, patients will rebreath more exhaled gas and higher levels of carbon dioxide. The oxygen supply to a patient can be mistakenly interrupted when the oxygen lines have been pressurized before the oxygen cylinder has been turned off. When the oxygen flowmeter is turned on again, oxygen flow is initially present, giving the impression the oxygen cylinder is open, but will cease when the oxygen in the lines is exhausted. This is more likely to occur when switching from a central supply of oxygen to smaller oxygen cylinders mounted onto the anesthetic machine. The endotracheal tube can kink during extreme flexion of the animal’s neck during positioning for cerebral spinal fluid tap, cervical spine radiographs, or ophthalmologic procedures. One should always determine patency of the endotracheal tube after extreme flexion of the head and neck. Use of a wire-reinforced endotracheal tube can reduce the incidence of obstruction (Fig. 53.7). If any problem is suspected

Fig. 53.7. The use of a wire-reinforced endotracheal tube will prevent kinking of the tube and obstruction of oxygen flow to patients. The protected endotracheal tube should be used when extreme flexion of the animal’s head and neck or of the endotracheal tube is anticipated.

with the anesthesia machine, the patient should be disconnected from the machine and temporarily ventilated with room air until the problem is solved.

Delayed Recovery

Occasionally, an animal will fail to recover normally from anesthesia. Common causes of this problem include hypothermia, hypoglycemia, and heavy narcotization. Hypoglycemia has been shown to decrease the minimum alveolar concentration of halothane in rats.⁷⁸ Hypoglycemia can be clinically silent in anesthetized patients, which emphasizes the importance of glucose monitoring in susceptible patients. During anesthesia, signs of sympathetic overactivity or ventricular arrhythmias may be the only detectable evidence of life-threatening hypoglycemia.⁷⁹ Patients at high risk of developing hypoglycemia in the peri-anesthetic period include neonates, very small patients, fasting diabetics treated with their usual insulin dose, and dogs with glucocorticoid deficiency.⁸⁰

Occasionally, coma or blindness can follow anesthetic-related insult to the central nervous system. If persistent neurological deficit follows an apparently uneventful anesthetic procedure, likely causes include hypoxia, severe hypotension, undiagnosed hydrocephalus, other preexisting neurological dysfunction, or an idiosyncratic drug-related response. In these cases, the exact etiology may be harder to determine. Treatment of these patients is primarily supportive, and the prognosis has to be guarded. In cases of anesthesia-related cortical blindness, vision may return as long as 2 weeks later, so cautious optimism is appropriate.

Reports of poor or delayed recoveries from anesthesia abound in popular canine and feline breed journals, and many breed societies relay stories of anesthetic-related problems. There are indeed situations where breed-specific anatomical or physiological peculiarities may complicate anesthetic management. Also, ge-

netic differences in specific populations of a species or breed can perhaps increase the risk of performing anesthesia in some individual animals. Nevertheless, most animals presented with non-specific warnings about delayed recovery from anesthesia respond normally to the careful dosing of commonly used anesthetic agents. Inappropriate dosage of anesthetic or inadequate patient monitoring is more likely the common culprit in many cases of reported “anesthetic sensitivity.”

Gastroesophageal Reflux and Regurgitation

Reflux of gastric contents into the esophagus has occurred if esophageal pH decreases below 4 (reflux of gastric acid) or above 7.5 (reflux of bile). This reflux is clinically silent and usually acidic.^{81,82} The lower esophageal sphincter is considered to be the primary barrier to the development of this reflux.⁸³ Lower esophageal sphincter pressure in dogs is decreased with the use of isoflurane, atropine, acepromazine, and xylazine.^{84,85} The effects of many other anesthetic agents on sphincter function have not been determined. Gastroesophageal reflux (GER) reportedly occurs during anesthesia in approximately 17% of dogs receiving thiopental, halothane, and other agents; in 50% of dogs receiving propofol; and in up to 60% of dogs receiving preanesthetic morphine.^{81,82,86,87} A 5% incidence of GER has been reported in a population of anesthetized people, which suggests that anesthetic-induced GER occurs less frequently in people than in dogs, even though opioids are commonly used in both species.⁸⁸ In some cases, the refluxate is of sufficient volume to reach the pharynx and even drain from the mouth (regurgitation). The incidence of regurgitation is currently estimated at around 0.1% in animals anesthetized at the Michigan State University Veterinary Teaching Hospital.⁸⁹ This material may be aspirated into the lungs, leading to pneumonitis, or may cause local irritation of the esophagus as a prelude to development of ulcerative esophagitis and stricture formation.^{83,88,90,91}

Hypothermia

This occurs commonly in anesthetized patients because of depressed thermoregulation, excessive heat loss relative to metabolic production, and mixing of core and peripheral blood by indiscriminant vasodilation. Heat is lost to the environment through convection, conduction, radiation, and evaporation, and occurs more rapidly when body surface is larger relative to body mass. Many anesthetic drugs, including opioids, the inhalant anesthetics, and α_2 -agonists, interfere with thermoregulation and contribute to prolonged postoperative hypothermia.^{92–94} Inhalation anesthetics lower the threshold for response to hypothermia in people to about 34.5°C, and presumably this occurs in animals, as well.⁹² The rate of core temperature decrease in horses under halothane anesthesia has been shown to be 0.37°C/h, which is reduced to 0.19°C/h with the application of a forced-air warmer to help maintain patient body temperature.⁹⁵ Anesthetized dogs have been shown to have a decrease in rectal temperature of 1.9°C/h in the first hour of anesthesia.⁹⁶

Hypothermia has been associated with pain, suppressed phagocytic activity including decreased migration of polymorphonuclear cells, reduced superoxide anion production, and reduced bacterial killing, and thus may contribute to systemic suppression of immune reactivity in the perioperative period.⁹⁷ In a retrospective study of dogs, mild decreases (1°C) in body temperature during surgery were not related to increased risk of incisional infections.⁹⁸ Accidental surgical hypothermia can be limited by increasing the ambient temperature, but this is seldom feasible. Circulating warm-water pads, especially applied to the legs, have been shown to help preserve body heat in dogs.⁹⁹ Forced-air warming systems currently are the most efficient and effective means of preserving or increasing body heat in anesthetized patients. This warming technique has been shown to delay or reduce the rate of heat loss in horses, dogs, and parrots.^{95,100} Humidification and warming of inhaled gas has been shown to be ineffective as a sole means of maintaining core temperature in dogs or cats.^{96,101,102} The use of uncovered electrical heating pads or “hot-water gloves” is discouraged because of potential for thermal injury.^{103,104}

Hyperthermia

Drug-induced hyperthermia is rare in the practice of veterinary anesthesia. However, μ -receptor opioid agonists such as hydromorphone and fentanyl have been associated with moderate hyperthermia in some cats. The most commonly used drugs in human practice that can cause hyperthermia include antipsychotic agents, serotonin antagonists, sympathomimetic agents, inhalation anesthetics, and agents with anticholinergic properties.¹⁰⁵ The resultant hyperthermia is frequently accompanied by intense skeletal muscle rigidity (contracture), rhabdomyolysis, and hyperkalemia. Neuroleptic malignant syndrome is a rare but potentially lethal reaction to antipsychotic drugs, including phenothiazines and lithium.⁹⁶ Dopaminergic antagonism, a direct myotoxicity, altered thermoregulation, or extrapyramidal hyperactivity are postulated to contribute to the development of this syndrome. It is very possible that this syndrome could even occur in phenothiazine-treated animals placed in a very warm environment.

Malignant hyperthermia is an inherited membrane-linked abnormality (ryanodine receptor mutation) that has been documented in several species, including pigs, dogs, cats, and horses.^{106–109} Susceptible patients should be anesthetized with barbiturates, propofol, opiates, and tranquilizers, and may be pretreated with dantrolene. Avoidance of known triggering agents—such as potent inhalation anesthetics, depolarizing muscle relaxants and stress—is advised.

Accidental iatrogenic hyperthermia can develop during warm ambient temperatures, in animals with thick hair coats, and with the use of forced-air warming systems. It is important to monitor body temperature in patients where active heating strategies are being used. Some smaller patients when treated with forced-air warming on the highest setting (43°C) heat up rapidly. In most situations, iatrogenic hyperthermia subsides rapidly after the heat source is removed.

Injuries

A number of other conditions can lead to injury during anesthesia:

Swollen feet: Limbs can be secured by ties placed so tight that they reduce venous drainage.

Corneal ulcers: Anesthetics reduce or eliminate the palpebral and corneal reflex and reduce tear formation. Chemical irritants, physical trauma, or drying can lead to ulceration. Artificial tears are important in preventing these problems.

Tracheal mucosal injury: Overinflation of the cuff or moving the cuff while it is inflated can cause mucosal injury, tracheal rupture, or tracheal chondromalacia. Tracheal rupture is an uncommon sequela to intubation in cats and can usually be treated medically.¹¹⁰ When changing patient positions, the endotracheal tube should be disconnected from the Y adapter, and the patient's head and neck supported to prevent sliding or movement of the endotracheal tube cuff. To prevent pressure-induced mucosal necrosis, it is wise to inflate the cuff of the endotracheal tube only sufficiently to seal a leak at 10 to 20 cm H₂O. It is not recommended to simply put "some air" in the cuff without checking its pressure.

Joint pain: Older animals with arthritic joints that are placed on their backs for surgery may have joint pain for days following anesthesia.

Pulmonary barotrauma: Overinflation of the lungs will damage the pulmonary structures significantly if pressures exceed 30 cm H₂O.^{111–113} Inadvertently leaving the adjustable pressure-limiting valve (pop-off valve) closed or using the oxygen flush when the patient is on a Bain's system can create pulmonary overpressurization. One simple way to provide protection for the patient if the pop-off valve inadvertently remains in the closed position is to place a commercially available PEEP valve in the breathing circuit (Fig. 53.8).

Epidural Analgesia and Regional Nerve Block

The use of the epidural route for delivery of opioids and local anesthetics is becoming increasingly popular, especially with prolonged drug delivery by epidural catheter.^{114–118} There are reports of epidural catheters having been placed and left in dogs for 7 days and in horses for up to 20 days, with the main complication being catheter dislodgement and local tissue response.^{116–118} Meticulous attention to aseptic technique is essential when drugs or catheters are placed in the epidural space. Epidural abscessation and discospondylitis have been reported following epidural injection.¹¹⁹ Other complications reported following epidural injection in dogs include urinary retention, prolonged cerebrospinal fluid levels of morphine, myotonus, and pruritus.^{114,120–122} Subarachnoid injection of preservative-free morphine in a dog caused such severe pruritus and myoclonus that the dog had to be anesthetized for several hours until the reaction resolved.¹²¹ The authors have observed one horse with severe pruritus of the hind feet after epidural injection of xylazine and local anesthetic. Sedation with detomidine was sufficient to calm

Fig. 53.8. A 20-cm water positive end-expiratory pressure (PEEP) valve can serve as an emergency release valve in case the adjustable pressure-limiting valve (pop-off valve) is accidentally closed and pressure begins to build in the anesthesia system. The PEEP valve can be used with circle and Bain's anesthesia delivery systems.

this horse. It appears from anecdotal reports that when a local anesthetic is combined with xylazine for epidural injection in horses, hind-limb ataxia and weakness are more likely to occur.

Regional nerve block has some risk of causing local anesthetic toxicity, although combining local anesthetics with epinephrine (5 µg/mL) will dramatically reduce this risk. Direct needle trauma to the nerve being blocked can cause a prolonged or permanent neural deficit. Local hemorrhage may result in hematoma formation, but this is generally self-limiting.

Electrolyte Abnormalities

Hyperkalemia is one electrolyte abnormality that can be associated with acute death.^{123,124} The causes of rapid-onset hyperkalemia during anesthesia and surgery include transfusion of old stored blood, chronic heparin therapy (dogs), uroperitoneum (especially foals and cats), iatrogenic administration (potassium penicillin or potassium chloride), and hyperkalemic periodic paralysis (HPP). Horses that are homozygous or heterozygous for HPP should be closely monitored. Diet change or the stress of fasting, anesthesia, and pain may lead to an attack in the peri-anesthetic period. Signs of an HPP attack are obvious even in anesthetized horses as hyperkalemia produces very characteristic ECG changes.¹²⁵ Arrhythmias caused by hyperkalemia can lead to cardiac arrest and may not respond to conventional antiarrhythmic therapies, but do respond to the rapid treatment of hyperkalemia.^{125,126} Aggressive lowering of serum potassium by using acetazolamide, furosemide, dextrose, and sodium bicarbonate, and the reversal of hyperkalemic effects on cell membrane potential by calcium administration can help resolve an HPP crisis if it occurs during anesthesia.^{125,126}

Hypokalemia caused by hemodilution and decreased intake is the most common cause of postoperative arrhythmias in people.

Arrhythmias (ventricular ectopy) associated with this electrolyte disturbance are not commonly observed in other animals. Hypocalcemia is an insidious electrolyte disturbance that can also be a problem for anesthetized patients. Hypocalcemia can lead to muscle weakness, which can be particularly problematic for horses trying to stand while recovering from anesthesia.

Appendix

Standard Values and Equivalents*

Metric Weights

1 gram (1 g) = weight of 1 cc water at 4°C
1,000 g = 1 kilogram (kg)
0.1 g = 1 decigram (dg)
0.01 g = 1 centigram (cg)
0.001 g = 1 milligram (mg)
0.001 mg = 1 microgram (µg)

Metric Volumes

1 liter (L) = 1 cubic decimeter or 1,000 cubic centimeters (cc)
0.001 liter = 1 milliliter (mL)

Solution Equivalents

1 part in	10 = 10.00 %	(1 mL contains	100 mg)
1 part in	50 = 2.00 %	(1 mL contains	20 mg)
1 part in	100 = 1.00 %	(1 mL contains	10 mg)
1 part in	200 = 0.50 %	(1 mL contains	5 mg)
1 part in	500 = 0.20 %	(1 mL contains	2 mg)
1 part in	1,000 = 0.10 %	(1 mL contains	1 mg)
1 part in	1,500 = 0.066%	(1 mL contains	0.66 mg)
1 part in	2,600 = 0.038%	(1 mL contains	0.38 mg)
1 part in	5,000 = 0.02 %	(1 mL contains	0.20 mg)
1 part in	50,000 = 0.002%	(1 mL contains	0.02 mg)

The number of milligrams in 1 milliliter of any solution of known percentage strength is obtained by moving the decimal one place to the right.

Apothecaries' or Troy Weight

(Used in Prescriptions)

1 pound (lb)	= 12 ounces	= 5,760 grains
1 ounce	= 8 drams	= 480 grains
1 dram	= 60 grains	

Apothecaries' Volume

1 pint	= 16 fluid ounces	
1 fluid ounce	= 8 fluid dram	= 480 minims
1 fluid dram	= 60 minims	

*Systeme International (SI) units and conversions are shown later in this appendix.

Avoirdupois or Imperial Weight

(Used in commerce in the United States and in the British Pharmacopeia)

Grain	= same as Troy grain	
Ounce (oz)	=	437.5 grains
Pound (lb)	= 16 oz	= 7,000 grains
Ton	= 2,000 lb	

Imperial Volume

		Apothecaries'
		System
Minims	=	0.96
Fluidrachm (fl dr)	= 60 minims	= 0.96 fl
Fluidounce (fl oz)	= 8 drachms	= 0.96 fl
Pint	= 20 fluid ounces	= 1.2 ounces
Gallon	= 8 pints	= 1.2 gallons

Approximate Equivalent Weights

1 kilogram	= 2.2 Avoirdupois/Imperial pounds
1 kilogram	= 2.6 Apothecary or Troy pounds
1 gram	= 15 (15.4) grains
1 milligram	= 1/60 (1/64) grain
1 ounce	= 30 grams
(Avoirdupois or Imperial)	= 28.350 grams)
(Apothecary or Troy)	= 31.1035 grams)
1 dram	= 4 grams
1 grain	= 60 milligrams

Approximate Equivalent Volumes

1 liter	= 1 quart
1 milliliter or cubic centimeter	= 15 minims
1 pint	= 500 cubic centimeters
1 fluid ounce	= 30 cubic centimeters
(Avoirdupois or Imperial)	= 28.412 cubic centimeters)
(Apothecary or Troy)	= 29.574 cubic centimeters)
1 fluid dram	= 4 cubic centimeters

Equivalents of Centigrade and Fahrenheit Thermometric Scales

<i>Centigrade Degree</i>	<i>Fahrenheit Degree</i>	<i>Centigrade Degree</i>	<i>Fahrenheit Degree</i>
-17	+ 1.4	14	57.2
-16	3.2	15	59.0
-15	5.0	16	60.8

11	51.8	42	107.6
12	53.6	43	109.4
13	55.4	44	111.2
		45	113.0

Gas Densities*(Weight of Unit Volume)*

22.4 liters of any gas are equal to its molecular weight in grams at a pressure of 760 mm of mercury (Hg) and 0°C.

Molecular Weights

Air	= 29 g
Oxygen	= 32 g
Nitrous oxide	= 44 g
Carbon dioxide	= 44 g
Ether	= 74 g

Special Symbols*

- A *dash* above any symbol indicates a mean value.
- A *dot* above any symbol indicates a time derivative.

For Gases

<i>Primary Symbols</i> (Large Capital Letters)		<i>Examples</i>	
V	= gas volume	V _A	= volume of alveolar gas
\dot{V}	= gas volume per unit time	\dot{V}_{O_2}	= oxygen consumption/min
P	= gas pressure	P _A O ₂	= alveolar oxygen pressure
\bar{P}	= mean gas pressure	P _A O ₂	= arterial partial pressure of oxygen
F	= fractional concentration in dry gas phase	P _C O ₂	= mean capillary oxygen pressure
f	= respiratory frequency (breaths per unit time)	F _I O ₂	= fractional concentration of oxygen in inspired gas
D	= diffusing capacity	DO ₂	= diffusing capacity for (O ₂ [mL O ₂ /min/mm/Hg])
R	= respiratory exchange ratio	R	= $\dot{V}CO_2/\dot{V}O_2$

<i>Secondary Symbols</i> (Small Capital Letters)		<i>Examples</i>	
I	= inspired gas	F _I CO ₂	= fractional concentration of carbon dioxide in inspired gas
E	= expired gas	V _E	= volume of expired gas
A	= alveolar gas	\dot{V}_A	= alveolar ventilation per minute
T	= tidal gas	V _T	= tidal volume
D	= dead space gas	V _D	= volume of dead-space gas
B	= barometric	P _B	= barometric pressure
ATPS	= ambient temperature and pressure saturated with water vapor	V _D /V _T	= ratio of physiological dead space to tidal volume
BTPS	= body temperature and pressure saturated with water vapor		
STPD	= 0°C, 760 mm Hg, dry		

For Blood

<i>Primary Symbols</i> (Large Capital Letters)		<i>Examples</i>	
Q	= volume of blood	Q _c	= volume of blood in pulmonary capillaries
\dot{Q}	= volume flow of blood per unit time	\dot{Q}_c	= blood flow through pulmonary capillaries/min
C	= concentration of gas in blood	C _a O ₂	= milliliters of oxygen in 100 mL of arterial blood
S	= percent saturation of hemoglobin with oxygen or carbon dioxide	S \bar{v} O ₂	= saturation of hemoglobin with oxygen in mixed venous blood
\dot{V}/\dot{Q}	= ventilation-perfusion ratio		

<i>Secondary Symbols</i> (Lowercase Letters)		<i>Examples</i>	
a	= arterial blood	P _a CO ₂	= partial pressure of carbon dioxide in arterial blood
v	= venous blood	P \bar{v} O ₂	= partial pressure of oxygen in mixed venous blood
c	= capillary blood	P _c CO ₂	= partial pressure of carbon dioxide in pulmonary capillary blood

*Adapted from Julius H. Comroe Jr. et al., *The Lung* (based on report in *Fed Proc* 9:602–605, 1950). Copyright © 1962 (second edition) Chicago: Year Book Medical Publishers. Used with permission.

For Lung Volumes

VC	= vital capacity	= maximal volume that can be expired after maximal inspiration
IC	= inspiratory capacity	= maximal volume that can be inspired from resting expiratory level
IRV	= inspiratory reserve volume	= maximal volume that can be inspired from end-tidal inspiration
ERV	= expiratory reserve volume	= maximal volume that can be expired from resting expiratory level
FRC	= functional residual capacity	= volume of gas in lungs at resting expiratory level
RV	= residual volume	= volume of gas in lungs at end of maximal expiration
TLC	= total lung capacity	= volume of gas in lungs at end of maximal inspiration

Systeme International*

The following information on SI units and factors for conversion between SI and older conventional units is provided for the convenience of readers.

Basic SI Units

Physical Quantity	Name	Symbol
Length	meter	m
Mass	kilogram	kg
Time	second*	s
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Luminous intensity	candela	cd
Amount of substance	mole	mol

*Minute (min), hour (h), and day (d) will remain in use although they are not official SI units.

Prefixes for SI Units

Factor	Name	Symbol	Factor	Name	Symbol
10^{18}	exa-	E	10^{-18}	atto-	a
10^{15}	peta-	P	10^{-15}	femto-	f
10^{12}	tera-	T	10^{-12}	pico-	p
10^9	giga-	G	10^{-9}	nano-	n
10^6	mega-	M	10^{-6}	micro-	μ
10^3	kilo-	k	10^{-3}	milli-	m
10^2	hecto-	h	10^{-2}	centi-	c
10^1	deca-	da	10^{-1}	deci-	d

Derived SI Units

Quantity	SI Unit	Symbol	Expression in Terms of SI Base Units or Derived Units
Frequency	Hertz	Hz	1 Hz = 1 cycle/s (1 s ⁻¹)
Force	Newton	N	1 N = 1 kg · m/s ² (1 kg · mPS ⁻²)
Work, energy, quantity of heat	Joule	J	1 J = 1 N · m
Power	Watt	W	1 W = 1 J/s (1 J · s ⁻¹)
Quantity of electricity	Coulomb	C	1 C = 1 A · s
Electric potential, potential difference, tension, electromotive force	Volt	V	1 V = 1 W/A (1 W · A ⁻¹)
Electric capacitance	Farad	F	1 F = 1 A · s/V (1 A · s · V ⁻¹)
Electric resistance	Ohm	Ω	1 Ω = 1 V/A (1 V · A ⁻¹)
Flux of magnetic induction, magnetic flux	Weber	Wb	1 Wb = 1 V · s
Magnetic flux density, magnetic induction	Tesla	T	1 T = 1 Wb/m ² (1 Wb · m ⁻²)
Inductance	Henry	H	1 H = 1 V · s/A (1 V · s · A ⁻¹)
Pressure	Pascal	Pa	1 Pa = 1 N/m ² (1 N · m ⁻²) = 1 kg/m · s ² (1 kg · m ⁻¹ · s ⁻²)

The liter (10⁻³ m⁻³ = dm³), though not official, will remain in use as a unit of volume as also will the dyne (dyn) as a unit of force (1 dyn = 10⁻⁵ N).

SI Unit Conversions

SI Unit	Old Unit	Conversion Factors	
		Old to SI (Exact)	SI to Old (Approx.)
kPa	mm Hg*	0.133	7.5
kPa	1 standard atmosphere [†] (approx. 1 Bar)	101.3	0.01
kPa	cm H ₂ O	0.0981	10
kPa	lbs/square inch	6.89	0.145

*For example, a systolic blood pressure of 120 mm Hg = 16 kPa and a diastolic blood pressure of 80 mm Hg = 11 kPa.

[†]= 760 mm Hg.

Blood Chemistry Units and Conversion Factors

Measurement (Approx.)	SI Unit	Old Unit	Conversion Factors	
			Old to SI (Exact)	SI to Old (Approx.)
Blood acid-base				
PCO ₂	kPa	mm Hg	0.133	7.5
PO ₂	kPa	mm Hg	0.133	7.5
Standard bicarbonate	mmol/liter	mEq/liter	Numerically equivalent	
Base excess	mmol/liter	mEq/liter	Numerically equivalent	
Glucose	mmol/liter	mg/100 mL	0.0555	18
Plasma				
Sodium	mmol/liter	mEq/liter	Numerically equivalent	
Potassium	mmol/liter	mEq/liter	Numerically equivalent	
Magnesium	mmol/liter	mEq/liter	0.5	2
Chloride	mmol/liter	mEq/liter	Numerically equivalent	
Phosphate (inorganic)	mmol/liter	mEq/liter	0.323	3.0
Creatinine	μmol/liter	mg/100 mL	88.4	0.01
Urea	mmol/liter	mg/100 mL	0.166	6.0
Serum				
Calcium	mmol/liter	mg/100 mL	0.25	4.0
Iron	μmol/liter	μg/100 mol	0.179	5.6
Bilirubin	μmol/liter	mg/100 mL	17.1	0.06
Cholesterol	mmol/liter	mg/100 mL	0.0259	39
Total proteins	g/liter	g/100 mL	10.0	0.1
Albumin	g/liter	g/100 mL	10.0	0.1
Globulin	g/liter	g/100 mL	10.0	0.1

Biochemical Content of Other Body Fluids

Measurement	SI Unit	Old Unit	Conversion Factors	
			Old to SI (Exact)	SI to Old (Approx.)
Urine				
Calcium	mmol/24 h	mg/24 h	0.025	40
Creatinine	mmol/24 h	mg/24 h	0.00884	113
Potassium	mmol/liter	mEq/liter	Numerically equivalent	
Sodium	mmol/liter	mEq/liter	Numerically equivalent	
Cerebrospinal fluid				
Protein	g/liter	mg/100 mL	0.01	100
Glucose	mmol/liter	mg/100 mL	0.0555	18

Hematology

Measurement	SI Unit	Old Unit	Conversion Factors	
			Old to SI	SI to Old
Hemoglobin (Hb)	g/dL	g/100 mL		Numerically equivalent
Packed cell volume	No unit*	Percent	0.01	100
Mean cell Hb concentration	g/dL	Percent		Numerically equivalent
Mean cell Hb	pg	pg		Numerically equivalent
Red cell count	Cells/liter	Cells/mm ³	10 ⁶	10 ⁻⁶
White cell count	Cells/liter	Cell/mm ³	10 ⁶	10 ⁻⁶
Reticulocytes	Percent	Percent		Numerically equivalent
Platelets	Cell/liter	Cell/mm ³	10 ⁶	10 ⁻⁶

*Expressed as decimal fraction; for example, the normal adult male value is 0.40 to 0.54.

pH and Nanomoles Per Liter of Hydrogen-Ion Activity

pH	nmol/Liter
6.80	158
6.90	126
7.00	100
7.10	79
7.20	63
7.25	56
7.30	50
7.35	45
7.40	40
7.45	36
7.50	32
7.55	28
7.60	25
7.70	20
